CHAPTER 1

A View of Life

In the 1950s developmental biologists Robert Briggs and Thomas King, then at the Institute for Cancer Research in Philadelphia, developed techniques for cloning frogs. They removed the nucleus (the structure in the cell that contains the genetic material) of a frog egg cell and replaced it with a nucleus from the cell of a developing frog embryo. Briggs and King found that nuclei from very early embryos were able to direct development to the tadpole stage, but nuclei from more developed embryos appeared to lose that ability. In the 1960s embryologist John Gurdon, now at Cambridge University, and his colleagues, using different techniques, showed that at least some nuclei retained the ability to direct development. Gurdon removed the nucleus of a frog egg cell and replaced it with the nucleus from a tadpole cell. The egg developed into a tadpole that was a clone, a genetic duplicate, of the animal that contributed the nucleus.

The research of Briggs and King and of Gurdon challenged the long-held belief that during development, the DNA (genetic material) of each cell becomes committed to coding for a specific type of cell and can no longer direct the development of an entire organism. However, attempts to clone other species were unsuccessful and many biologists concluded that frogs were an exception. Certainly, it was thought, cloning would not be possible in humans and other mammals. With the development of more sophisticated techniques, biologists became more optimistic about cloning mammals but speculated it would be well into the 21st century before this could be accomplished.

In 1997 biologist Ian Wilmut of the Roslin Institute in Edinburgh, Scotland, and his colleagues stunned the scientific community with their report in the journal *Nature* that they had successfully cloned a sheep. These researchers transferred nuclei from cultured mammary gland cells from a six-year-old ewe into specially prepared eggs from another sheep. One of these eggs developed into the clone that was named Dolly. Dolly represented the first time that DNA from an *adult mammal* had been successfully used to create a new, genetically identical animal. Shown here is Dolly with *her* new lamb, Bonnie. Bonnie was conceived naturally, further evidence that Dolly is a fully-functioning animal. (More about cloning and the techniques used to create Dolly are discussed in Chapter 16, *Genes and Development*.) Since Dolly, fetal cells have been used to clone cows, sheep, pigs and other mammals.

The recent successes in cloning have generated a great deal of controversy about possible ethical implications. A major concern centers on the future possibility of cloning humans.

(Roslin Institute/PA News Photo Library)

Wilmut has stated that his goal in cloning Dolly was not to make copies of animals, but to develop techniques for making “precise genetic changes in cells.” Already, cloning techniques have been combined with genetic engineering procedures to produce animals like Polly, a lamb that carries a human gene, and Genie, a sow that produces a human clotting protein in her milk. Such *transgenic* animals may become a routine source of relatively inexpensive human proteins needed by individuals suffering from medical conditions from hemophilia to strokes and heart attacks.

Among other applications for cloning technology are the preservation of endangered species and the development of animal strains that will be more resistant to disease or produce

low-fat milk or eggs. Genetically engineered, cloned cow or pig organs might be transplanted to ailing human patients. Human tissues could be engineered to treat spinal cord injuries or human diseases like leukemia or diabetes. Society will need to balance the potential benefits to health, medicine, and conservation with the concerns about misuse of cloning techniques.

The ethical questions posed by new technology in genet-

ics and developmental biology represent one group of issues that demand a biologically literate society. As we prepare to enter the 21st century, we face many challenges, such as the expanding human population, diminishing natural resources, decreasing biodiversity, and curing diseases such as cancer and AIDS. Meeting these challenges will require the combined efforts of biologists and other scientists, politicians, and biologically informed citizens.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Define biology and discuss its applications to human life and society.
 2. Distinguish between living and nonliving things by describing the features that characterize living organisms.
 3. Relate metabolism to homeostasis and give specific examples of these life processes.
 4. Summarize the importance of information transfer to living systems, giving specific examples.
 5. Give a brief overview of the theory of evolution and explain why it is the principal unifying concept in biology.
 6. Apply the theory of natural selection to any given adaptation, suggesting a logical explanation of how the adaptation may have evolved.
 7. Construct a hierarchy of biological organization, including individual and ecological levels.
 8. Demonstrate the binomial system of nomenclature using several specific examples and classify an organism (a human, for example) according to kingdom, phylum, class, order, family, genus, and species.
 9. Contrast the six kingdoms of living organisms and cite examples of each group.
 10. Contrast the roles of producers, consumers, and decomposers and cite examples of their interdependence.
 11. Design an experiment to test a given hypothesis, using the procedure and terminology of the scientific method.
-

WHAT IS BIOLOGY?

Biology is the science of life. More than any other discipline, biology helps us understand ourselves and the millions of other organisms with which we share our planet. As biologists continue to study interrelationships of organisms, they enhance our awareness of our own impact on our environment. Whatever your college major or career goals, a knowledge of biological concepts is a vital tool for understanding our world and for meeting many of the personal and global challenges that confront us. Applications of basic research in biology have provided us with the technology to transplant hearts, manipulate genes, and increase world food production. For example, research in molecular biology and genetics has led to new insights into disease processes, leading to the new science of gene therapy.

In this first chapter we will introduce three basic themes of biology: **evolution of life**, **transmission of information**, and **flow of energy through living systems**. Scientists have accumulated a wealth of evidence showing that the diverse life forms on our planet are related and that organisms have evolved through time from earlier life forms. The process of evolution is the framework for the science of biology and a major theme of this book.

The process of evolution, as well as the survival and function of every organism, depends on the orderly transmission of information. At the molecular level, instructions for producing and maintaining each living organism and each new

generation are encoded in the DNA molecules that make up the genes. At higher levels, the activities of organisms are coordinated by many forms of chemical signaling. Animals also use chemical, as well as behavioral, signals to communicate with one another. For example, many female animals release chemical substances that attract males.

Energy is required to maintain the precise order that characterizes living systems. Maintaining the chemical transactions and cellular organization essential to life requires a continuous input of energy. We begin our study of biology by developing a more precise understanding of what life is.

LIFE CAN BE DEFINED IN TERMS OF THE CHARACTERISTICS OF ORGANISMS

We can easily recognize that an oak tree, a butterfly, and a lamb are living, whereas a rock is not. Despite their diversity, the organisms that inhabit our planet share a common set of characteristics that distinguish them from nonliving things. These features include a precise kind of organization; growth and development; self-regulated metabolism; movement; the ability to respond to stimuli; reproduction; and adaptation to environmental change. We consider each of these characteristics in the following sections.

(a)

25 μm

(b)

Figure 1–1 Unicellular and multicellular life forms. (a) Unicellular organisms are generally smaller and consist of one intricate cell that performs all of the functions essential to life. Ciliates, such as this *Paramecium*, move about by beating their hairlike cilia. (b) Multicellular organisms, like this African buffalo (*Syncerus caffer*) and the plants on which it grazes, may consist of millions of cells specialized to perform specific functions. (a, Roland Birke/Peter Arnold, Inc.; b, McMurray Photography)

Organisms are composed of cells

Living organisms are highly organized, and, as discussed later in this chapter, we can identify a hierarchy of biological organization. As expressed in the **cell theory**, one of the fundamental unifying concepts of biology, all living organisms are composed of basic units called **cells**. Two German scientists are credited with the cell theory. Matthias Schleiden (in 1838) and Theodor Schwann (in 1839) were the first to report that plants and animals consist of groups of cells. Although they vary greatly in size and appearance, all organisms are composed of these small building blocks. Some of the simplest life forms, such as bacteria, are *unicellular*, meaning that each consists of a single cell. In contrast, the body of a lamb or a maple tree is made of billions of cells (Fig. 1–1). In such complex *multicellular* organisms, life processes depend on the coordinated functions of component cells that may be organized to form tissues, organs, and organ systems.

Organisms grow and develop

Some nonliving things appear to grow. For example, salt crystals form and enlarge in a supersaturated salt solution. However, this is not growth in the biological sense. Biological **growth** is an increase in the size of individual cells of an organism or in the number of cells, or both (Fig. 1–2). Growth may be uniform in the various parts of an organism, or it may

be greater in some parts than in others, causing the body proportions to change as growth occurs.

Some organisms, most trees, for example, continue to grow throughout their lives. Many animals have a defined growth period that terminates when a characteristic adult size is reached.

Figure 1–2 Biological growth. The young African elephant (*Loxodonta africana*) eats and grows until it reaches the adult size of its parents, the largest living land animals. These elephants were photographed in Kenya. (McMurray Photography)

One of the remarkable aspects of the growth process is that each part of the organism continues to function as it grows.

Living organisms develop as well as grow. **Development** includes all the changes that take place during the life of an organism. Each human, like many other organisms, begins life as a fertilized egg which then grows and develops. The structures and body form that develop are exquisitely adapted to the functions the organism must perform.

Organisms regulate their metabolic processes

Within all organisms, chemical reactions and energy transformations occur that are essential to nutrition, growth and repair of cells, and conversion of energy into usable forms. The sum of all the chemical activities of the organism is its **metabolism**. Metabolic processes occur continuously in every living organism, and they must be carefully regulated to maintain **homeostasis**, a balanced internal state. When enough of some cellular product has been made, its manufacture must be decreased or turned off. When a particular substance is needed, cellular processes that produce it must be turned on. These **homeostatic mechanisms** are self-regulating control systems that are remarkably sensitive and efficient.

The regulation of glucose (a simple sugar) concentration in the blood of complex animals is a good example of a homeostatic mechanism. The circulatory system delivers glucose and other nutrients to all the cells. Most cells require a constant supply of glucose, which they break down to obtain energy. When the concentration of glucose in the blood rises above normal limits, it is stored in the liver and in muscle cells. When the concentration begins to fall (between meals), stored nutrients are converted to glucose so that the concentration in the blood returns to normal levels. When glucose becomes depleted, we also feel hungry and restore nutrients by eating.

Movement is a basic property of cells

Organisms move as they interact with the environment, and in fact the living material within their cells is in continuous motion. In some organisms, locomotion results from the slow oozing of the cell (a process called *amoeboid motion*); in others, from the beating of tiny hairlike extensions of the cell called **cilia** or longer structures called **flagella** (Fig. 1–3). Most animals move very obviously; they wiggle, crawl, swim, run, or fly by contracting muscles. A few animals, such as sponges, corals, and oysters, have free-swimming larval stages but do not move from place to place as adults. Even though these adults, described as **sessile**, remain firmly attached to some surface, they may have cilia or flagella. These structures beat rhythmically, moving the surrounding water that brings food and other necessities to the organism.

Although plants move more slowly than most animals, they do move. For example, plants orient their leaves to the sun and grow toward light. In some plants, for example the Venus flytrap, movement is obvious, even dramatic (described in the next section).

Figure 1–3 Biological movement. These bacteria (*Helicobacter pylori*), equipped with flagella for locomotion, have been linked to stomach ulcers. (A. B. Dowsett/Science Photo Library/Photo Researchers, Inc.)

Organisms respond to stimuli

All forms of life respond to **stimuli**, physical or chemical changes in their internal or external environment. Stimuli that evoke a response in most organisms are changes in the color, intensity, or direction of light; changes in temperature, pressure, or sound; and changes in the chemical composition of the surrounding soil, air, or water. In simple organisms, the entire organism may be sensitive to stimuli. Certain unicellular organisms, for example, respond to bright light by retreating. In complex animals such as polar bears or humans, certain cells of the body are highly specialized to respond to specific types of stimuli. For example, cells in the retina of the eye respond to light.

Although their responses may not be as obvious as those of animals, plants do respond to light, gravity, water, touch, and other stimuli. Many plant responses involve different rates of growth of various parts of the plant body. A few plants, such as the Venus flytrap of the Carolina swamps (Fig. 1–4), are remarkably sensitive to touch and can catch insects. Their leaves are hinged along the midrib and they have a scent that attracts insects. Trigger hairs on the leaf surface detect the arrival of an

(a)

(b)

Figure 1-4 Plants respond to stimuli. (a) Hairs on the leaf surface of the Venus flytrap (*Dionaea muscipula*) detect the touch of an insect, and the leaf responds by folding. (b) The edges of the leaf come together and interlock, preventing the fly's escape. The leaf then secretes enzymes that kill and digest the insect. (David M. Dennis/Tom Stack & Associates)

insect and stimulate the leaf to fold. When the edges come together, the hairs interlock, preventing escape of the prey. The leaf then secretes enzymes that kill and digest the insect. The Venus flytrap is usually found in soil that is deficient in nitrogen. The plant obtains part of the nitrogen required for its growth from the insect prey it “eats.”

Organisms reproduce

At one time worms were thought to arise spontaneously from horsehairs in a water trough, maggots from decaying meat, and frogs from the mud of the Nile. We now know that each can come only from previously existing organisms. If any one characteristic can be said to be the very essence of life, it is the ability of an organism to reproduce its kind.

In simple organisms such as the amoeba, reproduction may be **asexual**, that is, without the fusion of egg and sperm to form a fertilized egg (Fig. 1-5). When an amoeba has grown to a certain size, it reproduces by splitting in half to form two new amoebas. Before an amoeba divides, its hereditary material (genes) duplicate and one complete set is distributed to each new cell. Except for size, each new amoeba is similar to the parent cell. The only way that variation occurs among asex-

(a) Asexual reproduction

100 μ m

(b) Sexual reproduction

► **Figure 1-5 Asexual and sexual reproduction.** (a) Asexual reproduction in *Diffugia*, a unicellular amoeba. In asexual reproduction, one individual gives rise to two or more offspring that are similar to the parent. (b) A pair of tropical flies mating. In sexual reproduction, typically two parents each contribute a gamete (sperm or egg). Gametes join to produce the offspring, which is a combination of the traits of both parents. (a, Visuals Unlimited/Cabisco; b, L.E. Gilbert, University of Texas at Austin/Biological Photo Service)

Figure 1–6 Adaptations. These Burchell's zebras (*Equus burchelli*), photographed at Ngorongoro Crater in Tanzania, are behaviorally adapted to position themselves to watch for lions and other predators. Stripes are thought to be an adaptation for visually protecting themselves against predators. They serve as camouflage or to break up form when spotted from a distance. The zebra stomach is adapted for feeding on coarse grass passed over by other grazers, an adaptation that helps them survive when food is scarce. (McMurray Photography)

ually reproducing organisms is by genetic mutation, a permanent change in the genes.

In most plants and animals, **sexual reproduction** is carried out by the production of specialized egg and sperm cells that fuse to form a fertilized egg. The new organism develops from the fertilized egg. Offspring produced by sexual reproduction are the product of the interaction of various genes contributed by both the mother and the father. Such genetic variation provides raw material for the vital processes of evolution and adaptation.

Populations evolve and become adapted to the environment

The ability of a population to evolve (change over time) and adapt to its environment enables it to survive in a changing world. **Adaptations** are traits that enhance an organism's ability to survive in a particular environment. They may be structural, physiological, behavioral, or a combination of all three (Fig. 1–6). The long, flexible tongue of the frog is an adaptation for catching insects, and the thick fur coat of the polar bear is an adaptation for surviving frigid temperatures. Every biologically successful organism is a complex collection of coordinated adaptations produced through evolutionary processes.

INFORMATION MUST BE TRANSMITTED WITHIN AND BETWEEN INDIVIDUALS

In order for an organism to grow, develop, carry on self-regulated metabolism, move, respond, and reproduce, it must have precise instructions. The information an organism needs to carry on these life processes is coded and delivered in the form of chemical substances and electrical impulses.

DNA transmits information from one generation to the next

Humans give birth only to human babies, not to giraffes or rose bushes. In organisms that reproduce sexually, each offspring is a combination of the traits of its parents. In 1953, James Watson and Francis Crick worked out the structure of deoxyribonucleic acid, more simply known as **DNA**. This chemical substance makes up the **genes**, the units of hereditary material. The work of Watson and Crick led to the understanding of the genetic code that transmits information from generation to generation. This code works somewhat like our alphabet; it can spell an amazing variety of instructions for making organisms as diverse as bacteria, frogs, and redwood trees. The genetic code is a dramatic example of the unity of life because it is used to specify instructions for making every living organism (Fig. 1–7).

Figure 1–7 DNA. An organism's ability to transmit information from one generation to the next is essential to the continuity of life. In all organisms, the hereditary material is DNA. This computer-generated image shows the double-helix configuration of DNA. (Will and Deni McIntyre/Photo Researchers, Inc.)

Information is transmitted by chemical and electrical signals

Genes control the development and functioning of every organism. DNA contains the “recipes” for making all of the **proteins** needed by the organism. Proteins are very large molecules that are important in determining structure and function of cells and tissues. Brain cells are different from muscle cells, in large part because they have different types of proteins. Some proteins are important in communication within and among cells. Certain proteins on the surface of a cell serve as markers so that other cells “recognize” them. Other cell surface proteins serve as receptors that combine with chemical messengers.

Cells use proteins and many other types of ions and molecules to communicate with one another. In a multicellular organism chemical compounds secreted by cells help regulate growth, development, and metabolic processes in other cells. The mechanisms involved in **cell signaling** are complex, often involving multistep biochemical sequences, and cell signaling is currently an area of intense research. A major focus has been the transfer of information among cells of the immune system. A better understanding of how cells communicate promises new insights into how the body protects itself against disease organisms. Learning to manipulate cell signaling may lead to new methods of delivering drugs into cells and new treatments for cancer and other diseases. Examples of cell signaling will be discussed throughout this book.

Hormones are molecules that function as chemical messengers that transmit information from one part of an organism to another. A hormone can signal cells to produce or secrete a certain protein or other substance.

Many organisms use electrical signals to transmit information. Most animals have nervous systems that transmit information by way of both electrical impulses and chemical compounds known as **neurotransmitters**. Information transmitted from one part of the body to another is important in regulating life processes. In complex animals, the nervous system transmits signals from sensory receptors like the eyes and ears to the brain, giving the animal information about its outside environment.

Information must also be transmitted from one organism to another. Mechanisms for this type of communication include release of chemicals, visual displays, and sounds.

EVOLUTION IS THE PRIMARY UNIFYING CONCEPT OF BIOLOGY

The theory of **evolution**, which explains how populations of organisms have changed over time, has become the greatest unifying concept of biology. Some element of an evolutionary perspective is present in every specialized field within biology. Biologists try to understand the structure, function, and behavior of organisms and their interactions with one another by considering them in light of the long, continuing process of evolution. Although evolution is discussed in depth in

Chapters 17 through 21, we present a brief overview here to give you the background necessary to understand other aspects of biology.

Species adapt in response to changes in their environment

Every organism is the product of complex interactions between environmental conditions and the genes of its ancestors. If every organism of a species¹ were exactly like every other, any change in the environment might be disastrous to all, and the species would become extinct. Adaptation to changes in the environment involves changes in populations rather than in individual organisms. Such adaptations are the result of evolutionary processes that occur over time and involve many generations.

Natural selection is an important mechanism by which evolution proceeds

Although the concept of evolution had been discussed by philosophers and naturalists through the ages, Charles Darwin and Alfred Wallace first brought the theory of evolution to general attention and suggested a plausible mechanism, **natural selection**, to explain it. In his book *On the Origin of Species by Means of Natural Selection*, published in 1859, Darwin synthesized many new findings in geology and biology. He presented a wealth of evidence that the present forms of life on Earth descended, with modifications, from previously existing forms. Darwin's book raised a storm of controversy in both religion and science, some of which still lingers.

Darwin's theory of evolution has helped shape the biological sciences to the present day. His work generated a great wave of scientific observation and research that has provided much additional evidence that evolution is responsible for the great diversity of organisms present on our planet. Even today, the details of the process of evolution are a major focus of investigation and debate.

Darwin based his theory of natural selection on the following four observations: (1) Individual members of a species show some variation from one another. (2) Organisms produce many more offspring than will survive to reproduce (Fig. 1–8). (3) Organisms compete for necessary resources like food, sunlight, and space. Individuals who happen to have characteristics that give them some advantage are more likely to survive. (4) The survivors live to reproduce and pass their adaptations for survival on to their offspring. Thus, the best adapted individuals of a population leave, on average, more offspring than do other individuals. Because of this differential reproduction, a greater proportion of the population becomes adapted to the prevailing environmental conditions. The environment *selects* the best adapted organisms for survival.

¹A species is a group of organisms with similar structure, function, and behavior; in nature they breed only with each other. Members of a species have a common gene pool and share a common ancestry.

Figure 1–8 Egg masses of the wood frog (*Rana sylvatica*).

Many more eggs are produced than can possibly develop into adult frogs. Random events are largely responsible for determining which of these developing frogs will hatch, reach adulthood, and reproduce. However, certain traits possessed by each organism will also contribute to its probability for success in its environment. Not all organisms are as prolific as the frog, but the generalization that more organisms are produced than survive is true throughout the living world. (J. Serrao/Photo Researchers, Inc.)

Darwin did not know about DNA or understand the mechanisms of inheritance. We now understand that the variations among organisms are a result of different varieties of genes that code for each characteristic. The ultimate source of these variations is random **mutations**, chemical changes in DNA that persist and can be inherited. Mutations modify genes; by this process they provide the raw material for evolution.

Populations evolve as a result of selective pressures from changes in the environment

All the genes present in a population make up its gene pool. By virtue of its gene pool, a population is a reservoir of variation. Natural selection acts on individuals within a population. Selection favors individuals with genes that specify traits that enable them to cope effectively with pressures exerted by the environment. These organisms are most likely to survive and produce offspring. As these successful organisms pass on their genetic recipe for survival, their traits become more widely distributed in the population. Over time, as organisms continue to change (and as the environment itself changes, bringing different selective pressures), the members of the population become better adapted to their environment and less like their ancestors.

An interesting case of evolution in action has been documented in England since 1850. The tree trunks in a certain region of England were once white because of a type of lichen that grew on them. (A lichen is a compound organism usually consisting of an alga and fungus.) The common peppered moth was beautifully adapted for resting on these white tree trunks because its light color blended with the trunks and protected it from predatory birds (Fig. 1–9). At that time black peppered moths were rare.

Figure 1–9 Evolution in action. Both a dark and a light peppered moth can be seen on the tree trunk. Which is most likely to become food for the bird? Note that the tree trunk is light in color because it is covered by lichens. (John D. Cunningham/Visuals Unlimited)

Then humans changed the environment. They built industries that polluted the air with soot, killing the lichens and coloring the tree trunks black. The light-colored moths became easy prey to the birds. The black moths blended with the dark trunks and escaped the sharp eyes of predators. In these new surroundings, the dark moths were better adapted and were selected for survival. Eventually, more than 90% of the peppered moths in the industrial areas of England were dark. This adaptation is known as *industrial melanism*. Interestingly, with efforts to control air pollution, there has been an increase in the population of the light-colored moths.

Adaptation of the peppered moth was studied in the 1950s by H. B. D. Kettlewell of Oxford, who marked hundreds of male moths with a spot of paint under their wings and then released them in both rural and industrial areas. Observers reported that birds preyed on the moths that were more visible. After a period of time, surviving moths were recaptured by attracting them with light or females. Based on observation and on the percentage of each type of moth recaptured, these studies confirmed that significantly more dark moths survived in industrial areas and more light moths survived in rural areas.

BIOLOGICAL ORGANIZATION IS HIERARCHICAL

Whether we study a single complex organism or the world of life as a whole, we can identify a hierarchy of biological organization (Fig. 1–10). At every level, structure and function are precisely coordinated. One way to study a particular level is by looking at its components. For example, biologists can learn about cells by studying atoms and molecules. Learning about a structure by studying its parts is known as **reductionism**. However, the whole is more than the sum of its parts. Each level has **emergent properties**, characteristics not found at lower levels. For example, populations have emergent properties such as density, age structure, and birth and death rates. The individuals that make up a population lack these characteristics.

Organisms have several levels of organization

The **chemical level**, the most basic level of organization, includes atoms and molecules. An **atom** is the smallest unit of a chemical element (fundamental substance) that retains the characteristic properties of that element. For example, an atom of iron is the smallest possible amount of iron. Atoms combine chemically to form **molecules**. Two atoms of hydrogen combine with one atom of oxygen to form a single molecule of water. Although composed of two types of atoms that are gases, water is a liquid with very different properties, an example of emergent properties.

At the **cellular level** many different types of atoms and molecules associate with one another to form cells. However, a cell is much more than a heap of atoms and molecules. Its emergent properties make it the basic structural and functional unit of life, the simplest component of living matter that can carry on all of the activities necessary for life. Every cell is surrounded by a **plasma membrane** that regulates the passage of materials between the cell and its surrounding environment. All cells have specialized molecules that contain genetic instructions. Cells typically have internal structures called **organelles** that are specialized to perform specific functions.

Two fundamentally different types of cells are known. Bacteria have **prokaryotic cells**. All other organisms are characterized by their **eukaryotic cells**. Unlike the structurally simpler prokaryotic cells, eukaryotic cells typically contain a variety of membrane-bounded organelles, including a **nucleus** which houses DNA.

During the evolution of multicellular organisms, cells associated to form **tissues**. For example most animals have muscle tissue and nervous tissue, and plants have epidermis (a tissue that serves as a protective covering). In most complex organisms, tissues organize into functional structures, called **organs**, such as the heart and stomach in animals and roots and leaves in plants. In animals, each major group of biological functions is performed by a coordinated group of tissues and organs called an **organ system**. The circulatory and digestive systems are examples of organ systems. Functioning together with great precision, organ systems make up a complex multicellular **organism**. Again, emergent properties are evident. An organism is much more than its component organ systems.

Several levels of ecological organization can be identified

Organisms interact to form still more complex levels of biological organization. All of the members of one species that live in the same geographic area at the same time make up a **population**. The populations of organisms that inhabit a particular area and interact with one another form a **community**. A community can consist of hundreds of different types of organisms. As populations within a community evolve, the community changes.

A community together with its nonliving environment is referred to as an **ecosystem**. An ecosystem can be as small as a pond (or even a puddle) or as vast as the Great Plains of North America or the Arctic tundra. All of planet Earth's ecosystems together are known as the **biosphere**. The biosphere includes all of Earth that is inhabited by living organisms—the atmosphere, the hydrosphere (water in any form), and the lithosphere (Earth's crust). The study of how organisms relate to one another and to their physical environment is called **ecology** (derived from the Greek *oikos*, meaning “house”).

Figure 1–10 Biological organization. Atoms join to form molecules of varying size, including very large molecules, or macromolecules. Atoms and molecules form organelles such as the nucleus or mitochondrion (the site of many energy transformations) of the cell. Cells associate to form tissues, such as bone tissue. Tissues form organs, such as bones, which, in turn, make up organ systems. The skeletal system and other organ systems work together to make up the functioning organism. A population is composed of organisms of the same species. The populations of different species that inhabit a particular area make up a community, which together with the nonliving environment, form an ecosystem. Planet Earth and all of its communities make up the biosphere.

TABLE 1–1 Classification of Domestic Cat, Human, and White Oak

Category	Classification of Cat	Classification of Human	Classification of White Oak
Kingdom	Animalia	Animalia	Plantae
Phylum	Chordata	Chordata	Anthophyta
Subphylum	Vertebrata	Vertebrata	None
Class	Mammalia	Mammalia	Dicotyledones
Order	Carnivora	Primates	Fagales
Family	Felidae	Hominidae	Fagaceae
Genus and specific epithet	<i>Felis catus</i>	<i>Homo sapiens</i>	<i>Quercus alba</i>

MILLIONS OF SPECIES HAVE EVOLVED

About 1.75 million species of extant (currently living) organisms have been scientifically identified, and biologists estimate that millions more remain to be discovered. In order to study life, we need a system for organizing, naming, and classifying its myriad forms. That system is part of **taxonomy**, the science of naming and classifying organisms. Biologists who specialize in classification are **taxonomists**.

Biologists use a binomial system for naming organisms

In the 18th century Carolus Linnaeus, a Swedish botanist, developed a hierarchical system of naming and classifying organisms that, with some modification, is still used today. The basic unit of classification is the **species**. Closely related species are grouped together in the next higher level of classification, the **genus** (pl. *genera*).

The Linnaean system of naming species is referred to as the **binomial system of nomenclature** because each species is assigned a two-part name. The first part of the name is the genus, and the second part, the **specific epithet**, designates a particular species belonging to that genus. The specific epithet is often a descriptive word expressing some quality of the organism. It is always used together with the full or abbreviated generic name preceding it. The generic name is always capitalized; the specific epithet is generally not capitalized. Both names are always italicized or underlined. For example, the dog, *Canis familiaris* (abbreviated *C. familiaris*), and the timber wolf, *Canis lupus* (*C. lupus*), belong to the same genus. The cat, *Felis catus*, belongs to a different genus. The scientific name of the American white oak is *Quercus alba*, whereas the name of the European white oak is *Quercus robur*. Another tree, the white willow, *Salix alba*, belongs to a different genus. The scientific name for our own species is *Homo sapiens* (“wise man”).

Taxonomic classification is hierarchical

Just as species may be grouped together in a common genus, a number of related genera can be grouped in a more inclu-

sive group, a **family** (Table 1–1). In turn, families may be grouped into **orders**, orders into **classes**, and classes into **phyla**. Note that each group is more inclusive. The family Canidae, which includes all doglike carnivores (animals that eat mainly meat), consists of 12 genera and about 34 living species. Family Canidae, along with family Ursidae (bears), family Felidae (catlike animals), and several other families that eat mainly meat, is placed in order Carnivora. Order Carnivora, order Primates (the order to which humans belong), and several other orders belong to class Mammalia (mammals). Class Mammalia, class Aves (birds), class Reptilia (reptiles), and four other classes are grouped together as subphylum Vertebrata. The vertebrates belong to phylum Chordata, which is part of kingdom Animalia.

Organisms can be assigned to six kingdoms

In the system of classification used in this book, every organism is assigned to one of six **kingdoms**: Archaeobacteria, Eubacteria, Protista, Fungi, Plantae, or Animalia (Fig. 1–11). Bacteria are unicellular, and they differ from all other organisms in that they are prokaryotes; their cells lack a discrete nucleus and other membrane-bounded organelles. Among the prokaryotes two very distinct groups have been recognized, so in the

► **Figure 1–11 A survey of the kingdoms of life.** (a) These bacteria (*Methanosarcina mazei*) members of kingdom Archaeobacteria, produce methane. (b) The large rod-shaped bacterium *Bacillus anthracis*, a member of kingdom Eubacteria, is the causative agent of anthrax, a disease of cattle and sheep that can infect humans. (c) Unicellular protozoa (*Tetrahymena* sp.) are classified in kingdom Protista. (d) Mushrooms, such as these fly agaric mushrooms (*Amanita muscaria*), belong to kingdom Fungi. (e) The plant kingdom claims many beautiful and diverse forms such as the lady’s slipper (*Phragmipedium carolinum*). (f) Among the fiercest members of the animal kingdom, lions (*Panthero leo*) are also among the most sociable. The largest of the big cats, lions live in prides (groups). (a, R. six-kingdom system, bacteria are assigned to two kingdoms, **Archaeobacteria** and **Eubacteria**. Kingdom **Protista** consists of protozoa, algae, water molds, and slime molds. These are single-celled or simple multicellular organisms. Some protists are adapted to carry out **photosynthesis**, the process in which light energy is converted to the chemical energy of food molecules.

Kingdom **Fungi** is composed of the yeasts, mildews, molds, and mushrooms. These organisms do not photosynthesize. They obtain their nutrients by secreting digestive enzymes into food and then absorbing the predigested food.

Members of kingdom **Plantae** are complex multicellular organisms adapted to carry out photosynthesis. Among characteristic plant features are the *cuticle* (a waxy covering over aerial parts that reduces water loss), *stomata* (tiny openings in stems and leaves for gas exchange), and multicellular *gametangia* (organs that protect developing reproductive cells). Kingdom Plantae includes both nonvascular plants (mosses) and vascular plants (ferns, conifers, and flowering plants).

Kingdom **Animalia** is made up of multicellular organisms that must eat other organisms for nourishment. Complex animals have high degrees of tissue specialization and body organization; these have evolved along with motility, complex sense organs, nervous systems, and muscular systems.

A more detailed presentation of the kingdoms can be found in Chapters 22 through 30, and classification is summarized in Appendix C. We refer to these groups repeatedly throughout this book as we consider the many kinds of challenges faced by living organisms and the various adaptations that have evolved in response to these challenges.

LIFE DEPENDS ON CONTINUOUS INPUT OF ENERGY

A continuous input of energy from the Sun enables life to exist. Every activity of a living cell or organism requires energy. Whenever energy is used to perform biological work, some is converted to heat and dispersed into the environment.

Energy flows through cells and organisms

Recall that all of the energy transformations and chemical processes that occur within an organism are referred to as metabolism. Energy is necessary in order to carry on the metabolic activities essential for growth, repair, and maintenance. Each cell of an organism requires nutrients. Some nutrients are used as fuel for **cellular respiration**, a process during which some of the energy stored in the nutrient molecules is released for use by the cells (Fig. 1–12). This energy can be used for cellular work or for synthesis of needed materials such as new cellular components.

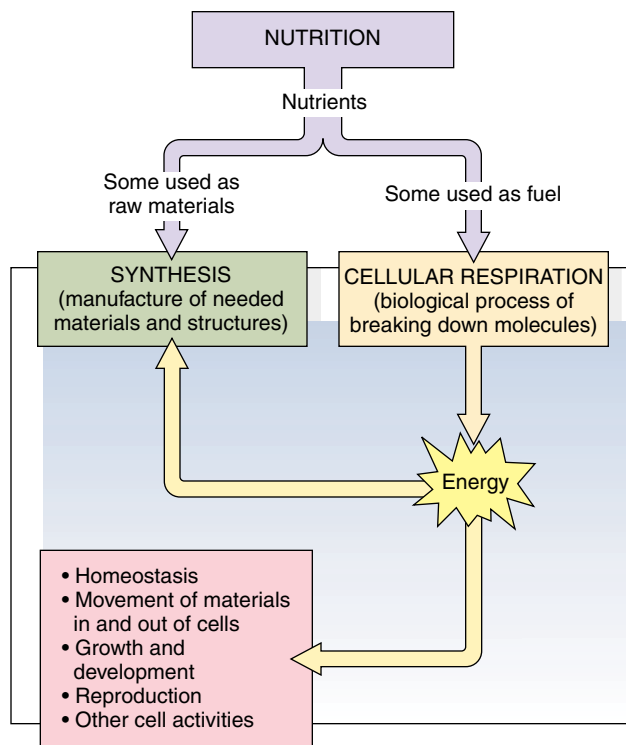

Figure 1–12 Relationships of metabolic processes. These processes occur continuously in every living organism. Some of the nutrients in food are used to synthesize needed materials and cell parts. Other nutrients are used as fuel for cellular respiration, a process that releases energy stored in food. This energy is needed for synthesis and for other forms of cellular work.

Energy flows through ecosystems

Like individual organisms, ecosystems depend on a continuous input of energy. A self-sufficient ecosystem contains three types of organisms—producers, consumers, and decomposers—and has a physical environment appropriate for their survival. These organisms depend on each other and on the environment for nutrients, energy, oxygen, and carbon dioxide. However, there is a one-way flow of energy through ecosystems. Organisms can neither create energy nor use it with complete efficiency. During every energy transaction, some energy is lost to biological systems as it is dispersed into the environment as heat (Fig. 1–13).

Producers manufacture their own food

Producers, or **autotrophs**, are plants, algae, and certain bacteria that can produce their own food from simple raw materials. Most of these organisms use sunlight as an energy source and carry out photosynthesis, in which complex molecules are synthesized from carbon dioxide and water. The light energy is transformed into chemical energy, which is stored within the chemical bonds of the food molecules produced. Oxygen, which is required not only by plant cells but also by the cells

Figure 1–13 Energy flow. Continuous energy input from the Sun operates the biosphere. During photosynthesis, producers use the energy from sunlight to make complex molecules from carbon dioxide and water. Consumers obtain energy, carbon, and other needed materials when they eat producers. Wastes and dead organic material supply decomposers with energy and carbon. During every energy transaction some energy is lost to biological systems as it is dispersed as heat.

of most other organisms, is produced as a byproduct of photosynthesis:

Consumers obtain energy by eating producers

Animals are **consumers**, or **heterotrophs**, organisms that depend on producers for food, energy, and oxygen. Consumers obtain energy by breaking down sugars and other food molecules originally produced during photosynthesis. Recall that the biological process of breaking down sugars and other fuel molecules is known as cellular respiration. When chemical bonds are broken during cellular respiration, their stored energy is made available for life processes.

Consumers contribute to the balance of the ecosystem. For example, consumers produce carbon dioxide needed by produc-

ers. The metabolism of consumers and producers helps maintain the life-sustaining mixture of gases in the atmosphere.

Decomposers obtain energy from wastes and dead organisms

Bacteria and fungi are **decomposers**, heterotrophs that obtain nutrients by breaking down wastes, dead leaves, and the bodies of dead organisms. In their process of obtaining energy, decomposers make the components of wastes and dead organisms available for reuse. If decomposers did not exist, nutrients would remain locked up in dead bodies, and the supply of elements required by living systems would soon be exhausted.

BIOLOGY IS STUDIED USING THE SCIENTIFIC METHOD

This book is a starting point for your exploration of biology. It will provide you with tools to become a part of this fascinating science and a more informed inhabitant of our planet. Biologists work both in laboratories and out in the field (Fig. 1–14). Their investigations range from the study of molecu-

(a)

(b)

Figure 1–14 Biologists at work. (a) This biologist studying the rainforest canopy in Costa Rica is part of an international effort to study and preserve tropical rain forests. Researchers study the interactions of organisms and the effects of human activities on the rain forests. (b) These researchers, working on developing an AIDS vaccine, are examining a DNA sequencing autoradiogram over a light box. (a, Mark Moffett/Minden Pictures; b, Hank Morgan/Photo Researchers, Inc.)

lar biology and viruses to the interactions of the communities of our biosphere. Perhaps you will decide to become a research biologist and help unravel the complexities of the human brain; discover new hormones that cause plants to flower; identify new species of animals or bacteria; or develop new treatments for diseases such as cancer, AIDS, or heart disease. Or perhaps you will choose to enter an applied field of biology such as forestry, dentistry, medicine, or veterinary medicine.

Biology is a **science**. The word *science* comes from a Latin word meaning “to know.” Science is a way of thinking and a method of investigating the world around us in a systematic manner. Science enables us to uncover ever more about the world we live in and leads us to an expanded appreciation of our universe.

The **process of science** is investigative, dynamic, and often controversial. It changes over time as it is influenced by cultural, social, and historical contexts as well as by the personalities of scientists themselves. The observations made, the range of questions posed, and the design of experiments depend on the creativity of the individual scientist. In contrast, the **scientific method** involves a series of ordered steps and is a framework used by most scientists.

Using the scientific method, scientists make careful observations, ask critical questions, develop **hypotheses** (testable statements), make predictions that can be tested, and perform experiments to test their predictions (Fig. 1–15). They interpret the results of their experiments and draw conclusions from them. Even results that do not support the hypothesis may be valuable and may lead to new hypotheses. If the results support a hypothesis, a scientist may use them to generate related hypotheses.

Science is systematic. Scientists organize, and often quantify, knowledge, making it readily accessible to all who wish to build on its foundation. In this way science is both a personal and a social endeavor. Science is not mysterious. Anyone who understands its rules and procedures can take on its challenges. What distinguishes science is its insistence on rigorous methods to examine a problem. Science seeks to give us precise knowledge about those aspects of the world that are accessible to its methods of inquiry. It is not a replacement for philosophy, religion, or art. Being a scientist does not prevent one from participating in other fields of human endeavor, just as being an artist does not prevent one from practicing science.

Science requires systematic thought processes

Two types of systematic thought processes used by scientists are deduction and induction. With **deductive reasoning**, we begin with supplied information, called *premises*, and draw conclusions on the basis of that information. Deduction proceeds from general principles to specific conclusions. For example, if we accept the premise that all birds have wings, and the second premise that sparrows are birds, we can conclude deductively that sparrows have wings (Fig. 1–16). Deduction helps us discover relationships among known facts. The **hypothetico-deductive approach** emphasizes the use of deductive reasoning to test hypotheses.

Scientists also use a **hypothetico-inductive approach** that focuses on discovering new general principles. **Inductive reasoning** is the opposite of deduction. We begin with specific observations and draw a conclusion or discover a general prin-

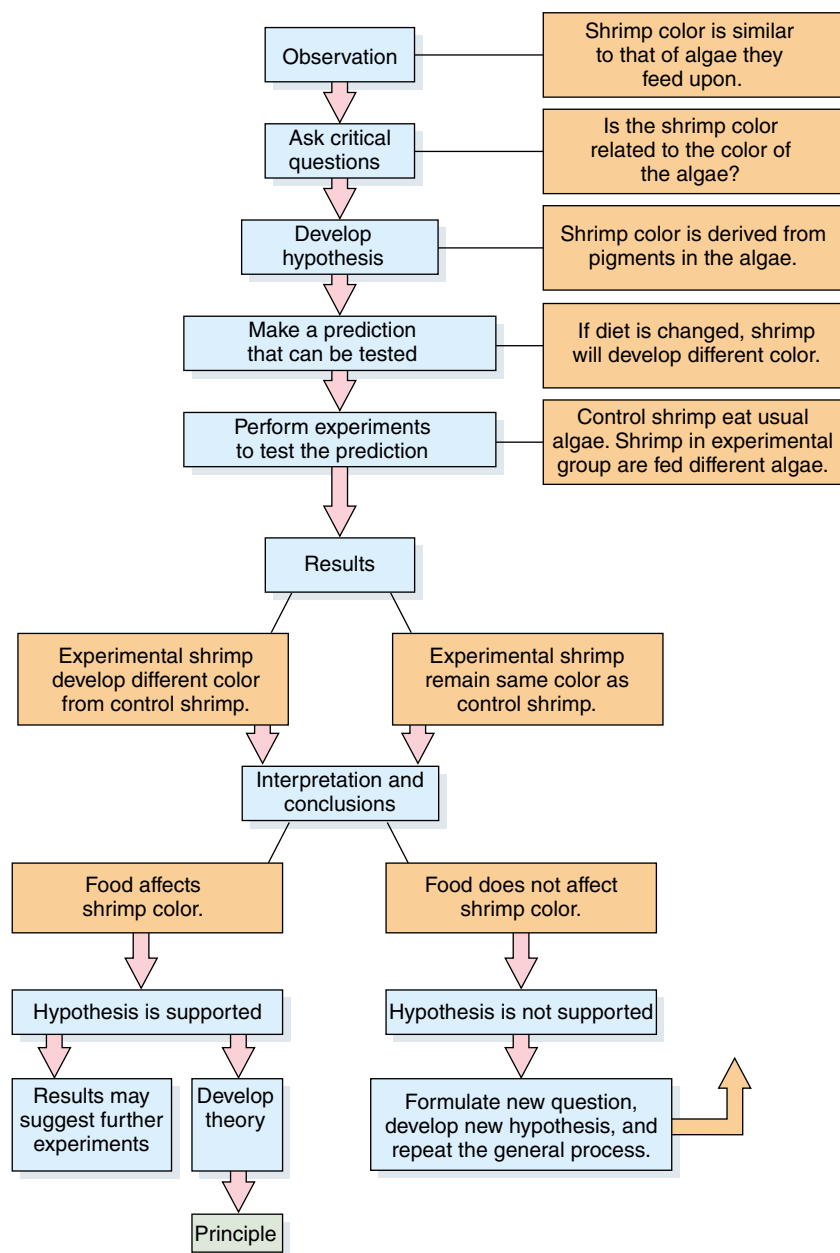

Figure 1–15 The scientific method. Scientists use the scientific method as a framework for their research.

ciple. For example, if we know that sparrows have wings and are birds, and we know that robins, eagles, pigeons, and hawks have wings and are birds, we might induce that all birds have wings. In this way, the inductive method can be used to organize raw data into manageable categories by answering the question, What do all these facts have in common?

A weakness of inductive reasoning is that conclusions generalize the facts to all possible examples. We go from many observed examples to all possible examples when we formulate

the general principle. This is known as the **inductive leap**. Without it, we could not arrive at generalizations. However, we must be sensitive to exceptions and to the possibility that the conclusion is not valid. For example, the kiwi bird of New Zealand does not have functional wings! The generalizations that inductive conclusions contain come from the creative insight of the human mind, and creativity, however admirable, is not infallible.

Figure 1–16 All birds have wings. A diagrammatic example of a syllogism, the classic form of deductive reasoning.

Scientists make careful observations and ask critical questions

Significant discoveries are usually made by those who are in the habit of looking critically at nature. Chance and luck are often involved in recognizing a phenomenon or problem. In 1928 the British bacteriologist Alexander Fleming observed that one of his bacterial cultures had become invaded by a blue mold. He almost discarded it, but before he did, he noticed that the area contaminated by the mold was surrounded by a zone where bacterial colonies did not grow well.

The bacteria were disease organisms of the genus *Staphylococcus*, which can cause boils and skin infections. Anything that could kill them was interesting! Fleming saved the mold, a variety of *Penicillium* (blue bread mold). It was subsequently discovered that the mold produced a substance that slowed reproduction of the bacterial population but was usually harmless to laboratory animals and humans. The substance was penicillin, one of the first antibiotics.

We may wonder how many times the same type of mold grew on the cultures of other bacteriologists who failed to make the connection and simply threw away their contaminated cultures. Fleming benefited from chance, but his mind was prepared to make observations and formulate critical questions, and his pen was prepared to publish them. It was left to others, however, to develop the practical applications. Though Fleming recognized the potential practical benefit of penicillin, he did not vigorously promote it, and more than ten years passed before the drug was put to significant use.

A hypothesis is a testable statement

In the early stages of an investigation, a scientist typically thinks of many possible hypotheses and hopes that the right one is among them. He or she then decides which, if any, could and should be subjected to experimental test. Why not test them

all? Time and money are important considerations in conducting research. We must establish priority among the hypotheses in order to decide which to test first. Fortunately, some guidelines do exist. A good hypothesis exhibits the following:

1. It is reasonably consistent with well established facts.
2. It is capable of being tested; that is, it should generate definite predictions, whether the results are positive or negative. Test results should also be repeatable by independent observers.
3. It is falsifiable, which means it can be proved false.

A hypothesis cannot really be proved true, but in theory (though not necessarily in practice) a well stated hypothesis can be proved false. If one believes in an unfalsifiable hypothesis (e.g., the existence of invisible and undetectable angels), it must be on grounds other than scientific ones.

Consider the following hypothesis: All female mammals (animals that have hair and produce milk for their young) bear live young. The hypothesis was based on the observations that dogs, cats, cows, lions, and humans are all mammals and all bear live young. Consider further that a new species, species X, was identified as a mammal. Biologists predicted that females of species X would bear live young. When a female of the new species gave birth to offspring, this supported the hypothesis. Yet it did not really *prove* the hypothesis.

Before the Southern Hemisphere was explored, most individuals would probably have accepted the hypothesis without question, because all known furry, milk-giving animals did, in fact, bear live young. But it was discovered that two Australian animals (the duck-billed platypus and the spiny anteater) had fur, produced milk for their young, but laid eggs (Fig. 1–17). The hypothesis, as stated, was false no matter how

Figure 1–17 Is this animal a mammal? The duck-billed platypus is classified as a mammal because it has fur and produces milk for its young. However, unlike most mammals, it lays eggs. (Tom McHugh/Photo Researchers, Inc.)

many times it had previously been supported. As a result, biologists either had to consider the platypus and the spiny anteater as nonmammals, or to broaden their definition of mammals to include them (they chose the latter).

A hypothesis is not true just because some of its predictions (the ones we happen to have thought of or have thus far been able to test) have been shown to be true. After all, they could be true by coincidence. Failure to observe a predicted outcome does not make a hypothesis false, but it does not show that the hypothesis is true, either.

A prediction is a logical consequence of a hypothesis

A hypothesis is an abstract idea, so there is no way to test it directly. But hypotheses suggest certain logical consequences, that is, observable things that cannot be false if the hypothesis is true. On the other hand, if the hypothesis is, in fact, false, other definite predictions should disclose that. As used here, then, a **prediction** is a deductive, logical consequence of a hypothesis. It does not have to be a future event.

Predictions can be tested by experiment

A prediction can be tested by controlled experiments. Early biologists observed that the nucleus was the most prominent part of the cell, and they hypothesized that it might be essential for the well-being of the cell. They predicted that if the nucleus were removed from the cell, the cell would die. Experiments were performed in which the nucleus of a single-celled amoeba was removed surgically with a micro-loop. After this surgery, the amoeba continued to live and move but it did not grow, and after a few days it died. These results suggested that the nucleus is necessary for the metabolic processes that provide for growth and cell reproduction (Fig. 1–18).

But, the investigators asked, what if the operation itself and not the loss of the nucleus caused the amoeba to die? They performed a *controlled* experiment in which two groups of amoebas were subjected to the same operative trauma. However, in the **experimental group** the nucleus was removed, whereas in the **control group** it was not. An experimental group ideally differs from a control group only with respect to the variable being studied. In the control group, a micro-loop was inserted into each amoeba and pushed around inside the cell to simulate the removal of the nucleus; then the needle was withdrawn, leaving the nucleus inside. Amoebas treated with such a sham operation recovered and subsequently grew and divided, but the amoebas without nuclei died. This experiment provided data that it was the removal of the nucleus and not simply the operation that caused the death of the amoebas. The data supported the hypothesis that the nucleus is essential for the well-being of the cell.

Let us consider another example of a scientific study. Steven N. Blair and his colleagues reported in 1996 in the *Journal of the American Medical Association* the results of their study of the relationship between cardiac fitness and cardio-

Figure 1–18 Testing a prediction. A controlled experiment tested the prediction that if the nucleus is removed from a cell, the cell would die. The data gathered from this and similar experiments provided support for the hypothesis that the nucleus is essential for the well-being of the cell. (a) When its nucleus is surgically removed with a micro-loop, the amoeba dies. (b) Control amoebas subjected to similar surgical procedures (including insertion of a micro-loop), but without actual removal of the nucleus, do not die.

vascular disease. The subjects were more than 25,000 men and 7,000 women, ages 20 to 88 years, who had completed a preventive medical examination. The investigators used treadmill time to group participants into fitness categories and then followed these subjects over several years. Outcome measures were cardiovascular disease and mortality from all causes. The investigators reported that low fitness and cigarette smoking were significant predictors of mortality in men and women. Moderately fit men and women had a significantly lower death rate compared to those in the low-fitness group.

In scientific studies, care must be taken to avoid **bias**. For example, to prevent bias, most medical experiments today are carried out in **double-blind** fashion. When a drug is being tested, one group of patients is given the new medication, while a second similar group of patients is given a placebo, a harmless starch pill similar in size, shape, color, and taste to the pill being tested. This is a double-blind study because neither the patient nor the physician knows who is getting the experimental drug and who is getting the placebo. The pills or treatments are coded in some way, and only after the experiment

is over and the results are recorded is the code broken. Not all experiments can be so neatly designed; for one thing, it is often difficult to establish appropriate controls.

Scientists interpret the results of experiments and make conclusions

Scientists gather data in an experiment, interpret their results, and then formulate conclusions. For example, in the amoeba experiment described above, investigators concluded that the nucleus was essential for the well-being of the cell. One reason for inaccurate conclusions is **sampling error**. Since *all* cases of what is being studied cannot be observed or tested (scientists cannot study every amoeba), we must be content with a sample, or subset, of them. Yet how can we know whether that sample is truly representative of whatever we are studying? In the first place, if the sample is too small, it may be different due to random factors. A study with only two, or even ten, amoebas might not yield reliable data that could be generalized to other amoebas. This problem can usually be solved by using large numbers of subjects and applying the mathematics of statistical analysis (Fig. 1–19).

We must also ensure that the sample is typical of the group that we intend to study. Scientists use statistical techniques to ensure that there is no consistent bias in the way that experimental samples are chosen.

Even if a conclusion is based on results from a carefully designed experiment, it is still possible that new observations or results from other experiments can challenge the conclusion. If we test a large number of cases, we are more likely to draw accurate scientific conclusions. The scientist seeks to state with confidence that any specific conclusion has a certain statistical probability of being correct.

Experiments must also be replicated. Approximately one year after Wilmut (see Chapter Opener) reported that he had cloned a lamb from adult DNA, some biologists challenged his work. Wilmut's critics were concerned that he had not repeated his experiment and that his results had not yet been replicated by other biologists. They pointed out that Wilmut himself reported that his cloning efforts had been successful only once out of about 400 attempts. Before scientists fully accept the experimental results, the study must be repeated in at least one other laboratory.

A well-supported hypothesis may lead to a theory

Nonscientists often use the word *theory* incorrectly to refer to a hypothesis. A **theory** can be developed only when a hypothesis has been supported by consistent results from many observations or experiments. A good theory relates facts that previously appeared to be unrelated. A good theory grows, building on additional facts as they become known. It predicts new facts and suggests new relationships among phenomena. It may even suggest practical applications.

Figure 1–19 Statistical probability. Taking a single sample can result in sampling error. The greater the number of samples we take of an unknown, the more likely we can make valid assumptions about it.

A good theory, by showing the relationships among classes of facts, simplifies and clarifies our understanding of natural phenomena. As Einstein wrote, “In the whole history of science from Greek philosophy to modern physics, there have been constant attempts to reduce the apparent complexity of natural phenomena to simple, fundamental ideas and relations.”

A theory that, over a long period of time, has yielded true predictions and is thus almost universally accepted is referred to as a scientific **principle**. The term **law** is sometimes used for a principle judged to be of great basic importance, such as the law of gravity.

Science has ethical dimensions

Researchers who publish their work in scientific journals describe their experiments in sufficient detail to be independently performed by others. This permits objective observers to detect errors or bias in the original study and helps to guard against the occasional odd result caused by random or uncontrolled factors, as well as those tainted by dishonesty on the part of the original researcher.

Scientific investigation depends on commitment to such practical ideals as truthfulness and the obligation to communicate results. Honesty is particularly important in science. Consider the great (though temporary) damage done whenever an unprincipled or even desperate researcher, whose ca-

reer might depend on publication of a research study, knowingly disseminates false data. Until the deception is uncovered, researchers might devote many thousands of dollars or hours of precious professional labor to futile lines of research inspired by erroneous reports.

Fortunately, science tends to be self-correcting through the consistent use of the scientific process itself. Sooner or later, someone's experimental results are bound to cast doubt on false data.

Scientists face many important ethical issues surrounding such issues as cloning, research on human embryos, human and animal experimentation, and applications of genetic engineering. Many of these concerns will be discussed in this book.

S U M M A R Y W I T H K E Y T E R M S

- I. **Biology** is the study of life. Basic themes of biology include the evolution of life, the transmission of information, and the flow of energy through organisms.
- II. A living organism is able to grow and develop, carry on self-regulated metabolism, move, respond to stimuli, and reproduce. In addition, species evolve and adapt to their environment.
 - A. All living organisms are composed of one or more **cells**.
 - B. Organisms grow by increasing the size and number of their cells.
 - C. **Metabolism** refers to all the chemical activities that take place in the organism, including the chemical reactions essential to nutrition, growth and repair, and the conversion of energy to usable forms. **Homeostasis** is the tendency of organisms to maintain a constant internal environment.
 - D. Movement, although not necessarily locomotion, is characteristic of living organisms. Some organisms use tiny extensions of the cell called **cilia**, or longer **flagella**, to move from place to place. Other organisms are **sessile** and remain rooted to some surface.
 - E. Organisms respond to **stimuli**, physical or chemical changes in their external or internal environment.
 - F. In **asexual reproduction** offspring are typically identical to the single parent; in **sexual reproduction** offspring are typically the product of genes contributed by two parents.
 - G. Populations evolve and become adapted to their environment. **Adaptations** are traits that increase an organism's ability to survive in its environment.
- III. Organisms transmit information chemically, electrically, and behaviorally.
 - A. DNA, which makes up the **genes**, contains the instructions for the development of an organism and for carrying out life processes.
 1. Information encoded in **DNA** is transmitted from one generation to the next.
 2. DNA codes for **proteins**, which are important in determining the structure and function of cells and tissues.
 - B. **Hormones** are chemical messengers that transmit messages from one part of an organism to another.
 - C. Many organisms use electrical signals to transmit information; most animals have nervous systems that transmit electrical impulses and release **neurotransmitters**.
- IV. **Evolution** is the process by which populations of organisms change over time in response to changes in the environment.
 - A. **Natural selection**, the mechanism by which evolution proceeds, favors organisms with traits that enable them to cope with environmental changes. These organisms are most likely to survive and to produce offspring.
 - B. Charles Darwin based his theory of natural selection on his observations that individuals of a species vary; organisms produce more offspring than survive to reproduce; individuals that are best adapted to their environment are more likely to survive and reproduce; as successful organisms pass on their genes, their traits become more widely distributed in the population.
 - C. The source of variation in a population is random **mutation**.
- V. Biological organization is hierarchical.
 - A. A complex **organism** is organized at the **chemical, cellular, tissue, organ, and organ system levels**.
 - B. The basic unit of ecological organization is the **population**. Various populations form **communities**; a community and its physical environment are referred to as an **ecosystem**; all of our planet's communities and ecosystems together make up the **biosphere**.
- VI. Millions of species have evolved on our planet.
 - A. Taxonomic classification is hierarchical; it includes **species, genus, family, order, class, phylum, and kingdom**.
 - B. Biologists use a **binomial system of nomenclature** in which the name of each species includes a genus name and a **specific epithet**.
 - C. Bacteria have **prokaryotic cells**; all other organisms have **eukaryotic cells**.
 - D. Organisms can be classified into six kingdoms: **Archaeobacteria, Eubacteria, Protista** (protozoa, algae, water molds, and slime molds), **Fungi** (molds and yeasts), **Plantae**, and **Animalia**.
- VII. Life depends on continuous energy input from the Sun. Activities of living cells require energy.
 - A. During **photosynthesis** plants and many other types of producers use the energy of sunlight to synthesize complex molecules from carbon dioxide and water.
 - B. During **cellular respiration**, cells capture the energy stored in nutrients by producers. Some of that energy is then used to synthesize needed materials or to carry on other cell activities.
 - C. A self-sufficient ecosystem includes **producers, or autotrophs**, that make their own food, **consumers** that eat producers or organisms that have eaten producers, and **decomposers** that obtain energy by breaking down wastes and dead organisms. Consumers and decomposers are **heterotrophs**, organisms that depend on producers as an energy source and for food and oxygen.
- VIII. The **process of science** is a dynamic approach to investigation. The **scientific method** is a framework that scientists use in their work; it includes observing, recognizing a problem or stating a critical question, developing a hypothesis, making a prediction that can be tested, performing experiments, interpreting results, and drawing conclusions that support or falsify the hypothesis.

- A. **Deductive reasoning** and **inductive reasoning** are two categories of systematic thought processes that can be used in the scientific method.
- B. A **hypothesis** is a testable statement about the nature of an observation or relationship.
- C. A properly designed scientific experiment includes both a **control group** and an **experimental group**, and must be as free as possible from **bias**.

ble from **bias**. The experimental group differs from a control group only with respect to the variable being studied.

- D. When a hypothesis has been supported by conclusions from many experiments, scientists may develop a **theory** based on it. A well established and tested theory may be referred to as a scientific **principle**.
- E. Science has important ethical dimensions.

POST-TEST

1. Metabolism (a) is the sum of all the chemical activities of an organism (b) results from an increase in the number of cells (c) is characteristic of plant and animal kingdoms only (d) refers to chemical changes in an organism's environment (e) does not take place in producers
2. Homeostasis (a) is the tendency of organisms to maintain a constant internal environment (b) generally depends on the action of cilia (c) is the long-term response of organisms to changes in their environment (d) occurs at the ecosystem level, not in cells or organisms (e) may be sexual or asexual
3. Structures used by some organisms for locomotion are (a) cilia (b) flagella (c) nuclei (d) answers a, b, and c are correct (e) answers a and b only are correct
4. The splitting of an amoeba into two is best described as an example of (a) locomotion (b) neurotransmission (c) asexual reproduction (d) sexual reproduction (e) metabolism
5. Cells (a) are the building blocks of living organisms (b) always have nuclei (c) are not found among the bacteria (d) answers a, b, and c are correct (e) answers a and b only are correct
6. An increase in size or number of cells best describes (a) homeostasis (b) biological growth (c) the chemical level of organization (d) asexual reproduction (e) adaptation
7. DNA (a) makes up the genes (b) transmits information from one species to another (c) cannot be changed (d) is a neurotransmitter (e) is produced during cellular respiration
8. Cellular respiration (a) is a process whereby sunlight is used to synthesize cellular components with the release of energy (b) occurs in heterotrophs only (c) is carried on by both autotrophs and heterotrophs (d) causes chemical changes in DNA (e) occurs in response to environmental changes
9. Which of the following is a correct sequence of levels of biological organization? (a) cellular, organ, tissue, organ system (b) chemical, cellular, organ, tissue (c) chemical, cellular, tissue, organ (d) tissue, organ, cellular, organ system (e) chemical, cellular, population, species

10. Which of the following is a correct sequence of levels of biological organization? (a) organism, population, ecosystem, community (b) organism, population, community, ecosystem (c) population, biosphere, ecosystem, community (d) species, population, ecosystem, community (e) population, species, community, biosphere
11. Darwin suggested that evolution takes place by (a) mutation (b) changes in the individuals of a species (c) natural selection (d) interaction of hormones (e) homeostatic responses to each change in the environment
12. Protozoa are assigned to kingdom (a) Protista (b) Fungi (c) Archaeobacteria (d) Animalia (e) Plantae
13. Yeasts and molds are assigned to kingdom (a) Protista (b) Fungi (c) Archaeobacteria (d) Animalia (e) Plantae
14. In the binomial system of nomenclature, the first part of an organism's name designates the (a) specific epithet (b) genus (c) class (d) kingdom (e) phylum
15. Which of the following is a correct sequence of levels of classification? (a) genus, species, family, order, class, phylum, kingdom (b) genus, species, order, phylum, class, kingdom (c) genus, species, order, family, class, phylum, kingdom (d) species, genus, family, order, class, phylum, kingdom (e) species, genus, order, family, class, kingdom, phylum
16. A testable statement is a(an) (a) theory (b) hypothesis (c) principle (d) inductive leap (e) critical question
17. Ideally, an experimental group differs from a control group (a) only with respect to the hypothesis being tested (b) only with respect to the variable being studied (c) by being less subject to bias (d) because it is less vulnerable to sampling error (e) because its subjects are more reliable.

REVIEW QUESTIONS

1. Contrast a living organism with a nonliving object.
2. In what ways might the metabolisms of an oak tree and a tiger be similar? Relate these similarities to the biological themes of transmission of information, energy, and evolution.
3. What would be the consequences if an organism's homeostatic mechanisms failed? Explain your answer.
4. What components do you think might be present in a balanced forest ecosystem? In what ways are consumers dependent on producers? On decomposers? Include energy considerations in your answer.
5. Why do you suppose that the binomial system of nomenclature has survived for more than 200 years and is still used by biologists?

6. How might you explain the sharp claws and teeth of tigers in terms of natural selection?
7. What is meant by a "controlled" experiment?
8. Make a prediction and devise a suitably controlled experiment to test each of the following hypotheses: (a) A type of mold found in your garden does not produce an effective antibiotic. (b) The rate of growth of a bean seedling is affected by temperature. (c) Estrogen alleviates the symptoms of Alzheimer's disease in elderly women.

YOU MAKE THE CONNECTION

1. How might a firm understanding of evolutionary processes be helpful to a biologist who is doing research in (a) animal behavior, (b) ecology, and (c) the development of a vaccine against HIV, the virus that causes AIDS?
2. If you could influence U. S. policy on continuing cloning research, what position would you take? Explain. What would be your position on the use of gene-modified animals for producing drugs like insulin or blood-clotting factors?

position would you take? Explain. What would be your position on the use of gene-modified animals for producing drugs like insulin or blood-clotting factors?

CHAPTER 2

Atoms and Molecules: The Chemical Basis of Life

This jaguar and the plants of the rain forest, as well as an abundance of insects and microorganisms, share fundamental similarities in their chemical composition and basic metabolic processes. These chemical similarities provide strong evidence for the evolution of all organisms from a common ancestor and explain why much of what biologists learn from studying bacteria or rats in laboratories can be applied to other organisms, including humans. Furthermore, the basic physical principles governing organisms are not unique to living things, for they apply to nonliving systems as well.

Today much attention is given to **molecular biology**—the chemistry and physics of the molecules that constitute living things. A molecular biologist might study how proteins interact with DNA in ways that control the expression of certain genes, or might investigate the precise interactions among a cell's atoms and molecules that maintain the energy flow essential to life. However, an understanding of chemistry is essential to *all* biologists. An evolutionary biologist might study evolutionary relationships by comparing proteins produced by different types of organisms. An ecologist might study the biological effects of changes in the salinity of the water in an estuary. A botanist might be a “chemical prospector,” seeking new sources of medicines from plants.

In this chapter we lay a foundation for understanding how the structure of atoms determines the way they form chemical bonds to produce complex compounds. Most of our discussion will center around small, simple substances known as **inorganic compounds**. Among the biologically important groups of inorganic compounds are water, simple acids and bases, and simple salts. We pay particular attention to water, the most abundant substance on Earth's surface and in organisms, and we examine how its unique properties affect living things as well as their nonliving environment. In Chapter 3

(Frans Lanting/Minden Pictures)

we extend our discussion to **organic compounds**, which are generally large and complex and which always contain carbon atoms joined together to form the backbone, or skeleton, of the molecule.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Name the principal chemical elements in living things and give an important function of each.
2. Compare the physical properties (mass and charge) and the locations of electrons, protons, and neutrons.
3. Distinguish between the atomic number and the mass number of an element.
4. Define the term *electron orbital*, and relate orbitals to energy levels.
5. Explain how the number of valence electrons of an atom is related to its chemical properties.
6. Distinguish among covalent bonds, hydrogen bonds, and ionic bonds. Compare them in terms of the mechanisms by which they form and their relative bond strengths.
7. Explain how cations and anions form and how they interact.
8. Distinguish between the terms *oxidation* and *reduction* and relate these processes to the transfer of energy.
9. Draw a simple ball-and-stick model of a water molecule, indicating the regions of partial positive and partial negative charge. Show how hydrogen bonds form between adjacent water molecules and explain how these are responsible for many of the properties of water.
10. Contrast acids and bases and discuss their properties.
11. Convert the hydrogen ion concentration (moles per liter) of a solution to a pH value. Describe how buffers help minimize changes in pH.
12. Describe the composition of a salt and explain why salts are important in organisms.

ELEMENTS ARE NOT CHANGED IN NORMAL CHEMICAL REACTIONS

Elements are substances that cannot be broken down into simpler substances by ordinary chemical reactions. Scientists have assigned each element a **chemical symbol**: usually the first letter or first and second letters of the English or Latin name of the element. For example, O is the symbol for oxygen, C for carbon, H for hydrogen, N for nitrogen, and Na for sodium (Latin *natrium*).

Just four elements—oxygen, carbon, hydrogen, and nitrogen—are responsible for over 96% of the mass of most organisms. Others, such as calcium, phosphorus, potassium, and magnesium, are also consistently present but in smaller quantities. Some elements, such as iodine and copper, are known as *trace elements* because they are present only in minute amounts. Table 2–1 lists the elements that make up two representative organisms, a human and a typical nonwoody plant, and briefly explains why each is important.

ATOMS ARE THE FUNDAMENTAL PARTICLES OF ELEMENTS

An **atom** is the smallest portion of an element that retains its chemical properties. Atoms are much smaller than the tiniest particle visible under a light microscope. By special scanning tunneling electron microscopy, with magnification as high as $\times 5$ million, researchers have been able to photograph the positions of some large atoms in molecules.

Physicists have discovered a number of subatomic particles, but for our purposes we need consider only three: electrons, protons, and neutrons. An **electron** is a particle that carries a unit of negative electrical charge; a **proton** carries a unit

of positive charge; and a **neutron** is an uncharged particle. In an electrically neutral atom, the number of electrons is equal to the number of protons.

Clustered together, protons and neutrons compose the **atomic nucleus**. Electrons, however, have no fixed locations and move rapidly through space outside the atomic nucleus.

An atom is uniquely identified by its number of protons

Each kind of element has a fixed number of protons in the atomic nucleus. This number, called the **atomic number**, is written as a subscript to the left of the chemical symbol. Thus ${}^1\text{H}$ indicates that the hydrogen nucleus contains one proton, and ${}^8\text{O}$ that the oxygen nucleus contains eight protons. It is the atomic number, the number of protons in its nucleus, that determines an atom's identity.

The **periodic table** (Fig. 2–1 and Appendix B) is a chart in which elements are arranged in order by atomic number. As will become evident in subsequent discussions, the periodic table is an extremely useful device because it allows us to simultaneously correlate a great many of the relationships among the various elements.

Figure 2–1 includes representations of the **electron configurations** of several elements important in organisms. These *Bohr models*, which show the electrons arranged in a series of concentric circles around the nucleus, are convenient to use, but inaccurate. As we will see, electrons do not actually circle the nucleus in fixed concentric pathways.

Protons plus neutrons determine atomic mass

The mass of a subatomic particle is exceedingly small, much too small to be conveniently expressed in grams or even micrograms. Such masses are expressed in terms of the **atomic**

TABLE 2–1 Elements That Make Up Some Representative Organisms

Element and Chemical Symbol	Approximate % of Total Mass of Human Body	Approximate % of Total Mass of Nonwoody Plant	Importance or Functions
Oxygen (O)	65	78	Required for cellular respiration; present in most organic compounds; component of water
Carbon (C)	18	11	Forms backbone of organic molecules; each carbon atom can form four bonds with other atoms
Hydrogen (H)	10	9	Present in most organic compounds; component of water; hydrogen ion (H^+) is involved in some energy transfers
Nitrogen (N)	3	*	Component of proteins and nucleic acids; component of chlorophyll in plants
Calcium (Ca)	1.5	*	Structural component of bones and teeth; calcium ion (Ca^{2+}) is important in muscle contraction, conduction of nerve impulses, and blood clotting; associated with plant cell wall
Phosphorus (P)	1	*	Component of nucleic acids and of phospholipids in membranes; important in energy transfer reactions; structural component of bone
Potassium (K)	*	*	Potassium ion (K^+) is principal positive ion (cation) in interstitial (tissue) fluid of animals; important in nerve function; affects muscle contraction; controls opening of stomata in plants
Sulfur (S)	*	*	Component of most proteins
Sodium (Na)	*	*	Sodium ion (Na^+) is principal positive ion (cation) in interstitial (tissue) fluid of animals; important in fluid balance; essential for conduction of nerve impulses; not essential in most plants
Magnesium (Mg)	*	*	Needed in blood and other tissues of animals; activates many enzymes; component of chlorophyll in plants
Chlorine (Cl)	*	*	Chloride ion (Cl^-) is principal negative ion (anion) in interstitial (tissue) fluid of animals; important in water balance; essential for photosynthesis
Iron (Fe)	*	*	Component of hemoglobin in animals; activates certain enzymes
*The asterisk indicates that these elements represent less than 1% of the total mass. Other elements found in very small (trace) amounts in animals, plants, or both include iodine (I), manganese (Mn), copper (Cu), zinc (Zn), cobalt (Co), fluorine (F), molybdenum (Mo), selenium (Se), boron (B), silicon (Si), and a few others.			

mass unit (amu), also called the **dalton** in honor of John Dalton, who formulated an atomic theory in the early 1800s. One amu is equal to the approximate mass of a proton or neutron. Protons and neutrons make up almost all of the mass of an atom. Each electron has only about 1/1800 of the mass of a proton or neutron.

The **atomic mass** of an atom is a number that indicates how massive it is compared with another atom. This value is determined by adding the number of protons to the number

of neutrons and expressing the result in atomic mass units or daltons.¹ The mass of the electrons is ignored because it is so small. The atomic mass number is indicated by a superscript to the left of the chemical symbol. The common form of the oxygen atom, with eight protons and eight neutrons in its nu-

¹Unlike weight, mass is independent of the force of gravity. For convenience, however, we will consider mass and weight to be equivalent. Atomic weight has the same numerical value as atomic mass, but has no units.

Figure 2–1 The periodic table. Note the Bohr models depicting the electron configuration of some biologically important atoms. Although the Bohr model does not depict electron configurations accurately, it is commonly used because of its simplicity and convenience.

neus, has an atomic number of 8 and a mass of 16 atomic mass units. It is indicated by the symbol $^{16}_8\text{O}$.

The characteristics of protons, electrons, and neutrons are summarized below:

Particle	Charge	Approximate Mass	Location
Proton	positive	1 amu	nucleus
Neutron	neutral	1 amu	nucleus
Electron	negative	approx. 1/1800 amu	outside nucleus

Isotopes differ in number of neutrons

Most elements consist of a mixture of atoms with different numbers of neutrons and thus different masses. Such atoms are called **isotopes**. Isotopes of the same element have the same number of protons and electrons; only the number of neutrons varies. The three isotopes of hydrogen, ^1_1H (ordinary hydrogen), ^2_1H (deuterium), and ^3_1H (tritium), contain zero, one, and two neutrons, respectively. Bohr models of two isotopes of carbon, $^{12}_6\text{C}$ and $^{14}_6\text{C}$, are illustrated in Figure 2–2. The mass of an element is expressed as an average of the masses of its isotopes (weighted by their relative abundance in nature). For example,

Figure 2–2 Isotopes differ in atomic mass. Carbon-12 ($^{12}_6\text{C}$) is the most common isotope of carbon. Its nucleus contains six protons and six neutrons, so its atomic mass is 12. Carbon-14 ($^{14}_6\text{C}$) is a rare radioactive carbon isotope. Because it contains eight neutrons, its atomic mass is 14.

the atomic mass of hydrogen is not 1.0 amu, but 1.0079 amu, reflecting the natural occurrence of small amounts of deuterium and tritium.

All isotopes of a given element have essentially the same chemical characteristics. However, some isotopes are unstable and tend to break down, or decay, to a more stable isotope (usually becoming a different element). For example, the radioactive decay of $^{14}_6\text{C}$ yields the common form of nitrogen, $^{14}_7\text{N}$. Such isotopes are termed **radioisotopes** because they emit radiation when they decay. (The radioactive decay of $^{14}_6\text{C}$ occurs as a neutron decomposes to form a proton and a fast-moving electron, which is emitted from the atom as a form of radiation known as a β particle.) Sophisticated instruments allow scientists to detect and measure this and other types of radiation. Radioactive decay can also be detected by a method known as **autoradiography**, in which radiation causes the appearance of dark silver grains in special x-ray film (Fig. 2–3).

Despite the difference in the number of neutrons, the different isotopes of a given element are usually metabolized and/or localized in the organism in a similar way. For this reason, radioisotopes such as ^3H (tritium), $^{14}_6\text{C}$, and ^{32}P have been extremely valuable research tools in studies ranging from determining the age of fossils, to DNA synthesis, to sugar transport in plants.

In medicine, radioisotopes are used for both diagnosis and treatment. The location and/or metabolism of a sugar, hormone, or drug can be followed in the body by labeling the substance with a radioisotope such as carbon-14 or tritium. For example, the active component in marijuana (tetrahydrocannabinol, or THC) can be labeled and administered intravenously. Then the amount of radioactivity in the blood and urine can be measured at successive intervals. Results of such measurements have determined that for several weeks this compound remains in the blood, and products of its metabolism can be detected in the urine. Radioisotopes are also used to test thyroid gland function, to measure the rate of red blood cell production, and to study many other aspects of body func-

Figure 2–3 Autoradiography. The chromosomes of the fruit fly, *Drosophila melanogaster*, shown in this light micrograph have been covered with a special type of x-ray film in which silver grains (dark spots) are produced when tritium (^3H) undergoes radioactive decay. The concentrations of silver grains (arrows) mark the locations of specific DNA molecules. ©(Peter J. Bryant/Biological Photo Service)

tion and chemistry. Because radiation can interfere with cell division, radioisotopes have been used in the treatment of cancer (a disease often characterized by rapidly dividing cells).

Electrons occupy orbitals corresponding to energy levels

Electrons move through characteristic regions of three-dimensional space, termed **orbitals**. Each orbital contains a maximum of two electrons. Because it is impossible to know an electron's position at any given time, orbitals are most accurately depicted as “electron clouds,” shaded areas whose density is proportional to the probability that an electron is present there at any given instant. The energy of an electron depends on the orbital it occupies. Electrons in orbitals with similar energies, said to be at the same **principal energy level**, make up an **electron shell**. These are illustrated in Figure 2–4.

In general, electrons in a shell distant from the nucleus have greater energy than those in a shell close to the nucleus. This is because energy is required to move a negatively charged electron farther away from the positively charged nucleus. The most energetic electrons, known as **valence electrons**, are said to occupy the **valence shell**. The valence shell is represented as the outermost concentric ring in a Bohr model.

An electron can move to an orbital farther from the nucleus by receiving more energy, or it can give up energy and sink to a lower energy level in an orbital nearer the nucleus. Changes in electron energy levels are important in energy conversions in organisms. For example, in photosynthesis (see Chapter 8) light energy absorbed by chlorophyll molecules causes electrons to move to a higher energy level.

Figure 2–4 Atomic orbitals. Each orbital is represented as an “electron cloud.” (a) The first principal energy level contains a maximum of two electrons, occupying a single spherical orbital (designated 1s). The electrons depicted in the diagram could be present anywhere within the deep blue area. (b) The second principal energy level includes four orbitals, each with a maximum of two electrons: one spherical (2s), and three dumbbell-shaped (2p) orbitals at right angles to each other. (c) Orbitals of the first and second principal energy levels are shown superimposed.

reactive because their valence shells are full. Note the valence shells of some the elements important in organisms, including carbon, hydrogen, oxygen, and nitrogen, in Figure 2–1.

ATOMS UNDERGO CHEMICAL REACTIONS

The chemical behavior of an atom is determined primarily by the number and arrangement of the valence electrons. The valence shell of hydrogen or helium is full (i.e., stable) when it contains two electrons. The valence shell of any other atom is full when it contains eight electrons. When the valence shell is not full, the atom tends to lose, gain, or share electrons to achieve a full outer shell. (The valence shells of all isotopes of an element are the same; this is why they have similar chemical properties and can substitute for each other in chemical reactions.)

Elements that fall into the same vertical column (said to belong to the same *group*) of the periodic table have similar chemical properties because their valence shells have similar tendencies to lose, gain, or share electrons. For example, chlorine and bromine, included in a group commonly known as the halogens, are highly reactive. Because their valence shells have seven electrons, they tend to gain an electron in chemical reactions. By contrast, hydrogen, sodium, and potassium each have a single valence electron, which they tend to give up or share with another atom. Helium (He) and neon (Ne) belong to a group referred to as the “noble gases.” They are quite un-

Atoms form molecules and compounds

Two or more atoms may combine chemically to form units called **molecules**. For example, when two atoms of oxygen combine chemically, a molecule of oxygen is formed. Atoms of *different* elements can combine to form chemical compounds. A **chemical compound** consists of two or more different elements combined in a fixed ratio. For example, water is a chemical compound consisting of hydrogen and oxygen in a ratio of 2:1. Water happens to be a molecular compound, with each molecule consisting of two atoms of hydrogen and one of oxygen. However, as we shall see, not all compounds are made up of molecules.

The properties of a chemical compound can be quite different from those of its component elements: at room temperature, water is usually a liquid, whereas hydrogen and oxygen are gases.

A substance can be described by a chemical formula

A **chemical formula** is a shorthand expression that describes the chemical composition of a substance. Chemical symbols indicate the types of atoms present, and subscript numbers indicate the ratios among the atoms. There are several types of chemical formulas, each providing specific kinds of information.

In a **molecular formula**, the subscripts indicate the actual numbers of each type of atom in a molecule. The formula for molecular oxygen, O_2 , tells us that this molecule consists

of two atoms of oxygen. The molecular formula for water, H_2O , indicates that each molecule consists of two atoms of hydrogen and one atom of oxygen. (Note that when a single atom of one type is present, the subscript number 1 is never written.)

Another type of formula is the **structural formula**, which shows not only the types and numbers of atoms in a molecule, but also their arrangement. From the molecular formula for water, H_2O , you would not know whether the atoms were arranged H—H—O or H—O—H . The structural formula, H—O—H , settles the matter, indicating that the two hydrogen atoms are attached to the oxygen atom.

One mole of any substance contains the same number of units

The **molecular mass** of a compound is the sum of the atomic masses of the component atoms of a single molecule; thus, the molecular mass of water, H_2O , is $(2 \times 1 \text{ amu}) + (16 \text{ amu})$, or 18 amu. (Owing to the presence of isotopes, atomic mass values are not whole numbers. However, for easy calculation each atomic mass value has been rounded off to a whole number.) The molecular mass of glucose ($\text{C}_6\text{H}_{12}\text{O}_6$), a simple sugar that is a key compound in cellular metabolism, is $(6 \times 12 \text{ amu}) + (12 \times 1 \text{ amu}) + (6 \times 16 \text{ amu})$, or 180 amu.

The amount of an element or compound whose mass in grams is equivalent to its atomic or molecular mass is termed 1 **mole**. Thus 1 mole of glucose has a mass of 180 grams. The mole is a useful concept because it allows us to make meaningful comparisons between atoms and molecules of very different mass. This is because *one mole of any substance always has exactly the same number of units*, whether they be small atoms or large molecules. The very large number of units in a mole, 6.02×10^{23} , is known as **Avogadro's number**, named for the Italian physicist, Amadeo Avogadro, who first calculated it. Thus 1 mole (180 grams) of glucose contains 6.02×10^{23} molecules, as does 1 mole (2 grams) of molecular hydrogen (H_2). Although it is impossible to count atoms and molecules individually, this fact allows a scientist to count them simply by weighing a sample. Molecular biologists usually deal with smaller values, either millimoles (a mmole is one thousandth of a mole) or micromoles (a μmole is one millionth of a mole).

The mole concept allows us to make useful comparisons among solutions. A 1-molar solution, represented by 1 *M*, contains 1 mole of that substance dissolved in 1 liter of solution. For example, we can compare 1 liter of a 1 *M* solution of glucose with 1 liter of a 1 *M* solution of sucrose (table sugar). They differ in the mass of the dissolved sugar (180 g and 340 g, respectively), but they each contain 6.02×10^{23} sugar molecules.

Chemical equations describe chemical reactions

During any moment in the life of an organism, be it a mushroom or a butterfly, many complex chemical reactions are taking place. Chemical reactions—for example, the reaction be-

tween glucose and oxygen—can be described by means of chemical equations:

In a chemical equation, the **reactants** (the substances that participate in the reaction) are generally written on the left side, and the **products** (the substances formed by the reaction) are written on the right side. The arrow means “yields” and indicates the direction in which the reaction tends to proceed.

Chemical compounds react with each other in quantitatively precise ways. The numbers preceding the chemical symbols or formulas (known as *coefficients*) indicate the relative number of atoms or molecules reacting. For example, 1 mole of glucose burned in a fire or metabolized in a cell reacts with 6 moles of oxygen to form 6 moles of carbon dioxide and 6 moles of water. Many reactions can proceed in the reverse direction (to the left) as well as in the forward direction (to the right); at **equilibrium** the rates of the forward and reverse reactions are equal (see Chapter 6). Reversible reactions are indicated by double arrows:

In this example, the arrows are drawn different lengths to indicate that when the reaction reaches equilibrium there will be more reactants (CO_2 and H_2O) than product (H_2CO_3).

ATOMS ARE JOINED BY CHEMICAL BONDS

The atoms of a compound are held together by forces of attraction called **chemical bonds**. Each bond represents a certain amount of chemical energy. **Bond energy** is the energy necessary to break a bond. The valence electrons dictate how many bonds an atom can participate in. The two principal types of strong chemical bonds are covalent bonds and ionic bonds.

In covalent bonds electrons are shared

Covalent bonds involve the sharing of electrons between atoms in a way that results in each having a filled valence shell. A compound consisting mainly of covalent bonds is called a **covalent compound**. A simple example of a covalent bond is the joining of two hydrogen atoms in a molecule of hydrogen gas, H_2 . Each atom of hydrogen has one electron, but two electrons are required to complete its valence shell. The hydrogen atoms have equal capacities to attract electrons, so neither donates an electron to the other. Instead, the two hydrogen atoms share their single electrons so that each of the two electrons is attracted simultaneously to the two protons in the two hydrogen nuclei. The two electrons thus whirl around *both* atomic nuclei, joining the two atoms.

Figure 2–5 Electron sharing in covalent compounds. (a) Two hydrogen atoms achieve stability by sharing electrons, thereby forming a molecule of hydrogen. In the structural formula shown on the right, the straight line between the hydrogen atoms represents a single covalent bond. (b) In molecular oxygen, two oxygen atoms share two pairs of electrons, forming a double covalent bond.

A simple way of representing the electrons in the valence shell of an atom is to use dots placed around the chemical symbol of the element. Such a representation is called the *Lewis structure* of the atom. In a water molecule, two hydrogen atoms are covalently bonded to an oxygen atom:

Oxygen has six valence electrons; by sharing electrons with two hydrogen atoms, it completes its valence shell of eight. At the same time each hydrogen atom obtains a complete valence shell of two. (Note that in the structural formula $\text{H}-\text{O}-\text{H}$, each pair of shared electrons constitutes a covalent bond, represented by a solid line. Unshared electrons are usually omitted in a structural formula.)

The carbon atom has four electrons in its valence shell. These four electrons are available for covalent bonding:

When one carbon and four hydrogen atoms share electrons, a molecule of methane, CH_4 , is formed:

The nitrogen atom has five electrons in its valence shell. Recall that each orbital can hold a maximum of two electrons. Usually two electrons occupy one orbital, leaving three available for sharing with other atoms:

When a nitrogen atom shares electrons with three hydrogen atoms, a molecule of ammonia, NH_3 , is formed:

When one pair of electrons is shared between two atoms, the covalent bond is referred to as a **single covalent bond** (Fig. 2–5a). Two oxygen atoms may achieve stability by forming covalent bonds with one another. Each oxygen atom has six electrons in its outer shell. To become stable, the two atoms share two pairs of electrons, forming molecular oxygen (Fig. 2–5b). When two pairs of electrons are shared in this way, the covalent bond is called a **double covalent bond**, which is represented by two parallel solid lines. Similarly, a **triple covalent bond** (represented by three parallel solid lines) is formed when three pairs of electrons are shared between two atoms.

The number of covalent bonds usually formed by the atoms commonly present in biologically important molecules is summarized as follows:

Atom	Symbol	Covalent Bonds
Hydrogen	H	1
Oxygen	O	2
Carbon	C	4
Nitrogen	N	3
Phosphorus	P	5
Sulfur	S	2

Figure 2–6 Methane. The four hydrogens are located at the corners of a tetrahedron.

The function of a molecule is related to its shape

Each kind of molecule has a characteristic size and a general overall shape. Although the shape of a molecule may change (within certain limits), the functions of molecules in living cells are largely dictated by their geometric shapes. A molecule that consists of two atoms, for example, is linear. Molecules composed of more than two atoms may have more complicated shapes. The geometric shape of a molecule provides the optimal distance between the atoms to counteract the repulsion of electron pairs.

When an atom forms covalent bonds with other atoms, the orbitals in the valence shell may become rearranged, thereby affecting the shape of the resulting molecule. For example, when four hydrogen atoms combine with a carbon atom to form a molecule of methane (CH₄), the valence shell orbitals of the carbon become rearranged such that a geometric structure known as a *tetrahedron* is formed, with one hydrogen atom present at each of its four corners (Fig. 2–6).

Covalent bonds can be nonpolar or polar

The atoms of each element have a characteristic affinity for electrons. **Electronegativity** is a measure of an atom's attraction for electrons in chemical bonds. Very electronegative atoms are sometimes called “electron-greedy.” When covalently

bound atoms have similar electronegativities, the electrons are shared equally, and the covalent bond is described as **nonpolar**. The covalent bond of the hydrogen molecule is nonpolar, as are the covalent bonds of molecular oxygen and methane.

In a covalent bond between two different elements, such as oxygen and hydrogen, the electronegativities of the atoms may be different. If so, electrons are pulled closer to the atomic nucleus of the element with the greater electron affinity (in this case, oxygen). A covalent bond between atoms that differ in electronegativity is called a **polar covalent bond**. Such a bond has two dissimilar ends (or poles), one with a partial positive charge and the other with a partial negative charge. Each of the two covalent bonds in water is polar because there is a partial positive charge at the hydrogen end of the bond and a partial negative charge at the oxygen end, where the “shared” electrons are more likely to be found (Fig. 2–7).

Covalent bonds differ in their degree of polarity, ranging from those in which the electrons are exactly shared (as in the nonpolar hydrogen molecule) to those in which the electrons are much closer to one atom than to the other (as in water). Oxygen is quite electronegative and forms polar covalent bonds with carbon, hydrogen, and many other atoms. Nitrogen is also relatively electronegative, although less so than oxygen.

A molecule with one or more polar covalent bonds can be polar even though it is electrically neutral as a whole. A **polar molecule** has one end with a partial positive charge and another end with a partial negative charge. One example is water (Fig. 2–7). The polar bonds between the hydrogens and the oxygens are arranged in a “V” shape, rather than linearly. The oxygen end therefore constitutes the negative pole, and the end with the two hydrogens is the positive pole.

Ionic bonds form between cations and anions

Some atoms or groups of atoms are not electrically neutral. A particle with one or more units of electrical charge is called an **ion**. An atom becomes an ion if it gains or loses one or more electrons. An atom with one, two, or three electrons in its va-

Figure 2–7 Water, a polar molecule. Note that the electrons tend to stay closer to the nucleus of the oxygen atom than to the hydrogen nuclei. This results in a partial negative charge on the oxygen portion of the molecule and a partial positive charge at the hydrogen end. Although the water molecule as a whole is electrically neutral, it is a polar covalent compound.

Figure 2–8 Ions and biological processes. Sodium, potassium, and chloride ions are essential for this nerve cell to stimulate these muscle fibers. Calcium ions in the muscle cell are required for muscle contraction. (D.W. Fawcett)

lence shell tends to lose electrons to other atoms. Such an atom then becomes positively charged because its nucleus contains more protons than the number of electrons orbiting around the nucleus. These positively charged ions are termed **cations**. Atoms with five, six, or seven valence electrons tend to gain electrons from other atoms and become negatively charged **anions**.

The properties of ions are very different from those of the electrically neutral atoms from which they were derived. For

example, although chlorine gas is a poison, chloride ions (Cl^-) are essential to life. Because their electrical charges provide a basis for many interactions, cations and anions are involved in energy transformations within the cell, the transmission of nerve impulses, muscle contraction, and many other life processes (Fig. 2–8).

A group of atoms can also become an ion (polyatomic ion). Unlike a single atom, a group of atoms can lose or gain protons (derived from hydrogen atoms) as well as electrons. Therefore, a group of atoms can become a cation if it loses one or more electrons or gains one or more protons. A group of atoms becomes an anion if it gains one or more electrons or loses one or more protons.

An **ionic bond** forms as a consequence of the attraction between the positive charge of a cation and the negative charge of an anion. An **ionic compound** is a substance consisting of anions and cations bonded together by their opposite charges.

A good example of how ionic bonds are formed is the attraction between sodium ions and chloride ions. A sodium atom has one electron in its valence shell. It cannot fill its valence shell by obtaining seven electrons from other atoms, for it would then have a very large unbalanced negative charge. Instead, it gives up its single valence electron to a very electronegative atom, such as chlorine, which acts as an electron acceptor (Fig. 2–9). Chlorine cannot give up the seven electrons in its valence shell, because it would then have a vast positive charge. Instead it strips an electron from an electron donor (sodium in this example) to complete its valence shell.

When sodium reacts with chlorine, its valence electron is transferred completely to chlorine. Sodium is now a cation, with one unit of positive charge (Na^+). Chlorine is now an anion, a chloride ion with one unit of negative charge (Cl^-).

Figure 2–9 Ionic bonding. Sodium becomes a positively charged ion when it donates its single valence electron to chlorine, which has seven valence electrons. With this additional electron, chlorine completes its valence shell and becomes a negatively charged chloride ion. These ions are attracted to one another by their unlike electrical charges, forming the ionic compound sodium chloride.

Figure 2–10 Hydration of an ionic compound. When the crystal of NaCl is added to water, the sodium and chloride ions are pulled apart as the partial negative ends of the water molecules are attracted to the positive sodium ions, and the partial positive ends of the water molecules are attracted to the negative chloride ions. When the NaCl is dissolved, each Na^+ and Cl^- is surrounded by water molecules electrically attracted to it.

These ions attract each other as a result of their opposite charges. They are held together by this electrical attraction in ionic bonds to form NaCl, sodium chloride,² or common table salt.

The term *molecule* does not adequately explain the properties of ionic compounds such as NaCl. When NaCl is in its solid crystal state, each ion is actually surrounded by six ions of opposite charge. The molecular formula NaCl indicates that sodium ions and chloride ions are present in a one-to-one ratio, but in the actual crystal, no discrete molecules composed of one Na^+ and one Cl^- ion are present.

Compounds joined by ionic bonds, such as sodium chloride, have a tendency to *dissociate* (separate) into their individual ions when placed in water:

²In both covalent and ionic binary compounds (*binary* denotes compounds consisting of two elements), the element having the greater attraction for electrons is named second, and an *-ide* ending is added to the stem name, e.g., sodium chloride, hydrogen fluoride. The *-ide* ending is also used to indicate an anion, as in chloride (Cl^-) and hydroxide (OH^-).

In the solid form of an ionic compound, the ionic bonds are very strong. Water, however, is an excellent **solvent**; as a liquid it is capable of dissolving many substances, particularly those that are polar or ionic. This is because of the polarity of water molecules. The localized partial positive charges (on the hydrogen atoms) and partial negative charges (on the oxygen atom) on each water molecule attract the anions and cations on the surface of an ionic solid. As a result, the solid dissolves. A dissolved substance is referred to as a **solute**. In solution, each cation and anion of the ionic compound is surrounded by oppositely charged ends of the water molecules (Fig. 2–10). This process is known as **hydration**. Hydrated ions still interact with each other to some extent, but the transient ionic bonds formed are much weaker than those in a solid crystal.

Hydrogen bonds are weak attractions

Another type of bond important in organisms is the **hydrogen bond**. When hydrogen combines with oxygen (or with another relatively electronegative atom such as nitrogen), it has a partial positive charge because its electron spends more time closer to the electronegative atom. Hydrogen bonds tend to form between an atom with a partial negative charge and a hydrogen atom that is covalently bonded to oxygen or nitrogen (Fig. 2–11). The atoms involved may be in two parts of the same large molecule or in two different molecules. Water molecules interact with each other extensively through hydrogen bond formation.

Hydrogen bonds are readily formed and broken. Although individually relatively weak, hydrogen bonds are collectively strong when present in large numbers. Furthermore, they have a specific length and orientation. As we will see in Chapter 3, these features are very important in helping determine the three-dimensional structure of large molecules such as DNA and proteins.

Figure 2–11 Hydrogen bonding. A hydrogen atom in a water molecule has a partial positive charge because of its polar covalent bond with oxygen. Nitrogen is relatively electronegative and, in molecules like ammonia (NH_3), has a partial negative charge because of its polar covalent bonds with hydrogen. Here, the nitrogen atom of the ammonia molecule is joined by a hydrogen bond to a hydrogen atom of a water molecule. A hydrogen bond is generally indicated by a dotted line.

ELECTRONS AND THEIR ENERGY ARE TRANSFERRED IN REDOX REACTIONS

Many of the energy conversions that go on in a cell involve reactions in which an electron is transferred from one substance to another. This is because the transfer of an electron also involves the transfer of the energy of that electron. Such an electron transfer is called an oxidation-reduction, or **redox reaction**. Both cellular respiration (Chapter 7) and photosynthesis (Chapter 8) are essentially redox processes.

Rusting, which is the combination of iron (symbol Fe) with oxygen, is a simple illustration of oxidation and reduction:

Oxidation and reduction always occur together, but initially we will discuss them separately. **Oxidation** is a chemical process in which an atom, ion, or molecule loses electrons. In rusting, each iron atom becomes oxidized as it loses three electrons.

The e^{-} is a symbol for an electron; the $+$ superscript represents an electron deficit. (When an atom loses an electron, it acquires one unit of positive charge from the excess of one proton. In our example, each iron atom loses three electrons and acquires three units of positive charge.)

You will recall that the oxygen atom is very electronegative, able to remove electrons from other atoms. In this reaction, oxygen gains electrons from iron.

Oxygen becomes reduced when it accepts electrons from the iron. **Reduction** is a chemical process in which an atom, ion, or molecule *gains* electrons. (The term reduction refers to the fact that the gain of an electron results in the *reduction* of any positive charge that might be present.)

Redox reactions occur simultaneously because one substance must accept the electrons that are removed from the other. In a redox reaction, one component, the *oxidizing agent*, accepts one or more electrons and becomes reduced. Oxidizing agents other than oxygen are known, but oxygen is such a common one that its name was given to the process. Another reaction component, the *reducing agent*, gives up one or more electrons and becomes oxidized.

In our example there was a complete transfer of electrons from iron to oxygen. Some redox reactions are not so obvious, however. In these, electrons simply move farther from the reducing agent and closer to the oxidizing agent.

Electrons are not easily removed from covalent compounds unless an entire atom is removed. In cells, oxidation often involves the removal of a hydrogen *atom* (an electron plus a proton that “goes along for the ride”) from a compound; reduction often involves the addition of hydrogen (see Chapter 6).

WATER IS ESSENTIAL TO LIFE

A large part of the mass of most organisms is water. In human tissues the percentage of water ranges from 20% in bones to 85% in brain cells. About 70% of our total body weight is water; as much as 95% of a jellyfish and certain plants is water. Water is the source, through photosynthesis (see Chapter 8), of the oxygen in the air we breathe, and its hydrogen atoms become incorporated into many organic compounds. Water is also the solvent for most biological reactions and a reactant or product in many chemical reactions.

Water is not only important inside organisms but also is one of the principal environmental factors affecting them. Many organisms live within the ocean or in freshwater rivers, lakes, or puddles. Water’s unique combination of physical and chemical properties has permitted living things to originate, survive, and evolve on Earth (Fig. 2–12).

Water molecules are polar

As discussed previously, water molecules are polar, that is, one end of each molecule bears a partial positive charge and the other a partial negative charge (see Fig. 2–7). The water molecules in liquid water and in ice associate by hydrogen bonds. The hydrogen atom of one water molecule, with its partial positive charge, is attracted to the oxygen atom of a neighboring water molecule, with its partial negative charge, forming a hydrogen bond. An oxygen in a water molecule has two regions of partial negative charge, and each of the two hydrogens has a partial positive charge. Each water molecule can therefore form hydrogen bonds with a maximum of four neighboring water molecules (Fig. 2–13).

Figure 2–12 Tardigrade. (a) Commonly known as “water bears,” tardigrades such as these members of the genus *Echiniscus* are small (less than 1.2 mm long) animals that normally live in moist habitats, such as thin films of water on mosses. (b) When subjected to desiccation tardigrades assume a barrel-shaped form known as a *tun*, remaining in this state, motionless but alive, for as long as 100 years. When rehydrated they assume their normal appearance and activities. (a, Diane R. Nelson; b, Robert O. Schuster, courtesy of Diane R. Nelson)

Figure 2–13 Hydrogen bonding of water molecules. Each water molecule can form hydrogen bonds (dotted lines) with as many as four neighboring water molecules.

Water is the principal solvent in organisms

Because its molecules are polar, water is an excellent solvent, a liquid capable of dissolving many different kinds of substances, especially polar and ionic compounds. Previously in this chapter, we discussed how polar water molecules pull the ions of ionic compounds apart so that they dissociate (see Fig. 2–10). Because of its solvent properties and the tendency of the atoms in certain compounds to form ions when in solution, water plays an important role in facilitating chemical reactions. Substances that interact readily with water are said to be **hydrophilic** (“water-loving”). Examples include table sugar (a polar compound) and NaCl (an ionic compound), which dissolve readily in water. Not all substances in organisms are hydrophilic, however. Many **hydrophobic** (“water-fearing”) substances found in living things are especially important because of their ability to form structures that are not dissolved by water. Examples, to be discussed more fully in Chapter 3, include fats and other nonpolar substances.

Hydrogen bonding makes water cohesive and adhesive

Water molecules have a very strong tendency to stick to each other; that is, they are **cohesive**. This is due to the hydrogen bonds among the molecules. Water molecules also stick to

Figure 2–14 Capillary action. (a) In a narrow tube, adhesive forces attract water molecules to the glass wall of the tube. Other water molecules inside the tube are then “pulled along” by cohesive forces, which are actually due to hydrogen bonds between the water molecules. (b) In the wider tube, a smaller percentage of the water molecules line the glass wall. Because of this, the adhesive forces are not strong enough to overcome the cohesive forces of the water beneath the surface level of the container, and water in the tube rises only slightly.

many other kinds of substances, most notably those with charged groups of atoms or molecules on their surfaces. These **adhesive** forces explain how water makes things wet.

A combination of adhesive and cohesive forces accounts for the tendency, termed **capillary action**, of water to move in narrow tubes, even against the force of gravity (Fig. 2–14). For example, water moves through the microscopic spaces between soil particles to the roots of plants by capillary action. Because of the cohesive nature of water molecules, any force exerted on part of a column of water will be transmitted to the column as a whole. The major mechanism of water movement in plants (see Chapter 33) depends on this fact.

Water has a high degree of **surface tension** because of the cohesiveness of its molecules, which have a much greater attraction for each other than for molecules in the air. Thus, water molecules at the surface crowd together, producing a strong layer as they are pulled downward by the attraction of other water molecules beneath them (Fig. 2–15).

Water helps maintain a stable temperature

Raising the temperature of a substance involves adding heat energy to make its molecules move faster, that is, to increase the **kinetic energy** (energy of motion) of the molecules (see Chapter 6). The term **heat** refers to the *total* amount of kinetic energy in a sample of a substance; **temperature** refers to the *average* kinetic energy of the particles. Water has a high **specific heat**; that is, the amount of energy required to raise the temperature of water is quite large. A **calorie** is a unit of heat energy (equivalent to 4.184 joules) that equals the amount

Figure 2–15 Surface tension of water. Hydrogen bonding between water molecules is responsible for the surface tension of water, which is strong enough to support these water striders, and causes the dimpled appearance of the surface. Although they are denser than water, water striders can walk on the surface of a pond because fine hairs at the ends of their legs spread their weight over a large area. (Dennis Drenner)

of heat required to raise the temperature of 1 gram of water 1 degree Celsius. The specific heat of water is therefore 1 calorie per gram of water per degree Celsius. Most other common substances have much lower specific heat values.

The high specific heat of water results from the hydrogen bonding of its molecules. Some of the hydrogen bonds holding the water molecules together must first be broken to permit the molecules to move more freely. Much of the energy added to the system is used up in breaking the hydrogen bonds, and only a portion of the heat energy is available to speed the movement of the water molecules (thereby increasing the temperature of the water). Conversely, when liquid water changes

to ice, additional hydrogen bonds must be formed, liberating a great deal of heat into the environment.

Because so much heat input is required to raise the temperature of water (and so much heat is lost when the temperature is lowered), the ocean and other large bodies of water have relatively constant temperatures. Thus, many organisms living in the ocean are provided with a relatively constant environmental temperature. The properties of water are crucial in stabilizing temperatures on the surface of Earth. Although surface water is only a thin film relative to Earth's volume, the quantity is enormous compared to the exposed land mass. This relatively large mass of water resists both the warming effect of heat and the cooling effect of low temperatures. In addition, hydrogen bonding gives ice unique properties that have important environmental consequences (see *Making the Connection: Hydrogen Bonding and the Environment*).

The high water content of organisms helps them maintain relatively constant internal temperatures. Such minimizing of temperature fluctuations is important because biological reactions can take place only within a relatively narrow temperature range.

Because its molecules are held together by hydrogen bonds, water has a high **heat of vaporization**. To change 1 gram of liquid water into 1 gram of water vapor, 540 calories of heat are required. The heat of vaporization of most other common liquid substances is much less. As a sample of water is heated, some molecules are moving much faster than others (that is, they have more heat energy). These faster moving molecules are more likely to escape the liquid phase and enter the vapor phase (Fig. 2–16). When they do, they take their heat energy with them (thus lowering the temperature of the sample, in a process called **evaporative cooling**). For this reason the human body can dissipate excess heat as sweat evaporates from the skin, and a leaf can keep cool in the bright sunlight as water evaporates from its surface.

MAKING THE CONNECTION

HYDROGEN BONDING AND THE ENVIRONMENT

Why does ice float? This is because hydrogen bonds contribute to another important property of water. Liquid water expands as it freezes because the hydrogen bonds joining the water molecules in the crystalline lattice keep the molecules far enough apart to give ice a density about 10% less than the density of liquid water (see Fig. 2–16). When ice has been heated enough to raise its temperature above 0° C (32° F), these hydrogen bonds among the water molecules are broken, freeing the molecules to slip closer together. The density of water is greatest at 4° C, above which water begins to expand again as the speed of its molecules increases. As a result, ice floats on the denser cold water.

This unusual property of water has been important in enabling life as we know it to appear, survive, and evolve on Earth. If ice had a greater density than water, it would sink; eventually all ponds, lakes, and even the ocean would freeze solid from the bottom to the surface, making life impossible. When a body of deep water cools, it becomes covered with floating ice. The ice insulates the liquid water below it, preventing it from freezing and permitting a variety of animals and plants to survive below the icy surface.

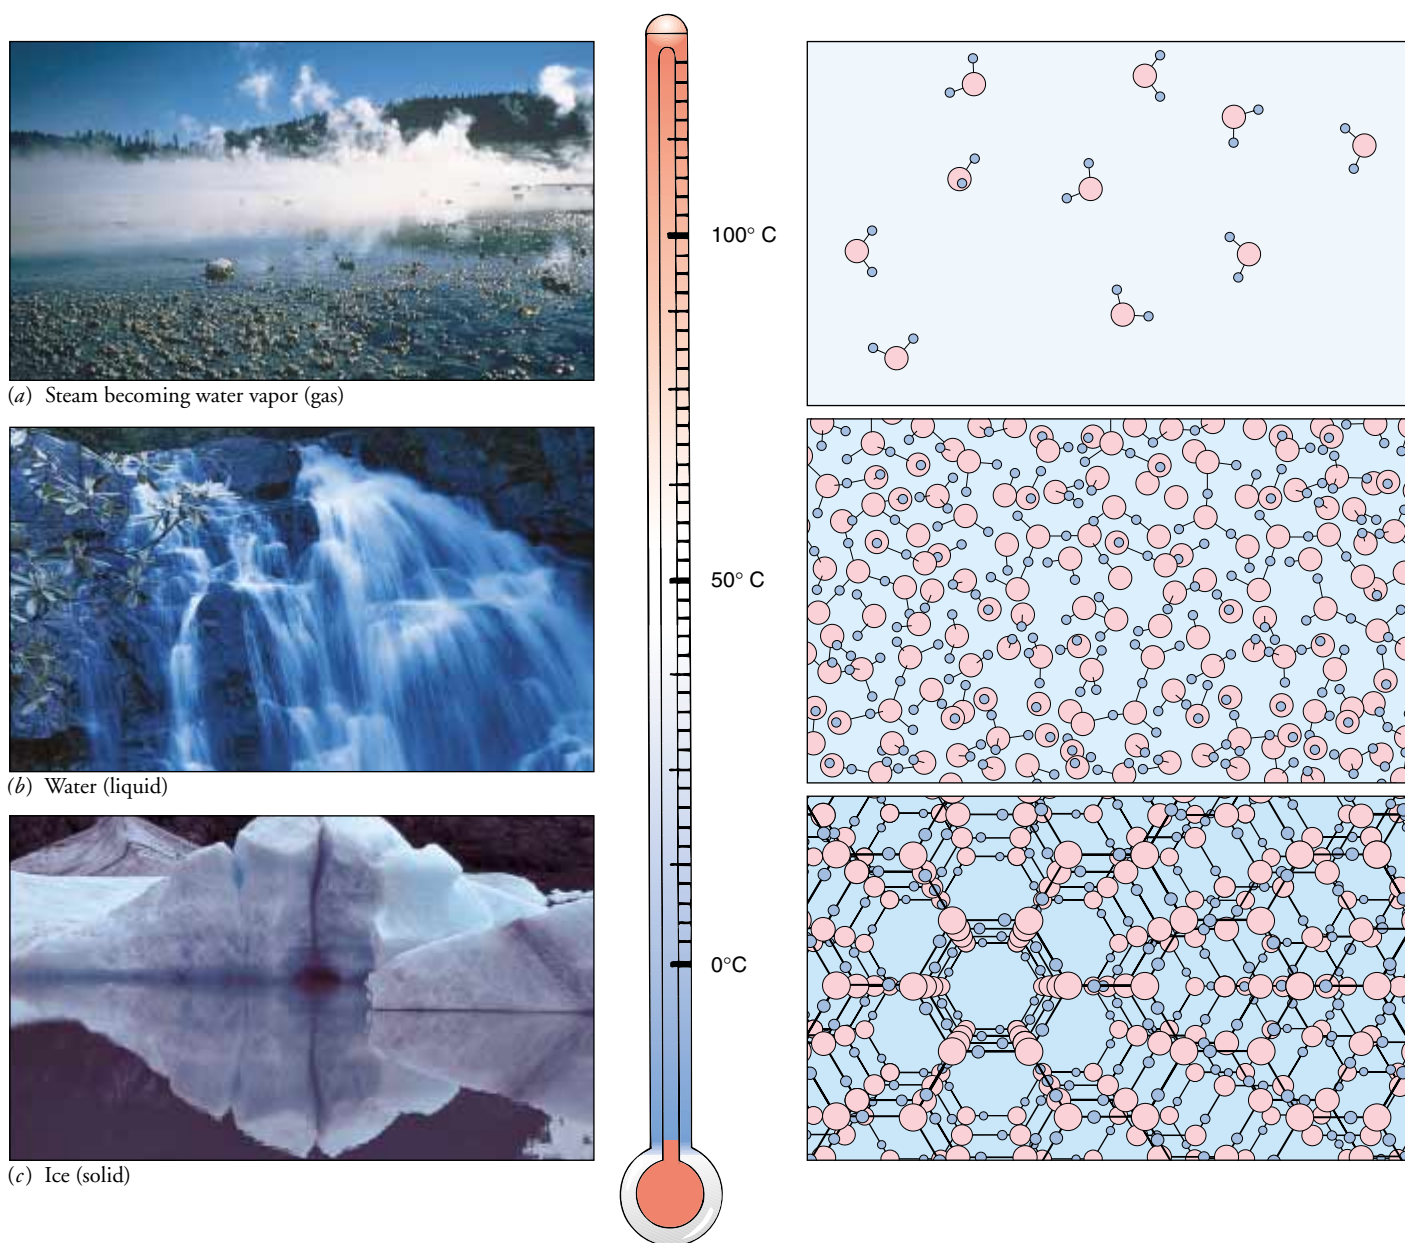

Figure 2-16 Three forms of water. (a) When water boils, as in this hot spring at Yellowstone National Park, many hydrogen bonds are broken, causing steam, consisting of minuscule water droplets, to form. If most of the remaining hydrogen bonds are subsequently broken, the molecules begin to move freely and rapidly as water vapor (a gas). (b) Water molecules in a liquid state continually form, break, and re-form hydrogen bonds with each other. (c) In ice, each water molecule participates in four hydrogen bonds with adjacent molecules, resulting in a regular, evenly distanced crystalline lattice structure. Because the water molecules move apart slightly as the hydrogen bonds form, water expands as it freezes; thus ice floats on water. (a, Woodbridge Wilson/National Park Service; b, Gary R. Bonner; c, Barbara O'Donnell/Biological Photo Service)

ACIDS ARE PROTON DONORS; BASES ARE PROTON ACCEPTORS

Water molecules have a slight tendency to **ionize**, that is, to dissociate into hydrogen ions (H^+) and hydroxide ions (OH^-).³ In pure water, a very small number of water molecules ionize. This slight tendency of water to dissociate is reversible as hydrogen ions and hydroxide ions reunite to form water:

³The H^+ immediately combines with a negatively charged region of a water molecule, forming a hydronium ion (H_3O^+). However, by convention H^+ , rather than the more accurate H_3O^+ , is used.

Because each water molecule splits into one hydrogen ion and one hydroxide ion, the concentrations of hydrogen ions and hydroxide ions in pure water are exactly equal (0.0000001 or 10^{-7} moles per liter for each ion). Such a solution is said to be **neutral**, neither acidic nor basic (alkaline).

An **acid** is a substance that dissociates in solution to yield hydrogen ions (H^+) and an anion.

An acid is a proton *donor*. (Recall that a hydrogen ion, or H^+ , is nothing more than a proton.) An acidic solution has a hydrogen ion concentration that is higher than its hydroxide ion concentration. Acidic solutions turn blue litmus paper red and have a sour taste. Hydrochloric acid (HCl) and sulfuric acid (H_2SO_4) are examples of inorganic acids. Lactic acid ($CH_3CHOHCOOH$) from sour milk and acetic acid (CH_3COOH) from vinegar are two common organic acids.

A **base** is defined as a proton *acceptor*. Most bases are substances that dissociate to yield a hydroxide ion (OH^-) and a cation when dissolved in water. A hydroxide ion can act as a base by accepting a proton (H^+) to form water. Sodium hydroxide ($NaOH$) is a common inorganic base.

Some bases do not dissociate to yield hydroxide ions directly. For example, ammonia (NH_3) acts as a base by accepting a proton from water, producing an ammonium ion (NH_4^+) and releasing a hydroxide ion.

A basic solution is one in which the hydrogen ion concentration is lower than the hydroxide ion concentration. Basic solutions turn red litmus paper blue and feel slippery to the touch. In later chapters we will encounter a number of organic bases, such as the purine and pyrimidine bases that are components of nucleic acids.

pH is a convenient measure of acidity

The degree of a solution's acidity is generally expressed in terms of **pH**, defined as the *negative logarithm (base 10) of the hydrogen ion concentration (expressed in moles per liter)*.

$$pH = -\log_{10}[H^+]$$

The brackets refer to concentration; therefore the term $[H^+]$ means "the concentration of hydrogen ions," which is expressed in moles per liter because we are interested in the *number* of hydrogen ions per liter. Because the range of possible pH values is very broad, a logarithmic scale (with a tenfold difference between successive units) is more convenient than a linear scale.

Hydrogen ion concentrations are nearly always less than 1 mole per liter. One gram of hydrogen ions dissolved in 1 liter of water (a 1-molar solution) may not sound very impressive, but such a solution would be extremely acidic. The logarithm

TABLE 2-2 The Relationship Between pH and Hydrogen Ion Concentration

Substance	$[H^+]$ *	$\log [H^+]$	pH
Gastric juice	$0.01, 10^{-2}$	-2	2
Pure water, neutral solution	$0.0000001, 10^{-7}$	-7	7
Household ammonia	$0.00000000001, 10^{-11}$	-11	11

* $[H^+]$ = hydrogen ion concentration (moles/L)

of a number less than one is a negative number; thus the *negative* logarithm corresponds to a *positive* pH value.

Whole number pH values are easy to calculate (Table 2-2). For instance, consider our example of pure water, which has a hydrogen ion concentration of 0.0000001 (10^{-7}) moles per liter. The logarithm is -7 . The negative logarithm is 7; therefore the pH is 7.

If the hydrogen ion concentration of a solution is known, the hydroxide ion concentration can be easily calculated. The product of the hydrogen ion concentration and the hydroxide ion concentration is 1×10^{-14} :

$$[H^+][OH^-] = 1 \times 10^{-14}$$

In pure (freshly distilled) water, the hydrogen ion concentration is 10^{-7} ; therefore the hydroxide concentration is also 10^{-7} . Such a solution, in which the concentrations are equal, is said to be neutral. Acidic solutions (those with an excess of hydrogen ions) have pH values smaller than 7. For example, the hydrogen ion concentration of a solution with pH 1 is ten times that of a solution with pH 2. Basic solutions (those with an excess of hydroxide ions) have pH values greater than 7.

The pH values of some common substances are shown in Figure 2-17. Although some very acidic compartments exist within cells (Chapter 4), most of the interior of an animal or plant cell is neither strongly acidic nor strongly basic but instead an essentially neutral mixture of acidic and basic substances. Although certain bacteria are adapted to life in extremely acidic environments (Chapter 23), a substantial change in pH is incompatible with life for most cells (Fig. 2-18). The pH of most types of plant and animal cells (and their environment) ordinarily ranges from around 7.2 to 7.4.

Buffers minimize pH change

Many homeostatic mechanisms operate to maintain appropriate pH values. For example, the pH of human blood is about 7.4 and must be maintained within very narrow limits. Should the blood become too acidic (for example, as a result of res-

Figure 2-17 pH values. The pH meter is an electronic device used to measure the acidity of a solution. A neutral solution (pH 7) has equal concentrations of H^+ and OH^- . Acidic solutions have pH values lower than 7, while basic solutions have pH values higher than 7.

Figure 2-18 Acid rain damage. Oxides of sulfur emitted from fossil fuel plants and other industries, and oxides of nitrogen from automobile exhaust, are converted in the moist atmosphere into acids that become dispersed over wide areas. Unlike unpolluted rain (average pH 5.6), the pH of acid rain has been measured at 4.2 and even lower. Plants, such as these trees photographed in the Black Forest, Germany, may be damaged when the resulting increase in soil acidity causes certain minerals, particularly calcium ions, to leach out of the soil. (Hans Reinhard/Bruce Coleman)

piratory disease), coma and death may result. Excessive alkalinity can result in overexcitability of the nervous system and even convulsions. Organisms contain many natural buffers. A **buffer** is a substance or combination of substances that resists changes in pH when an acid or base is added. A buffering system includes a weak acid or a weak base (Fig. 2-19). A weak acid or weak base does not ionize completely. That is, at any given instant only a fraction of the molecules are ionized; most are undissociated.

One of the most common buffering systems is found in the blood of vertebrates (see Chapter 44). Carbon dioxide, produced as a waste product of cellular metabolism, enters the blood, the main constituent of which is water. The carbon dioxide reacts with the water to form carbonic acid, a weak acid that dissociates to yield a hydrogen ion and a bicarbonate ion. The buffering system is described by the following expression:

As indicated by the arrows, all the reactions are reversible. Because carbonic acid is a weak acid, undissociated molecules are always present, as are all the other components of the system. The expression describes the system when it is at equilibrium,

Figure 2-19 Buffering. Sodium bicarbonate, which ionizes to form bicarbonate ions (HCO_3^-), is sometimes used as a remedy for excess stomach acid. The bubbles are CO_2 produced by the reaction between a weak acid (citric acid) and the sodium bicarbonate. (Charles D. Winters)

when the rates of the forward and reverse reactions are equal and the relative concentrations of the components are not changing. If a system is at equilibrium, it can be “shifted to the right” by adding reactants or removing products. Conversely, it can be “shifted to the left” by adding products or removing reactants. Hydrogen ions are the important products to consider in this system.

The addition of excess hydrogen ions temporarily shifts the system to the left, as they combine with the bicarbonate ions to form carbonic acid. Eventually a new equilibrium is established; at this point the hydrogen ion concentration is similar to the original concentration.

If hydroxide ions are added, they combine with the hydrogen ions to form water, effectively removing a product and thus shifting the system to the right. More carbonic acid then ionizes, replacing the hydrogen ions that were removed.

Organisms contain many weak acids and weak bases, thus maintaining an essential reserve of buffering capacity and avoiding pH extremes.

An acid and a base react to form a salt

When an acid and a base are mixed together, the H^+ of the acid unites with the OH^- of the base to form a molecule of water. The remainder of the acid (an anion) combines with the remainder of the base (a cation) to form a salt. For exam-

TABLE 2-3 Some Biologically Important Ions

Name	Formula	Charge
Sodium	Na^+	1+
Potassium	K^+	1+
Hydrogen	H^+	1+
Magnesium	Mg^{2+}	2+
Calcium	Ca^{2+}	2+
Iron	Fe^{2+} or Fe^{3+}	2+ [iron(II)] or 3+ [iron(III)]
Ammonium	NH_4^+	1+
Chloride	Cl^-	1-
Iodide	I^-	1-
Carbonate	CO_3^{2-}	2-
Bicarbonate	HCO_3^-	1-
Phosphate	PO_4^{3-}	3-
Acetate	CH_3COO^-	1-
Sulfate	SO_4^{2-}	2-
Hydroxide	OH^-	1-
Nitrate	NO_3^-	1-
Nitrite	NO_2^-	1-

ple, hydrochloric acid reacts with sodium hydroxide to form water and sodium chloride:

A **salt** is a compound in which the hydrogen ion of an acid is replaced by some other cation. Sodium chloride, NaCl , is a compound in which the hydrogen ion of HCl has been replaced by the cation Na^+ .

When a salt, an acid, or a base is dissolved in water, its dissociated ions can conduct an electrical current; these substances are called **electrolytes**. Sugars, alcohols, and many other substances do not form ions when dissolved in water; they do not conduct an electrical current and are referred to as **nonelectrolytes**.

Cells and extracellular fluids (such as blood) of animals and plants contain a variety of dissolved salts that are the source of the many important mineral ions essential for fluid balance and acid-base balance. The concentrations and relative amounts of the various cations and anions are kept remarkably constant. Any marked change results in impaired cellular functions and may lead to death. Nitrates and ammonium from the soil are the important nitrogen sources for plants. In animals, nerve and muscle function, blood clotting, bone formation, and many other aspects of body function depend on ions. Sodium, potassium, calcium, and magnesium are the chief cations present; chloride, bicarbonate, phosphate, and sulfate are important anions (Table 2-3).

S U M M A R Y W I T H K E Y T E R M S

- I. The chemical composition and metabolic processes of all organisms are very similar. The physical and chemical principles that govern non-living things also govern organisms.
- II. Organisms are made up of small, simple, **inorganic compounds** as well as large, complex, carbon-containing **organic compounds**.
- III. An **element** is a substance that cannot be decomposed into simpler substances by normal chemical reactions. Four elements—carbon, hydrogen, oxygen, and nitrogen—make up 96% or more of an organism's mass.
- IV. Each **atom** is composed of a nucleus containing **protons** and **neutrons**. In the space outside the nucleus, **electrons** move rapidly in **orbitals** that correspond to energy levels.
 - A. An atom is identified by its number of protons (**atomic number**).
 - B. Atoms of the same element with different numbers of neutrons (different **atomic masses**) are **isotopes**. Some isotopes are radioactive (**radioisotopes**).
 - C. In an electrically neutral atom, the number of protons equals the number of electrons.
 - D. The chemical properties of an atom are determined chiefly by the number and arrangement of its most energetic electrons, known as **valence electrons**.
- V. Different atoms are joined by chemical bonds to form **compounds**. A **chemical formula** gives the types and relative numbers of atoms in a substance.
 - A. One **mole** (the atomic or molecular mass in grams) of any substance contains 6.02×10^{23} atoms, molecules, or ions.
 - B. **Covalent bonds** are strong, stable bonds formed when atoms share **valence electrons**, forming **molecules**. A **molecular formula** gives the actual numbers of each type of atom in a molecule; a **structural formula** shows their arrangement.
 1. Covalent bonds are **nonpolar** if the electrons are shared equally between the two atoms.
 2. Covalent bonds are **polar** if one atom is more electronegative (has a greater affinity for electrons) than the other.
 - C. An **ionic bond** is formed between a positively charged **cation** and a negatively charged **anion**.
 - D. **Hydrogen bonds** are relatively weak bonds formed when a hydrogen atom with a partial positive charge is attracted to an atom (usually oxygen or nitrogen) with a partial negative charge already bonded to another molecule or in another part of the same molecule.
- VI. **Oxidation** and **reduction (redox)** reactions are chemical processes in which electrons (and their energy) are transferred from a reducing agent to an oxidizing agent.
- VII. Water accounts for a large part of the mass of most organisms. It is important in many chemical reactions within living things and has unique properties that also affect the environment.
 - A. Water is a **polar molecule** because one end has a partial positive charge and the other has a partial negative charge.
 - B. Because its molecules are polar, water is an excellent **solvent** for ionic or polar **solutes**.
 - C. Water molecules are **cohesive** because they form hydrogen bonds with each other; they are also **adhesive** through hydrogen bonding to substances with ionic or polar regions.
 - D. Water has a high **specific heat**, which helps organisms maintain a relatively constant internal temperature; this property also helps keep the ocean and other large bodies of water at a constant temperature.
 - E. Water has a high **heat of vaporization**. Molecules entering the vapor phase carry a great deal of heat, which accounts for **evaporative cooling**.
 - F. The fact that ice is less dense than liquid water makes the environment less extreme.
 - G. Water has a slight tendency to **ionize**, that is, to dissociate to form hydrogen ions (protons, H^+) and hydroxide ions (OH^-).
- VIII. **Acids** are proton (H^+) donors; **bases** are proton acceptors. Many bases dissociate in solution to yield hydroxide ions, which then accept protons.
 - A. The **pH scale** is a logarithmic expression of the hydrogen ion concentration of a solution. As a solution becomes more acidic, its pH falls below 7 (neutrality). As a solution becomes more basic (alkaline), its pH rises above 7.
 - B. A buffering system is based on a weak acid or a weak base. A **buffer** resists changes in the pH of a solution when acids or bases are added.
 - C. A **salt** is a compound in which the hydrogen atom of an acid is replaced by some other cation. Salts provide the many mineral ions essential for life functions.

P O S T - T E S T

1. Which of the following elements is mismatched with its properties or function? (a) carbon—forms the backbone of organic compounds (b) nitrogen—component of proteins (c) hydrogen—very electronegative (d) oxygen—can participate in hydrogen bonding (e) all of the above are correctly matched
2. Which of the following applies to a neutron? (a) positive charge and located in an orbital (b) negligible mass and located in the nucleus (c) positive charge and located in the nucleus (d) uncharged and located in the nucleus (e) uncharged and located in an orbital
3. $^{32}_{15}P$, a radioactive form of phosphorus, has (a) an atomic number of 32 (b) an atomic mass of 15 (c) an atomic mass of 47 (d) 32 electrons (e) 17 neutrons
4. Which of the following facts allows you to determine that atom A and atom B are isotopes of the same element? (a) they each have six protons (b) they each have four neutrons (c) in each, the sum of their electrons and neutrons is 14 (d) they each have four valence electrons (e) they each have a mass number of 14
5. Sodium and potassium behave similarly in chemical reactions. This is because (a) they have the same number of neutrons (b) each has a single valence electron (c) they have the same atomic mass (d) they have the same number of electrons (e) they have the same number of protons
6. The orbitals comprising an atom's valence electron shell (a) are arranged as concentric spheres (b) contain the atom's least energetic electrons (c) may change shape when covalent bonds are formed (d) never contain more than one electron each (e) more than one of the above is correct
7. Which of the following bonds and properties are correctly matched? (a) ionic bonds—strong only if the participating ions are hydrated (b) hydrogen bonds—responsible for bonding oxygen and hydrogen to form a single water molecule (c) polar covalent bonds—can occur between two atoms of the same element (d) covalent bonds—may be single, double, or triple (e) hydrogen bonds—stronger than covalent bonds
8. In a redox reaction (a) energy is transferred from a reducing agent to an oxidizing agent (b) a reducing agent becomes oxidized as it accepts an electron (c) an oxidizing agent accepts a proton (d) a reducing agent donates a proton (e) the electrons in an atom move from its valence shell to a shell closer to its nucleus
9. A solution with a pH of 2 has a hydrogen ion concentration that is _____ the hydrogen ion concentration of a solution with a pH of 4. (a) $1/2$ (b) $1/100$ (c) two times (d) ten times (e) one hundred times
10. The high heat of vaporization of water accounts for (a) evaporative cooling (b) the fact that ice floats (c) the fact that heat is liberated when ice forms (d) the cohesive properties of water (e) capillary action

11. NaOH and HCl react to form Na^+ , Cl^- , and water. Which of the following statements is true? (a) Na^+ is an anion, and Cl^- is a cation (b) Na^+ and Cl^- are both anions (c) a hydrogen bond can form be-

tween Na^+ and Cl^- (d) Na^+ and Cl^- are electrolytes (e) Na^+ is an acid, and Cl^- is a base

REVIEW QUESTIONS

1. What is the relationship between molecules and compounds? Are all compounds composed of molecules?
2. What are the ways an atom or molecule can become an anion or a cation?
3. What is a radioisotope? Why is it able to substitute for an ordinary (non-radioactive) atom of the same element in a molecule? What are some of the ways radioisotopes are used in biological research?
4. How do ionic and covalent bonds differ?
5. Why does water form hydrogen bonds? List some of the properties of water that result from hydrogen bonding. How do these properties contribute to the role of water as an essential component of organisms?
6. How can weak forces, such as hydrogen bonds, have significant effects in organisms?
7. A solution has a hydrogen ion concentration of 0.01 moles/liter. What is its pH? What is its hydroxide ion concentration? How would this solution differ from one with a pH of 1?
8. Why are buffers important in organisms? Give a specific example of how a buffering system works.
9. Differentiate clearly among acids, bases, and salts.
10. Why must oxidation and reduction occur simultaneously? Why are redox reactions important in some energy transfers?
11. Describe a reversible reaction that is at equilibrium. What would be the consequences of adding or removing a reactant or a product?

YOU MAKE THE CONNECTION

1. Element A has two electrons in its valence shell (which is complete when it contains eight electrons). Would you expect element A to share, donate, or accept electrons? What would you expect of element B, which has four valence electrons, and element C, which has seven?
2. A hydrogen bond formed between two water molecules is only about one-twentieth as strong as a covalent bond between hydrogen and oxygen. In what ways would the physical properties of water be different if

these hydrogen bonds were stronger (e.g., one-tenth the strength of covalent bonds)?

3. Consider the following reaction (in water).

Name the reactant(s) and product(s). Does the expression indicate that the reaction is reversible? Could HCl be used as a buffer?

CHAPTER 3

The Chemistry of Life: Organic Compounds

Both inorganic and organic forms of carbon occur widely in nature. The human, plant, paper, and the wood of the desk in the photograph all contain **organic compounds**, formed from backbones of covalently bonded carbon. Inorganic elemental carbon is represented by the diamond and the pencil “lead,” which is called graphite. Some very simple carbon compounds are also considered inorganic, especially if the carbon is not bonded to hydrogen. Organic compounds are so named because at one time they were thought to be produced only by living (organic) organisms. In 1928 the German chemist Friedrich Wöhler synthesized urea, a metabolic waste product. Since that time, scientists have learned to synthesize many organic molecules and have discovered organic compounds not found in organisms.

In this chapter we focus on some of the major groups of organic compounds important in organisms, including carbohydrates, lipids, proteins, and nucleic acids (DNA and RNA). Organic compounds are the main structural components of cells and tissues. They participate in and regulate metabolic reactions, transmit information, and provide energy for life processes. Evolution involves chemical changes in the organic compounds produced by organisms.

More than five million organic compounds have been identified. Perhaps because it can form a greater variety of molecules than any other element, carbon is the central component of all organic compounds. There are many reasons that organic molecules are so diverse. **Hydrocarbons**, organic compounds consisting only of carbon and hydrogen, can be produced in a wide variety of three-dimensional shapes. Furthermore, the carbon atom can form bonds with a greater number of different elements than any other type of atom. The addi-

(Kenneth Knott/Fine Light Photography)

tion of chemical groups containing atoms of other elements, especially oxygen, nitrogen, phosphorus, and sulfur, can profoundly change the properties of an organic molecule.

Further diversity is provided by the fact that a great many organic compounds found in organisms are extremely large **macromolecules**. Cells construct these from simpler modular subunits. For example, protein molecules are built from smaller compounds called amino acids.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Distinguish between organic and inorganic compounds.
2. Describe the properties of carbon that make it the central component of organic compounds.
3. Distinguish among the three principal types of isomers.
4. Identify the major functional groups present in organic compounds and describe their properties.
5. Compare the functions and chemical compositions of the major groups of organic compounds: carbohydrates, lipids, proteins, and nucleic acids.
6. Distinguish among monosaccharides, disaccharides, and polysaccharides. Compare storage polysaccharides with structural polysaccharides.
7. Distinguish among neutral fats, phospholipids, and steroids; describe the compositions, characteristics, and biological functions of each.
8. Sketch the structure of an amino acid. Explain how amino acids are grouped into classes based on the characteristics of their side chains.
9. Distinguish among the levels of organization of protein molecules.
10. Describe the components of a nucleotide. Name some nucleic acids and discuss the importance of these compounds in living organisms.

CARBON ATOMS FORM AN ENORMOUS VARIETY OF STRUCTURES

Carbon has unique properties that permit formation of the carbon backbones of the large, complex molecules essential to life. Because a carbon atom has four valence electrons, it can complete its valence shell by forming a total of four covalent bonds. Each bond can link it to another carbon atom or to an atom of a different element. Carbon is particularly well suited to serve as the backbone of a large molecule because carbon-to-carbon bonds are strong and not easily broken. However, they are not so strong that it would be impossible for cells to break them. Carbon-to-carbon bonds are not limited to single bonds (based on sharing of one electron pair). Two carbon atoms can share two electron pairs with each other, forming double bonds:

In some compounds, triple carbon-to-carbon bonds are formed:

Carbon chains can be unbranched or branched, and carbon atoms can also be joined into rings (Fig. 3–1). Rings and chains are joined in some compounds.

The molecules in the cell are analogous to the components of a machine. Each component has a shape that permits it to fill certain roles and to interact with other components (often with a complementary shape). Similarly, the shape of a molecule is important in determining its biological properties and function. Carbon atoms are able to link to each other and to other atoms to produce a wide variety of three-dimensional molecular shapes. This is because the four covalent bonds of carbon do not form in a single plane. Instead, as discussed in Chapter 2, the valence electron orbitals become elongated and project from the carbon atom toward the corners of a tetrahedron (Fig. 3–2). The structure is highly symmetrical, with an angle of about 109.5 degrees between any two of these

bonds. Keep in mind that, for simplicity, many of the figures in this book are drawn as two-dimensional graphic representations of three-dimensional molecules. For example, hydrocarbon chains, such as those seen in Figure 3–1, are not actually straight but have a three-dimensional zigzag structure.

Generally, there is freedom of rotation around each carbon-to-carbon single bond. This property permits organic molecules to be flexible and to assume a variety of shapes, depending on the extent to which each single bond is rotated. Double and triple bonds do not permit rotation, so regions of a molecule with such bonds tend to be inflexible.

One reason for the very great number of possible carbon-containing compounds is the fact that the same components usually can link together in more than one pattern, generating an even wider variety of molecular shapes.

ISOMERS HAVE THE SAME MOLECULAR FORMULA, BUT DIFFERENT STRUCTURES

Compounds with the same molecular formulas but different structures and thus different properties are called **isomers**. Isomers do not have identical physical or chemical properties and may have different common names. Cells can distinguish between isomers. Usually, one isomer is biologically active and the other is not. Three types of isomers are structural isomers, geometric isomers, and enantiomers.

Structural isomers are compounds that differ in the covalent arrangements of their atoms. For example, Figure 3–3a illustrates two structural isomers with the molecular formula C_2H_6O . Similarly, there are two structural isomers of the four-carbon hydrocarbon butane (C_4H_{10}), one with a straight chain and the other with a branched chain (isobutane). Large compounds have more possible structural isomers. There are only two structural isomers of butane, but there can be up to 366,319 isomers of $C_{20}H_{42}$.

Figure 3-1 Organic molecules. Note that each carbon atom forms four covalent bonds, producing a wide variety of shapes.

Figure 3-2 Carbon bonding. The three-dimensional arrangement of the bonds of a carbon atom (a) is responsible for the tetrahedral architecture of methane (b). (c) In carbon dioxide oxygen atoms are joined to a central carbon by polar double bonds. Because the bonds are arranged linearly, carbon dioxide does not have a positively charged end and a negatively charged end, and is therefore a nonpolar molecule.

Geometric isomers are compounds that are identical in the arrangement of their covalent bonds, but different in the spatial arrangement of groups of atoms. Geometric isomers are present in some compounds with carbon-to-carbon double bonds. Because double bonds are not flexible like single bonds, atoms joined to the carbons of a double bond cannot rotate freely about the axis of the bonds. The *cis-trans* isomers may be drawn as shown in Figure 3-3b. The designation *cis* (Latin, “on this side”) indicates that the two larger components are on the same side of the double bond. If they are on opposite sides of the double bond, the compound is designated a *trans* (Latin, “across”) isomer.

Enantiomers are molecules that are mirror images of one another (Fig. 3-3c). Recall that the four groups bonded to a single carbon atom are arranged at the vertices of a tetrahedron. If the four bonded groups are all different, the central carbon is described as asymmetric. Figure 3-3d illustrates that the four groups can be arranged about the asymmetric carbon in two different ways that are mirror images of each other. The two molecules are enantiomers if they cannot be superimposed on one another no matter how they are rotated in space. Although enantiomers have similar chemical properties and iden-

(c) Enantiomers are mirror images

(d) Enantiomers of glyceraldehyde

Figure 3–3 Isomers. Isomers have the same molecular formula, but their atoms are arranged differently. (a) Structural isomers differ in the covalent arrangement of their atoms. (b) Geometric, or *cis-trans*, isomers have identical covalent bonds but differ in the order in which groups of atoms are arranged in space. (c) and (d) Enantiomers are isomers that are mirror images of one another. The arrows indicate the asymmetric carbons. (c, Dennis Drenner)

tical physical properties, cells recognize the difference in shape and usually only one form is found in organisms.

The existence of isomers is not the only source of variety among organic molecules. The addition of various combinations of atoms, known as functional groups, can generate a vast array of molecules with differing properties.

FUNCTIONAL GROUPS CHANGE THE PROPERTIES OF ORGANIC MOLECULES

Because covalent bonds between hydrogen and carbon are non-polar, hydrocarbons lack distinct charged regions. For this reason, hydrocarbons are insoluble in water and tend to cluster together, through **hydrophobic** (“water-fearing”) **interactions**. This is not because bonds form among the hydrocarbons, but rather because the hydrogen-bonded water molecules exclude them and, in a sense, drive them together. Because of their hydrophobic nature, hydrocarbons do not interact readily with most other compounds.

However, the characteristics of an organic molecule can be changed dramatically by replacing one of the hydrogens with a group of atoms known as a **functional group**. Functional groups help determine the types of chemical reactions in which the compound participates. Most functional groups readily form associations, such as ionic and hydrogen bonds, with other molecules. Polar and ionic functional groups are hydrophilic because they associate strongly with polar water molecules.

The properties of the major classes of organic compounds—carbohydrates, lipids, proteins, and nucleic acids—are largely a consequence of the types and arrangement of functional groups they contain. When we know what kinds of functional groups are present in an organic compound, we can predict its chemical behavior. As you read the rest of this section please refer to Table 3–1 for the complete structural formulas of these groups, as well as additional information. Note that the symbol R is used to represent the *remainder* of the molecule of which each functional group is a part.

The **hydroxyl group** (abbreviated R—OH) must not be confused with the hydroxide ion (OH[−]) discussed in Chapter 2. The hydroxyl group is polar due to the presence of a

TABLE 3-1 Some Biologically Important Functional Groups

Functional group	Structural formula	Class of compounds characterized by group	Description
Hydroxyl	$\text{R}-\text{OH}$	Alcohols $\begin{array}{c} \text{H} \quad \text{H} \\ \quad \\ \text{H}-\text{C}-\text{C}-\text{OH} \\ \quad \\ \text{H} \quad \text{H} \end{array}$ Ethanol	Polar because electronegative oxygen attracts covalent electrons

strongly electronegative oxygen atom. If a hydroxyl group replaces one of the hydrogens of a hydrocarbon, the resulting molecule can have significantly altered properties. For example, ethane (Fig. 3-1*a*) is a hydrocarbon that is a gas at room temperature. If a hydrogen is replaced by a hydroxyl group, the resulting molecule is ethyl alcohol, or ethanol, which is found in alcoholic beverages (Fig. 3-3*a*). Ethanol is somewhat cohesive because the polar hydroxyl groups of adjacent molecules interact; it is therefore liquid at room temperature. Unlike ethane, ethyl alcohol can dissolve in water because the polar hydroxyl groups interact with the polar water molecules.

The **carbonyl group** consists of a carbon atom that has a double covalent bond with an oxygen atom. This double bond is polar because of the electronegativity of the oxygen; thus the carbonyl group is hydrophilic. The position of the carbonyl group in the molecule determines the class to which the molecule belongs. An **aldehyde** has a carbonyl group positioned at the end of the carbon skeleton (abbreviated $\text{R}-\text{CHO}$); a **ketone** has an internal carbonyl group (abbreviated $\text{R}-\text{CO}-\text{R}$).

The **carboxyl group** (abbreviated $\text{R}-\text{COOH}$) consists of a carbon atom joined by a double covalent bond to an oxygen atom, and by a single covalent bond to another oxygen, which is in turn bonded to a hydrogen atom. Two electronegative oxygen atoms in such close proximity establish an extremely polarized condition, which can cause the hydrogen

atom to be stripped of its electron and released as a hydrogen ion (H^+). The carboxyl group then has one unit of negative charge ($\text{R}-\text{COO}^-$):

Carboxyl groups are weakly acidic; only a fraction of the molecules ionize in this way. This group can therefore exist in one of two hydrophilic states: ionic or polar. Carboxyl groups are essential constituents of amino acids.

An **amino group** (abbreviated $\text{R}-\text{NH}_2$) includes a nitrogen atom covalently bonded to two hydrogen atoms. Amino groups are weakly basic because they are able to accept a hydrogen ion (proton), thus acquiring a unit of positive charge. Amino groups are components of amino acids and of nucleic acids.

A **phosphate group** (abbreviated $\text{R}-\text{PO}_4\text{H}_2$) is weakly acidic. The attraction of electrons by the oxygens can result in the release of one or two hydrogen ions, producing ionized forms with one or two units of negative charge. Phosphates are constituents of nucleic acids and certain lipids.

The **sulfhydryl group** (abbreviated $\text{R}-\text{SH}$), consisting of an atom of sulfur covalently bonded to a hydrogen atom,

is found in molecules called *thiols*. As we will see, amino acids that contain a sulfhydryl group can make important contributions to the structure of proteins.

The **methyl group** (abbreviated $R-CH_3$), a common hydrocarbon group, is nonpolar.

MANY BIOLOGICAL MOLECULES ARE POLYMERS

Many biological molecules such as proteins and nucleic acids are very large, consisting of thousands of atoms. Such giant molecules are known as **macromolecules**. Most macromolecules are **polymers**, produced by linking small organic compounds called **monomers** (Fig. 3–4). Just as all the words in this book have been written by arranging the 26 letters of the alphabet in various combinations, monomers can be grouped together to form an almost infinite variety of larger molecules. Just as we use different words to convey information, cells use different molecules to convey information. The thousands of different complex organic compounds present in organisms are constructed from about 40 small, simple monomers. For example, the 20 monomers called amino acids can be linked end-to-end in countless ways to form the polymers we know as proteins.

Each organism is unique because of differences in the monomer sequence within its DNA, the polymer that constitutes the information in the genes. Cells and tissues within the same organism are also different, due to variations in their component polymers. Muscle tissue and brain tissue differ in large part because of differences in the types and sequences of amino acids in proteins. Ultimately this protein structure is dictated by the sequence of monomers within the DNA of the organism, which is expressed somewhat differently in each cell type.

Polymers can be degraded to their component monomers by **hydrolysis** (which means “to break with water”). In a reaction regulated by a specific enzyme,¹ a hydrogen from a water molecule attaches to one monomer, and a hydroxyl from water attaches to the adjacent monomer.

The synthetic process by which monomers are covalently linked is called **condensation**. Because the *equivalent* of a molecule of water is removed during the reactions that combine monomers, the term *dehydration synthesis* is sometimes used to describe the process. However, in biological systems the synthesis of a polymer is not simply the reverse of hydrolysis, even though the net effect is the opposite of hydrolysis. Synthetic processes require energy and are regulated by different enzymes.

In the following sections we will examine carbohydrates, lipids, proteins, and nucleic acids. Our discussion will begin

Figure 3–4 A simple polymer. This small polymer of polyethylene is formed by linking two-carbon ethylene (C_2H_4) monomers. One such monomer is outlined.

with the smaller, simpler forms of these compounds and will extend to the linking of these monomers to form macromolecules.

CARBOHYDRATES INCLUDE SUGARS, STARCHES, AND CELLULOSE

Sugars, starches, and cellulose are **carbohydrates**. Sugars and **starches** serve as energy sources for cells; **cellulose** is the main structural component of the walls that surround plant cells. Carbohydrates contain carbon, hydrogen, and oxygen atoms in a ratio of approximately one carbon to two hydrogens to one oxygen (CH_2O)_n. The term *carbohydrate*, meaning “hydrate (water) of carbon,” reflects the 2:1 ratio of hydrogen to oxygen, the same ratio found in water (H_2O). Carbohydrates contain one sugar unit (*monosaccharides*), two sugar units (*disaccharides*), or many sugar units (*polysaccharides*).

Monosaccharides are simple sugars

Monosaccharides typically contain from three to seven carbon atoms. In a monosaccharide, a hydroxyl group is bonded to each carbon except one; that carbon is double-bonded to an oxygen atom, forming a carbonyl group. If the carbonyl group is at the end of the chain, the monosaccharide is an aldehyde; if the carbonyl group is at any other position, the monosaccharide is a ketone. (By convention, the numbering of the carbon skeleton of a sugar begins with the carbon at or nearest the carbonyl end of the open chain.) The large number of polar hydroxyl groups, plus the carbonyl group, gives a monosaccharide hydrophilic properties.

Figure 3–5 shows simplified, two-dimensional representations of some common monosaccharides. The simplest carbohydrates are the three-carbon sugars (trioses): glyceraldehyde and dihydroxyacetone. Ribose and deoxyribose are common pentoses, sugars that contain five carbons; they are components of nucleic acids (DNA, RNA, and related compounds). Glucose, fructose, galactose, and other six-carbon sugars are called **hexoses**. (Note that the names of carbohydrates typically end in *-ose*.)

Glucose ($C_6H_{12}O_6$), the most abundant monosaccharide, is used as an energy source in most organisms. During cellular

¹An enzyme (see Chapter 6) is a protein catalyst that accelerates a specific chemical reaction.

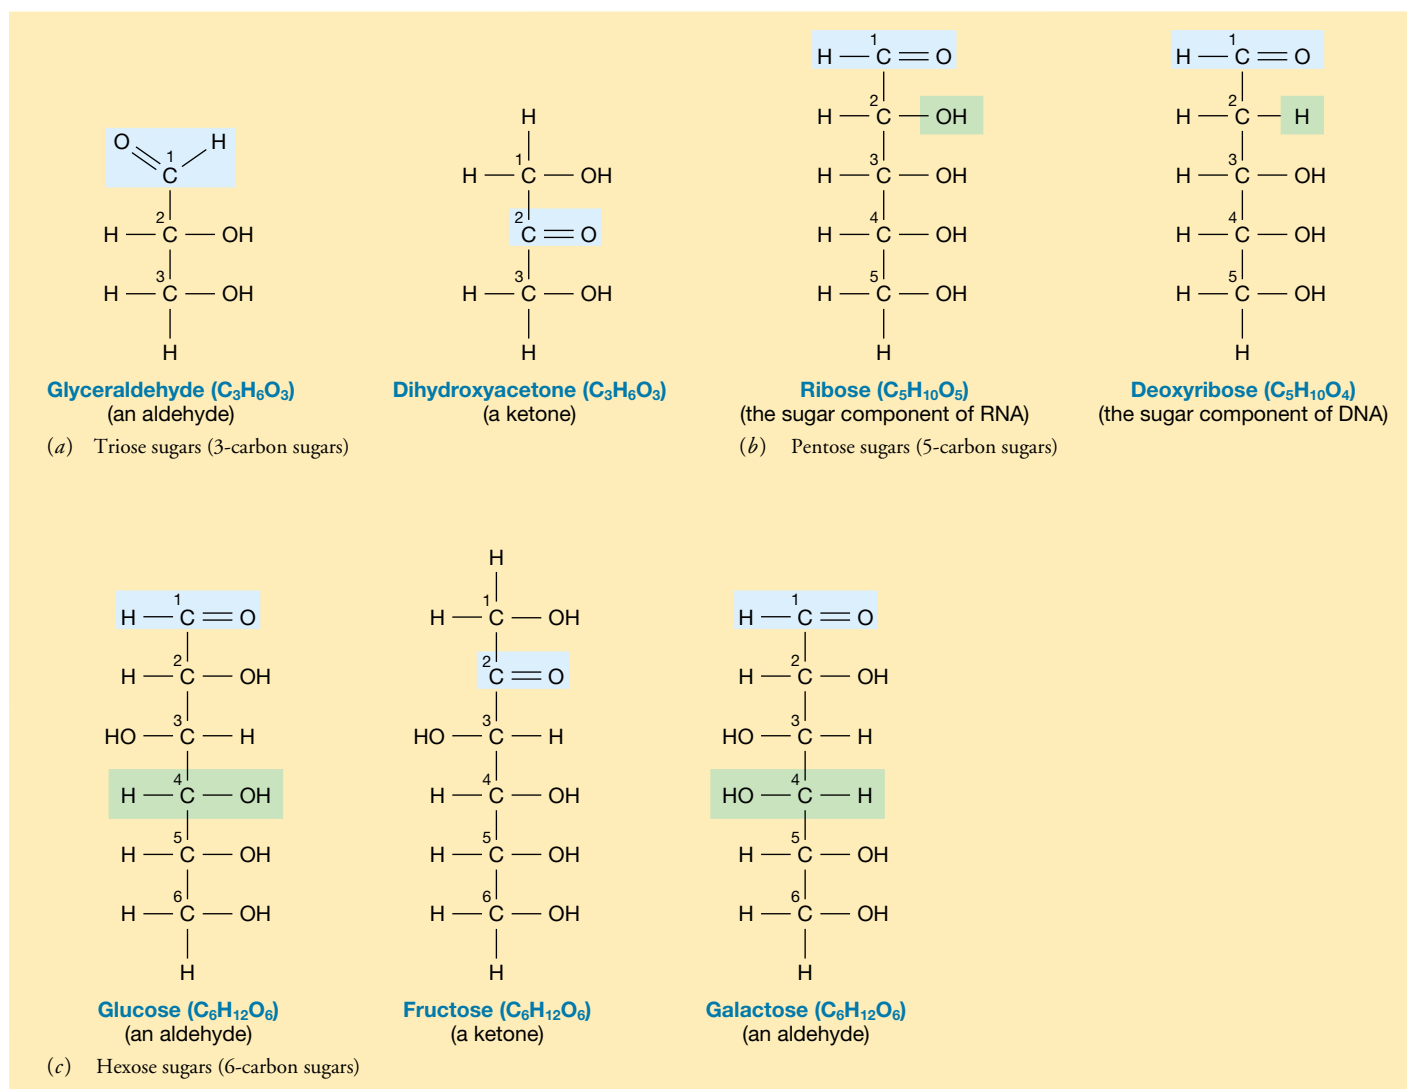

Figure 3-5 Monosaccharides. Shown are two-dimensional chain structures of (a) 3-carbon trioses, (b) 5-carbon pentoses, and (c) 6-carbon hexoses. Although it is convenient to show monosaccharides in this form, the pentoses and hexoses are more accurately depicted as ring structures, as in Figure 3-6.

respiration (Chapter 7), cells oxidize glucose molecules, converting the stored energy to a form that can be readily used for cellular work. Glucose is also used as a component in the synthesis of other types of compounds such as amino acids and fatty acids. So important is glucose in metabolism that its concentration is carefully kept at a homeostatic (relatively constant) level in the blood of humans and other complex animals.

Glucose and fructose are structural isomers: they have identical molecular formulas, but their atoms are arranged differently. In fructose (a ketone) the double-bonded oxygen is linked to a carbon within the chain rather than to a terminal carbon as in glucose (which is an aldehyde). Because of these differences, the two sugars have different properties. For example, fructose tastes sweeter than glucose.

Glucose and galactose are both hexoses and aldehydes.

However, they are mirror images (enantiomers) because they differ in the arrangement of the atoms attached to asymmetric carbon atom 4.

The “stick” formulas in Figure 3-5 give a clear but somewhat unrealistic picture of the structures of some common monosaccharides. As has been discussed, molecules are not two-dimensional; in fact, the properties of each compound depend largely on its three-dimensional structure. Thus, three-dimensional formulas are helpful in understanding the relationship between molecular structure and biological function. Molecules of glucose and other pentoses and hexoses in solution are actually rings, rather than extended straight carbon chains.

Glucose in solution (as in the cell) typically exists as a ring of five carbons and one oxygen. It assumes this configuration

Figure 3–6 α and β forms of glucose. (a) When dissolved in water, glucose undergoes a rearrangement of its atoms, forming one of two possible ring structures, α -glucose or β -glucose. Although the drawing does not attempt to show the complete three-dimensional structure, the thick, tapered bonds in the lower portion of each ring represent the part of the molecule that would project out of the page toward you. (b) The essential differences between α -glucose and β -glucose are more readily apparent in these simplified structures. By convention, a carbon atom is assumed to be present at each angle in the ring unless another atom is shown. Most hydrogen atoms have been omitted.

when its atoms undergo a rearrangement, permitting a covalent bond to connect carbon 1 to the oxygen attached to carbon 5 (Fig. 3–6). When glucose forms a ring, two isomeric forms are possible, differing only in the orientation of the hydroxyl (—OH) group attached to carbon 1. When this hydroxyl group is on the same side of the plane of the ring as the $\text{—CH}_2\text{OH}$ side group, the glucose is designated β -glucose. When it is on the side (with respect to the plane of the ring) opposite the $\text{—CH}_2\text{OH}$ side group, the compound is designated α -glucose.

Disaccharides consist of two monosaccharide units

A disaccharide (two sugars) contains two monosaccharide rings joined by a **glycosidic linkage**, consisting of a central oxygen

covalently bonded to two carbons, one in each ring (Figure 3–7). The glycosidic linkage of a disaccharide generally forms between carbon 1 of one molecule and carbon 4 of the other molecule. The disaccharide maltose (malt sugar) consists of two covalently linked α -glucose units. Sucrose, common table sugar, consists of a glucose unit combined with a fructose unit. Lactose (the sugar present in milk) is composed of one molecule of glucose and one of galactose.

A disaccharide can be hydrolyzed, that is, split by the addition of water, into two monosaccharide units. During digestion, maltose is hydrolyzed to form two molecules of glucose:

Similarly, sucrose is hydrolyzed to form glucose and fructose:

Figure 3–7 Hydrolysis of disaccharides. (a) Maltose may be broken down (as it is during digestion) to form two molecules of glucose. The highlighted glycosidic linkage is broken in a hydrolysis reaction, which requires the addition of water. (b) Sucrose can be hydrolyzed to yield a molecule of glucose and a molecule of fructose. Note that an enzyme (a protein catalyst) is needed to promote these reactions.

Polysaccharides can store energy or provide structure

The most abundant carbohydrates are the **polysaccharides**, a group that includes starches, glycogen, and cellulose. A polysaccharide is a macromolecule consisting of repeating units of simple sugars, usually glucose. Although the precise number of sugar units varies, thousands of units are typically present in a single molecule. The polysaccharide may be a single long chain or a branched chain. Because they are composed of different isomers and because the units may be arranged differently, polysaccharides vary in their properties. Those that can be easily broken down to their subunits are well suited for energy storage, whereas the macromolecular three-dimensional architecture of others makes them particularly well suited to form stable structures.

Starch is the main storage carbohydrate of plants

Starch, the typical form of carbohydrate used for energy storage in plants, is a polymer consisting of α -glucose subunits. These monomers are joined by α 1—4 linkages, which means that carbon 1 of one glucose is linked to carbon 4 of the next glucose in the chain (Fig. 3–8). Starch occurs in two forms,

amylose and amylopectin. Amylose, the simpler form, is unbranched. Amylopectin, the more common form, usually consists of about 1000 units in a branched chain.

Plant cells store starch mainly as granules within specialized organelles called **amyloplasts** (Fig. 3–8a). When energy is needed for cellular work, the plant can hydrolyze the starch, releasing the glucose subunits. Humans and other animals that eat plant foods have enzymes to hydrolyze starch.

Glycogen is the main storage carbohydrate of animals

Glycogen (sometimes referred to as *animal starch*) is the form in which glucose is stored as an energy source in animal tissues. It is similar in structure to plant starch, but more extensively branched and more water-soluble. Glycogen is stored mainly in liver and muscle cells.

Cellulose is a structural carbohydrate

Carbohydrates are the most abundant group of organic compounds on Earth, and **cellulose** is the most abundant carbohydrate; it accounts for 50% or more of all the carbon in plants (Fig. 3–9). Cellulose is a structural carbohydrate. Wood is about half cellulose, and cotton is at least 90% cellulose. Plant

Figure 3–8 Starch, a storage polysaccharide. (a) Starch (stained purple) is stored in specialized organelles, called *amyloplasts*, in these cells of a buttercup root. (b) Starch is made up of highly branched chains; the arrows indicate the branch points. Each chain is actually in the form of a coil or helix, stabilized by hydrogen bonds between the glucose subunits. (c) Starch is composed of α -glucose molecules joined by glycosidic bonds. At the branch points are bonds between carbon 6 of the glucose in the straight chain and carbon 1 of the glucose in the branching chain. (a, Ed Reschke)

cells are surrounded by strong supporting cell walls consisting mainly of cellulose.

Cellulose is an insoluble polysaccharide composed of many glucose molecules joined together. The bonds joining these sugar units are different from those in starch. Recall that starch is composed of α -glucose subunits, joined by α 1—4 glycosidic linkages. Cellulose contains β -glucose monomers joined by β 1—4 linkages. These bonds are not split by the enzymes that hydrolyze the alpha linkages in starch. Humans, like most organisms, do not have enzymes that can digest cellulose and therefore cannot use it as a nutrient. Because cel-

lulose remains fibrous, as discussed in Chapter 45, it helps keep the digestive tract functioning properly.

Some microorganisms can digest cellulose to glucose. In fact, cellulose-digesting bacteria live in the digestive systems of cows and sheep, enabling these grass-eating animals to obtain nourishment from cellulose. Similarly, the digestive systems of termites contain microorganisms that digest cellulose (see Fig. 24–5a).

Cellulose molecules have characteristics that make them well suited for a structural role. The β -glucose subunits are joined in a way that allows extensive hydrogen bonding among

Figure 3-9 Cellulose, a structural polysaccharide. (a) An electron micrograph of cellulose fibers from a cell wall. The fibers visible in the photograph consist of bundles of cellulose molecules, interacting through hydrogen bonds. (b and c) The cellulose molecule is an unbranched polysaccharide composed of approximately 10,000 β -glucose units joined by glycosidic bonds. (a, Omikron/Photo Researchers, Inc.)

different cellulose molecules. Thus, cellulose molecules aggregate in long bundles of fibers, as shown in Figure 3-9a.

Some modified and complex carbohydrates have special roles

Many derivatives of monosaccharides are important biological molecules. Some form important structural components. The amino sugars galactosamine and glucosamine are compounds in which a hydroxyl group ($-\text{OH}$) is replaced by an amino group ($-\text{NH}_2$). Galactosamine is present in cartilage, a constituent of the skeletal system of vertebrates. *N*-acetyl glucosamine (NAG) subunits, joined by glycosidic bonds, compose **chitin**, a main component of the external skeletons of insects, crayfish, and other arthropods (Fig. 3-10), and of the cell walls of fungi. Chitin forms very tough structures because, as in cellulose, its molecules interact through multiple hydrogen bonds.

Carbohydrates may also be combined with proteins to form **glycoproteins**, compounds present on the outer surface

of cells other than bacteria. Some of these carbohydrate chains allow cells to adhere to one another, while others provide protection. Most proteins secreted by cells are glycoproteins. Carbohydrates can combine with lipids to form **glycolipids**, compounds present on the surfaces of animal cells that are thought to allow cells to recognize and interact with one another (see Chapters 4 and 5).

LIPIDS ARE FATS OR FATLIKE SUBSTANCES

Lipids are a heterogeneous group of compounds that are defined, not by their structure, but rather by the fact that they are soluble in nonpolar solvents (ether, chloroform, etc.) and are relatively insoluble in water. Lipid molecules have these properties because they consist mainly of carbon and hydrogen, with few oxygen-containing functional groups. Oxygen

Figure 3–10 Chitin, a structural polysaccharide. (a) Chitin is a polymer composed of *N*-acetyl glucosamine (NAG) subunits. (b) Chitin is an important component of the exoskeleton (outer covering) that this dragonfly is shedding. (b, Dwight R. Kuhn)

atoms are commonly found in hydrophilic functional groups; therefore lipids, with little oxygen, tend to be hydrophobic. Among the biologically important groups of lipids are neutral fats, phospholipids, carotenoids (orange and yellow plant pigments), steroids, and waxes. Some lipids are used for energy storage, others serve as structural components of cellular membranes, and some are important hormones.

Neutral fats contain glycerol and fatty acids

The most abundant lipids in living organisms are the **neutral fats**. These compounds are an economical form of reserve fuel storage because they yield more than twice as much energy per gram as do carbohydrates. Carbohydrates and proteins can be transformed by enzymes into fats and stored within the cells of adipose (fat) tissue of animals and in some seeds and fruits of plants.

A neutral fat consists of glycerol joined to one, two, or three fatty acids. **Glycerol** is a three-carbon alcohol that contains three hydroxyl (—OH) groups (Fig. 3–11). A **fatty acid** is a long, unbranched hydrocarbon chain with a carboxyl group (—COOH) at one end. About 30 different fatty acids are commonly found in lipids, and they typically have an even number of carbon atoms. For example, butyric acid, present in ran-

cid butter, has four carbon atoms. Oleic acid, with 18 carbons, is the most widely distributed fatty acid in nature and is found in most animal and plant fats.

Saturated fatty acids contain the maximum possible number of hydrogen atoms. Fats high in saturated fatty acids, such as animal fat and solid vegetable shortening, tend to be solid at room temperature. This is because even electrically neutral, nonpolar molecules can develop transient regions of weak positive charge and weak negative charge, as the constant motion of their electrons causes some regions to have a temporary excess of electrons, while others have a temporary electron deficit. These slight opposite charges result in attractions, known as **van der Waals forces**, between adjacent molecules. Although van der Waals interactions are individually weak, they can be strong when many occur among long hydrocarbon chains.

Unsaturated fatty acids include one or more adjacent pairs of carbon atoms joined by a double bond. Therefore they are not fully saturated with hydrogen. Fatty acids with one double bond are called **monounsaturated fatty acids**, while those with more than one double bond are **polyunsaturated fatty acids**. Fats containing a high proportion of monounsaturated or polyunsaturated fatty acids tend to be liquid at room temperature. This is because each double bond produces a bend in the hydrocarbon chain that prevents it from aligning closely

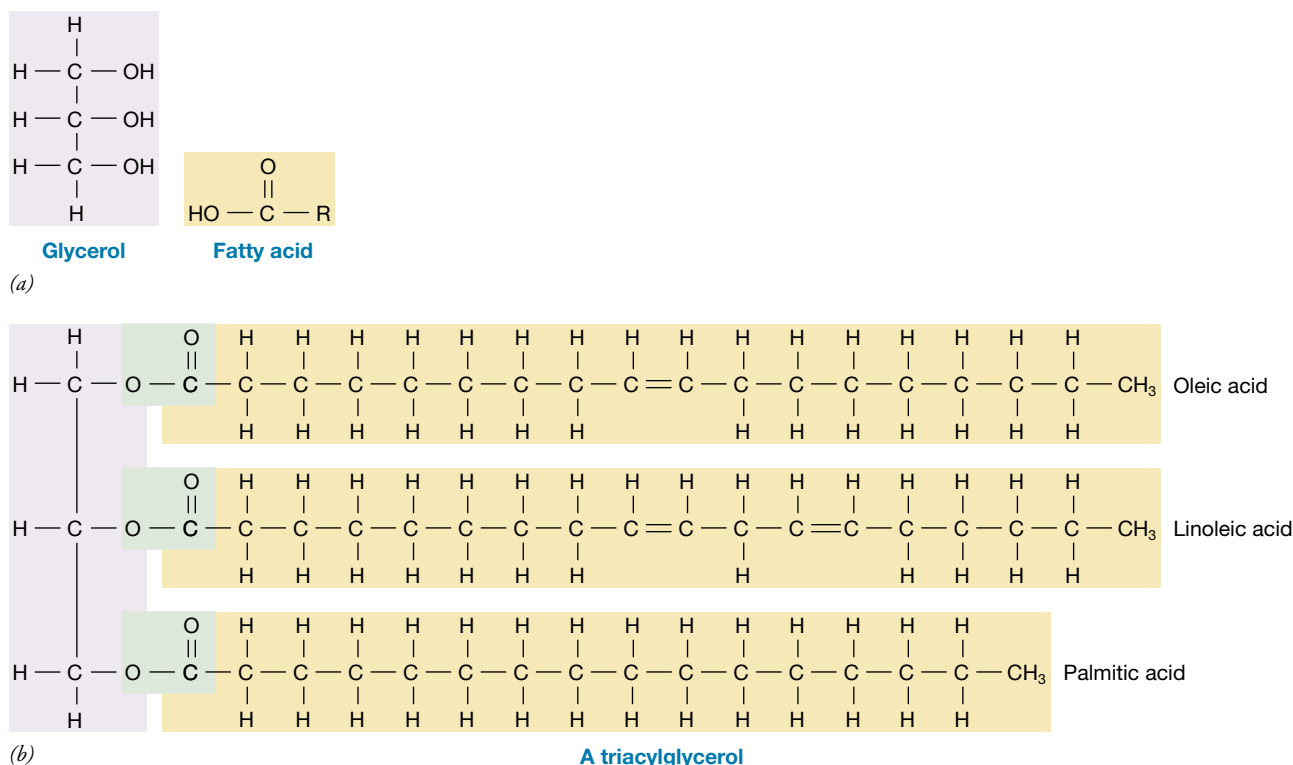

Figure 3-11 Neutral fats. (a) Glycerol and fatty acids are the components of neutral fats. Every fatty acid contains a carboxyl (—COOH) group, plus a long hydrocarbon (represented by “R”) that is specific for that particular fatty acid. (b) Glycerol is attached to fatty acids by ester linkages, shown in green. Note that oleic and linoleic acid are unsaturated fatty acids. They are drawn as straight chains, but the molecules are actually bent or kinked wherever a carbon-to-carbon double bond appears. (c) Commonly used cooking fats contain triacylglycerols. (c, Kenneth Knott/Fine Light Photography)

with an adjacent chain, thereby limiting van der Waals interactions.

At least two unsaturated fatty acids (linoleic acid and arachidonic acid) are essential nutrients that must be obtained from food because the human body cannot synthesize them. However, the amounts required are small, and deficiencies are rarely seen. There is no dietary requirement for saturated fatty acids.

When a glycerol molecule combines chemically with one fatty acid, a **monoacylglycerol** (sometimes called *monoglyceride*) is formed. **Diacylglycerols** (or *diglycerides*) and **triacylglycerols** (or *triglycerides*) contain two or three fatty acids, respectively. In each condensation reaction, the equivalent of a water molecule is removed as one of the glycerol’s hydroxyl groups reacts with the carboxyl group of a fatty acid. Such a reaction between a hydroxyl group and a carboxyl group results in the formation of a covalent linkage known as an **ester linkage** (Fig. 3-11b). During digestion, neutral fats are hydrolyzed to produce fatty acids and glycerol (see Chapter 45).

Phospholipids are components of cellular membranes

Phospholipids belong to a group of lipids, called **amphipathic lipids**, in which one end of each molecule is hydrophilic and the other end is hydrophobic. The two ends of a phospholipid differ both physically and chemically. A phospholipid consists of a glycerol molecule attached at one end to two fatty acids, and at the other end to a phosphate group linked to an organic compound such as choline. The organic compound usually contains nitrogen (Fig. 3-12). (Note that phosphorus and nitrogen are absent in the neutral fats.) The fatty acid portion of the molecule (containing the two hydrocarbon “tails”) is hydrophobic and not soluble in water. However, the portion composed of glycerol, phosphate, and the organic base (the “head” of the molecule) is ionized and readily water-soluble. The amphipathic properties of these lipid molecules make them uniquely suited to form cellular membranes, structures that will be discussed in Chapters 4 and 5.

Figure 3–12 A phospholipid. Note the hydrophobic tail, made up of two fatty acids, and the hydrophilic head, which includes a glycerol bonded to a phosphate group, which is in turn bonded to an organic group that can vary. Choline is the organic group in the molecule shown, lecithin (or phosphatidylcholine). The lower fatty acid in the figure is monounsaturated; it contains one double bond that produces a characteristic bend in the chain.

Carotenoid plant pigments are derived from isoprene units

The orange and yellow plant pigments called **carotenoids** are classified with the lipids because they are insoluble in water and have an oily consistency. These pigments, found in the cells of all plants, play a role in photosynthesis. As discussed in *Making the Connection: Molecules that Absorb Light*, carotenoid molecules and many other important pigments consist of five-carbon hydrocarbon monomers known as *isoprene units*.

Steroids contain four rings of carbon atoms

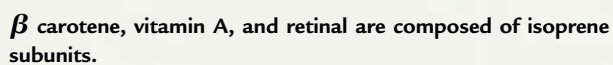

A **steroid** consists of carbon atoms arranged in four attached rings; three of the rings contain six carbon atoms, and the fourth contains five (Fig. 3–13). The length and structure of the side chains that extend from these rings distinguish one

Figure 3–13 Steroids. Four attached rings—three six-carbon rings and one with five carbons—make up a steroid. Note that some carbons are shared by two rings. In these simplified structures, a carbon atom is present at each angle of a ring; the hydrogen atoms attached directly to the ring have not been drawn. (a) Cholesterol is an essential component of animal cellular membranes. (b) Cortisol is a steroid hormone secreted by the adrenal glands. Notice that cortisol differs from cholesterol in its attached functional groups.

MOLECULES THAT ABSORB LIGHT

Notice that all these molecules have a pattern of double bonds alternating with single bonds. The electrons that make up these bonds can move about relatively easily when light strikes the molecule. Such molecules tend to be highly colored pigments because they strongly absorb light of certain wavelengths and reflect other wavelengths.

steroid from another. Steroids are synthesized from isoprene units.

Among the steroids of biological importance are cholesterol, bile salts, reproductive hormones, and cortisol and other hormones secreted by the adrenal cortex. Cholesterol is a structural component of animal cell membranes; plant cell membranes contain molecules similar to cholesterol. Bile salts emulsify fats in the intestine so that they can be enzymatically hydrolyzed. Steroid hormones regulate certain aspects of metabolism in a variety of animals, including vertebrates, insects, and crabs.

Some chemical mediators are derived from fatty acids

Animal cells secrete chemicals that permit them to communicate with each other or to regulate their own activities. Some chemical mediators are produced by the modification of fatty acids that have been removed from membrane phospholipids. These include prostaglandins, which have varied roles, including promoting inflammation and smooth muscle contraction. Certain hormones, such as the juvenile hormone of insects, are also fatty acid derivatives (Chapter 47).

PROTEINS ARE MACROMOLECULES FORMED FROM AMINO ACIDS

Because **proteins** are extraordinarily versatile macromolecules, they are of central importance in the chemistry of life. Proteins can be assembled into a variety of shapes, allowing them to serve as major structural components of cells and tissues. For this reason, growth and repair, as well as maintenance of the organism, depend on an adequate supply of these compounds. Most **enzymes** (molecules that speed up the thousands of different chemical reactions that take place in an organism) are proteins. Proteins serve in a great many other specialized capacities, including cellular motors, hormones and other chemical messengers, regulators of cellular activities, and defenders against foreign invaders.

The protein constituents of a cell are the clues to its lifestyle. Each cell type contains characteristic forms, distributions, and amounts of protein that largely determine what the cell looks like and how it functions. A muscle cell contains large amounts of the proteins myosin and actin, which are responsible for its appearance as well as for its ability to contract. The protein hemoglobin, found in red blood cells, is responsible for the specialized function of oxygen transport.

Although carbohydrates and lipids tend to have the same structures among different species, most proteins are species-specific; that is, their structures vary from species to species. The specific proteins present (determined by the instructions in the genes) are largely responsible for differences among species. Thus, the proteins in the cells of a dog vary somewhat from those of a fox and even more from those of an oak tree. The degree of difference in the proteins of two species is

thought to depend on evolutionary relationships. Distantly related organisms have proteins that differ more markedly than those of closely related forms.

Some proteins differ slightly even among individuals of the same species. Although it is common for individuals to have many identical proteins, most individuals are biochemically unique in the sense that no two are likely to have *all* identical proteins unless they are also genetically identical (i.e., identical twins or members of closely inbred strains).

Amino acids are the subunits of proteins

Amino acids, the constituents of proteins, have an amino group ($-\text{NH}_2$) and a carboxyl group ($-\text{COOH}$) bonded to the same asymmetric carbon atom, known as the **alpha carbon**. There are about 20 amino acids commonly found in proteins, each uniquely identified by the variable group (R group) bonded to the alpha carbon (Fig. 3–14). Glycine, the simplest amino acid, has a hydrogen atom as its R group; alanine has a methyl ($-\text{CH}_3$) group.

Amino acids in solution at neutral pH are mainly dipolar ions. This is generally how amino acids exist at cellular pH. Each carboxyl group ($-\text{COOH}$) donates a proton and becomes dissociated ($-\text{COO}^-$), while each amino group ($-\text{NH}_2$) accepts a proton and becomes $-\text{NH}_3^+$ (Fig. 3–15). Because of their amino and carboxyl groups, amino acids in solution resist changes in acidity and alkalinity and so are important biological buffers.

The amino acids are grouped in Figure 3–14 by the properties of their side chains. These broad groupings actually include amino acids with a fairly wide range of properties. Amino acids classified as having *nonpolar* side chains tend to have hydrophobic properties, whereas those classified as *polar* are more hydrophilic. An acidic amino acid has a side chain that contains a carboxyl group. At cellular pH the carboxyl group is dissociated, giving the R group a negative charge. A basic amino acid becomes positively charged when the amino group in its side chain accepts a hydrogen ion. Acidic and basic side chains are ionic at cellular pH and therefore hydrophilic.

In addition to the 20 common amino acids, some proteins have unusual ones. These rare amino acids are produced by the modification of common ones after they have become part of a protein. For example, lysine and proline may be converted to hydroxylysine and hydroxyproline after they have been incorporated into collagen. These amino acids can form cross links between the peptide chains that make up collagen. Such cross links are responsible for the firmness and great strength of the collagen molecule, which is a major component of cartilage, bone, and other connective tissues.

With some exceptions, bacteria and plants can synthesize all their needed amino acids from simpler substances. If the proper raw materials are available, the cells of humans and animals can manufacture some, but not all, of the biologically significant amino acids. Those that animals cannot synthesize and so must obtain from the diet are known as **essential amino acids**. Animals differ in their biosynthetic capacities; what is

Figure 3–14 The twenty common amino acids. Amino acids designated *polar* have relatively hydrophilic side chains, while the side chains of those referred to as *nonpolar* are relatively hydrophobic. Carboxyl groups and amino groups are electrically charged at cellular pH; therefore acidic and basic amino acids are hydrophilic. The three-letter symbols are the conventional abbreviations for the amino acids.

Figure 3–15 An amino acid at pH 7. In living cells, amino acids exist mainly as dipolar ions.

an essential amino acid for one species may not be for another. The essential amino acids for humans include isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, valine, histidine, and (in children) arginine.

Peptide bonds join amino acids

Amino acids combine chemically with one another by a condensation reaction that bonds the carboxyl carbon of one molecule to the amino nitrogen of another (Fig. 3–16). The covalent carbon-to-nitrogen bond linking two amino acids together is called a **peptide bond**. When two amino acids combine, a **dipeptide** is formed; a longer chain of amino acids is a **polypeptide**. A protein consists of one or more polypeptide chains. Each polypeptide has a free amino group at one end and a free carboxyl group (belonging to the last amino acid added to the chain) at the opposite end. The other amino and carboxyl groups of the amino acid monomers (except those in side chains) are part of the peptide bonds. The complex process by which polypeptides are synthesized is discussed in Chapter 12.

A polypeptide may contain hundreds of amino acids joined in a specific linear order. The backbone of the chain includes the repeating sequence

plus all other atoms *except those in the R groups*. The R groups of the amino acids extend from this backbone.

An almost infinite variety of protein molecules is possible, differing from one another in the number, types, and sequences of amino acids they contain. The 20 types of amino acids found in proteins may be thought of as letters of a protein alphabet; each protein is a very long sentence made up of amino acid letters.

Proteins have four levels of organization

The polypeptide chains making up a protein are twisted or folded to form a macromolecule with a specific *conformation*, or three-dimensional shape. Some polypeptide chains form long fibers. **Globular** proteins are tightly folded into compact, roughly spherical shapes. There is a close relationship between a protein's conformation and its function. For example, a typical enzyme is a globular protein with a unique shape that permits it to catalyze a specific chemical reaction. Similarly, the shape of a protein hormone enables it to combine with receptors on its target cell (the cell the hormone acts upon).

Four main levels of protein organization can be recognized: primary, secondary, tertiary, and quaternary. An analogy for secondary and tertiary structure is depicted in Figure 3–17.

Figure 3–16 Peptide bonds. (a) A dipeptide is formed by the removal of the equivalent of a water molecule from the carboxyl group of one amino acid and the amino group of another amino acid. The resulting peptide bond is a covalent, carbon-to-nitrogen bond. (b) The carboxyl group of the dipeptide reacts with the amino group of a third amino acid to form a chain of three amino acids (a tripeptide, or small polypeptide). Additional amino acids can be added to form a long polypeptide chain with a free amino group at one end and a free carboxyl group at the other.

Figure 3-17 Levels of protein structure. A telephone cord provides a familiar analogy for the levels of protein structure. (a) Secondary structure, in this case analogous to an α -helix. (b) Tertiary structure, in which interactions among side chains cause the molecule to fold back on itself.

Primary structure is the amino acid sequence

The sequence of amino acids, joined by peptide bonds, is the **primary structure** of a polypeptide chain. As discussed in Chapter 12, this sequence is specified by the instructions in a gene. Using analytical methods developed in the early 1950s, investigators can determine the exact sequence of amino acids in a protein molecule. Insulin, a hormone secreted by the pancreas and used in the treatment of diabetes, was the first protein for which the exact sequence of amino acids in the polypeptide chains was identified. Insulin is a very small protein, consisting of 51 amino acid units in two linked chains, each with its own primary structure (Fig. 3-18).

Primary structure is always represented in a simple, linear, “beads-on-a-string” form. However, the overall conformation of a protein is far more complex, involving interactions among the various amino acids that comprise the primary structure of the molecule. Therefore, the higher orders of structure—secondary, tertiary, and quaternary—ultimately derive from the specific amino acid sequence (i.e., the primary structure).

Secondary structure results from hydrogen bonding involving the backbone

Some regions of a polypeptide exhibit **secondary structure**, which is highly regular because it is maintained by hydrogen

bonds between certain atoms of the polypeptide chain’s uniform backbone.

A common secondary structure in protein molecules is the **α -helix**, a region where a polypeptide chain forms a uniform spiral coil (Fig. 3-19a). The helical structure is determined and maintained by the formation of hydrogen bonds between the backbones of the amino acids in successive turns of the spiral coil. Each hydrogen bond forms between an oxygen with a partial negative charge and a hydrogen with a partial positive charge. The oxygen is part of the remnant of the carboxyl group of one amino acid; the hydrogen is part of the remnant of the amino group of the fourth amino acid down the chain. Thus 3.6 amino acids are included in each complete turn of the helix. Every amino acid in an α -helix is hydrogen-bonded in this way.

The α -helix is the basic structural unit of some fibrous proteins that make up wool, hair, skin, and nails. The elasticity of these fibers is due to a combination of physical factors (the helical shape) and chemical factors (hydrogen bonding). Although hydrogen bonds maintain the helical structure, these bonds can be broken, allowing the fibers to stretch under tension (like a telephone cord). When the tension is released, the fibers recoil and hydrogen bonds reform. This is why human hairs can stretch to some extent and then snap back to their original length.

Another type of secondary structure is the **β -pleated sheet**² (Fig. 3-19b). The hydrogen bonding in a β -pleated sheet takes place between different polypeptide chains, or different regions of a polypeptide chain that has turned back on itself. Each chain is fully extended, but because each has a zigzag structure, the resulting “sheet” has an overall pleated conformation (much like a sheet of paper that has been folded to make a fan). Although the pleated sheet is strong and flexible, it is not elastic. This is because the distance between the pleats is fixed, determined by the strong covalent bonds of the polypeptide backbones. Fibroin, the protein of silk, is characterized by a β -pleated sheet structure, as are the cores of many globular proteins.

It is not uncommon for a single polypeptide chain to include both α -helical regions and regions with β -pleated sheet

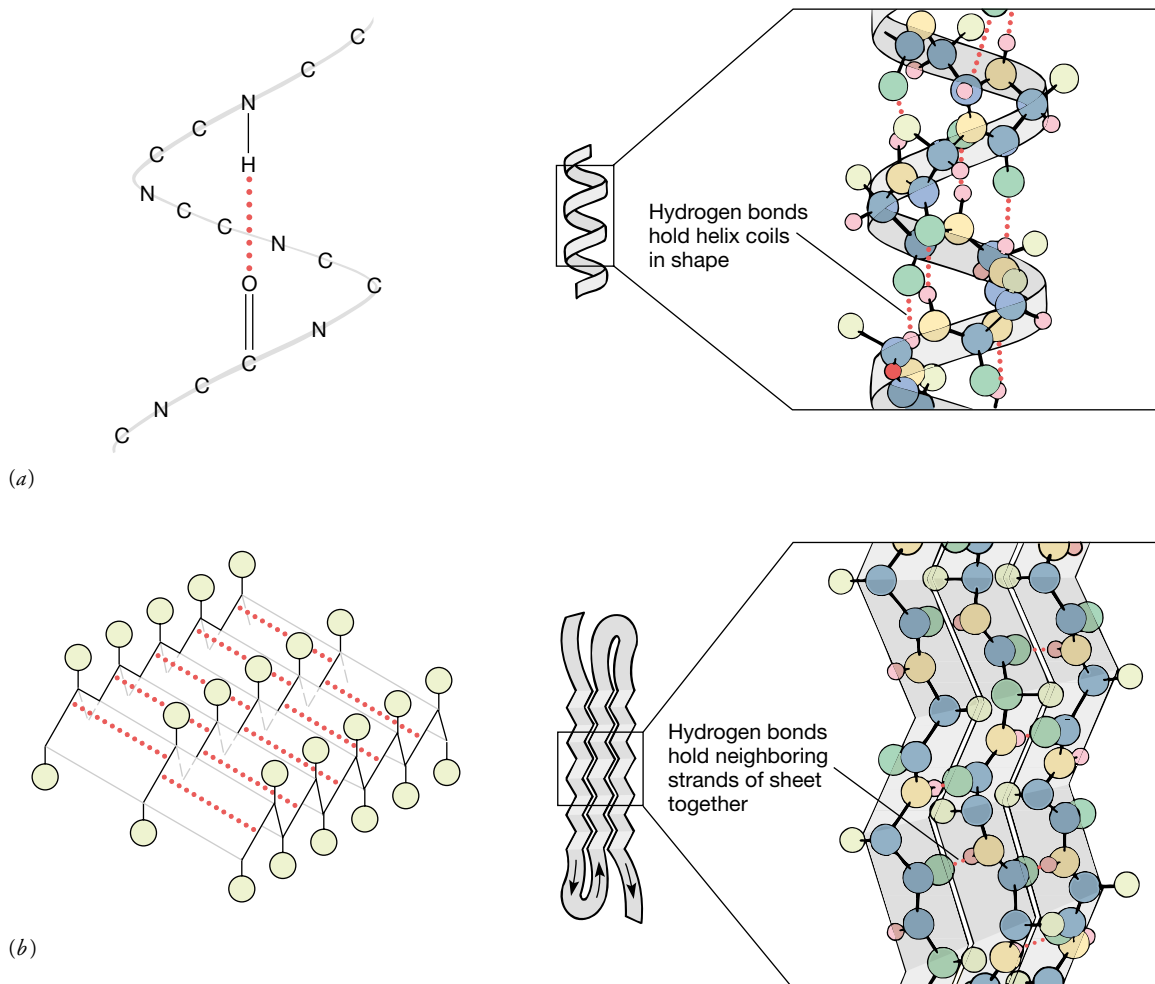

Figure 3-18 Primary structure of a polypeptide. Insulin is a very small protein made up of two polypeptides, each with its own primary structure. The linear sequence of amino acids is indicated by ovals containing their abbreviated names (see Fig. 3-14).

²Note that the designations α and β refer simply to the order in which these two types of secondary structures were discovered.

KEY: ● Carbon atom ● Oxygen atom ● Nitrogen atom ● Hydrogen atom ● R group

(c)

conformations. In addition, the properties of some complex biological materials result from such combinations. A spider's web is composed of a material that is extremely strong, flexible, and elastic. Once again we see function and structure

Figure 3–19 Secondary structure of a protein. (a) Note that the R groups project out from the sides of the α -helix. (The R groups have been omitted in the simplified diagram at left.) (b) In a β -pleated sheet, half the R groups project above the sheet and the other half project below it. (c) The strength and elasticity of a spider's web result from combining proteins with β -pleated sheet conformations and those with α -helical regions. (c, Skip Moody/Dembinsky Photo Associates)

working together, as these properties derive from the fact that it is a composite of proteins with α -helical conformations (providing elasticity) and others with β -pleated sheet conformations (providing strength) (Fig. 3–19c).

Tertiary structure depends on interactions among side chains

The **tertiary structure** of a protein molecule is the overall shape assumed by each individual polypeptide chain (Fig. 3–20). This three-dimensional structure is determined by four main factors that involve *interactions among R groups (side chains) belonging to the same polypeptide chain*.

(a)

(b)

Figure 3–20 Tertiary structure of a protein. (a) Hydrogen bonds, hydrophobic interactions, and ionic attractions between R groups hold the parts of the molecule in the designated shape. Disulfide bonds are covalent bonds between the sulfur atoms of two cysteines. (b) Schematic drawing of the tertiary structure of a polypeptide. α -helical regions are represented as blue tubes lettered A through F; β -pleated sheets are the gray arrows numbered 1 through 12. Green lines represent connecting regions. Although the molecule seems very complicated, it is a single polypeptide chain, starting at the amino end (bottom left) and terminating at the carboxyl end. Most of the bends and foldbacks that give the molecule its overall conformation (tertiary structure) are stabilized by R-group interactions. This polypeptide is a subunit of a DNA-binding protein (CAP) from the bacterium *Escherichia coli*.

1. Hydrogen bonds form between R groups of certain amino acid subunits.
2. Ionic attraction can occur between an R group with a unit of positive charge and one with a unit of negative charge.
3. Hydrophobic interactions result from the tendency of non-polar R groups to be excluded by the surrounding water and therefore to associate in the interior of the globular structure.
4. Covalent bonds known as disulfide bonds or disulfide bridges (—S—S—) may link the sulfur atoms of two cysteine subunits belonging to the same chain. A disulfide bridge forms when the sulfhydryl groups of two cysteines react; the two hydrogens are removed and the two sulfur atoms that remain become covalently linked.

Quaternary structure results from interactions among polypeptides

Many functional proteins are composed of two or more polypeptide chains, interacting in specific ways to form the biologically active molecule. **Quaternary structure** is the resulting three-dimensional architecture of these polypeptide chains

(each with its own primary, secondary, and tertiary structure). The same types of interactions that produce secondary and tertiary structure can also contribute to quaternary structure; these include hydrogen bonding, ionic bonding, hydrophobic interactions, and disulfide bridges.

For example, Figure 3–18 illustrates not only primary structure, but also an aspect of quaternary structure; i.e., the two disulfide bridges joining the separate polypeptide chains that make up a functional insulin molecule. (Note that the disulfide bridges of insulin would contribute to tertiary structure if they were between cysteines belonging to the *same* polypeptide chain.) A functional antibody molecule consists of four polypeptide chains joined by disulfide bridges (Chapter 43). Disulfide bridges are a common feature of proteins, such as antibodies and insulin, that are secreted from cells; these strong bonds stabilize the molecules in the extracellular environment.

Hemoglobin, the protein in red blood cells that is responsible for oxygen transport, is an example of a globular protein with quaternary structure (Fig. 3–21). Hemoglobin consists of 574 amino acids arranged in four polypeptide chains: two identical chains called alpha chains and two identical chains called beta chains.

Figure 3–21 Quaternary structure of hemoglobin. Hemoglobin has quaternary structure because it consists of more than one polypeptide. Each polypeptide is joined to an iron-containing molecule, a heme.

The amino acid sequence of a protein determines its conformation

Under defined experimental conditions *in vitro* (that is, outside a living cell) a polypeptide can be demonstrated to spontaneously undergo folding processes that allow it to attain its normal, functional conformation. For example, researchers at the University of Illinois at Urbana-Champaign recently conducted an experiment in which they completely unfolded myoglobin, a polypeptide that stores oxygen in muscle cells, and then used sophisticated technology to track the refolding process. They found that within a few fractions of a microsecond the molecule had coiled up to form α -helices, and formation of the tertiary structure was completed within four microseconds.

This and other types of evidence support the widely held conclusion that amino acid sequence is the ultimate determinant of protein conformation. However, because conditions *in vivo* (in the cell) are quite different from defined laboratory conditions, proteins do not necessarily always fold spontaneously. On the contrary, in recent years it has been learned that proteins known as **molecular chaperones** mediate the folding of certain proteins. Chaperones are thought to make the folding process more orderly and efficient, and to prevent partially folded proteins from becoming inappropriately aggregated. However, there is no evidence that chaperones actually dictate the folding pattern. For this reason, the existence of chaperones is not an argument against the idea that amino acid sequence determines conformation.

Protein conformation is studied through a variety of methods

The conformation of a protein is ascertained directly through sophisticated types of analysis, such as the x-ray diffraction studies discussed in Chapter 11. Because these studies are tedious and costly, efforts have been made to develop alternative approaches. Today protein amino acid sequences can be determined rapidly through the application of genetic engineering techniques (Chapter 14). A variety of efforts are being made to effectively use these data to predict a protein's architecture. As we have seen, side chains can interact in relatively predictable ways, through ionic bonds, hydrogen bonds, etc. In addition, regions with certain types of side chains appear more likely to form α -helices or β -pleated sheets. Very complex computer programs are used to make such predictions, but these are imprecise because of the many possible combinations of folding patterns.

Computers are an essential part of yet another strategy. Once the amino acid sequence of a polypeptide has been determined, researchers use computers to search large databases, many accessible through the Internet, to find polypeptides with similar sequences. If the conformations of any of those polypeptides or portions of them are already known, this information can be extrapolated to make similar correlations between amino acid sequence and three-dimensional structure for the protein under investigation. These predictions are becoming increasingly reliable as more information is added to the databases on a daily basis.

Protein conformation determines function

The overall structure of a protein helps determine its biological activity. A single protein may have more than one distinct structural region, each with its own function. Many proteins are modular, consisting of two or more globular regions, called *domains*, connected by less compact regions of the polypeptide chain. Each domain may have a different function. For example, a protein might have one domain that attaches it to a membrane and another that allows it to act as an enzyme.

The biological activity of a protein can be disrupted by a change in amino acid sequence that results in a change in conformation. For example, the genetic disease known as *sickle cell anemia* (see Chapter 15) is due to a mutation that causes the substitution of the amino acid valine for glutamic acid at position 6 (the sixth amino acid from the amino end) in the beta chain of hemoglobin. The substitution of valine (which has a nonpolar side chain) for glutamic acid (which has a charged side chain) makes the hemoglobin less soluble and more likely to form crystal-like structures. This alteration of the hemoglobin affects the red blood cells, changing them to the crescent or sickle shapes that characterize this disease.

Changes in the three-dimensional structure of a protein also disrupt its biological activity. When a protein is heated, subjected to significant pH changes, or treated with any of a number of chemicals, its structure can become disordered and

the coiled peptide chains can unfold to give a more random conformation. This unfolding, which is mainly due to the disruption of hydrogen bonds and ionic bonds, is typically accompanied by a loss of normal function. Such changes in shape and the accompanying loss of biological activity are termed **denaturation** of the protein. For example, a denatured enzyme would lose its ability to catalyze a chemical reaction. An everyday example of denaturation occurs when we fry an egg. The consistency of the egg white protein, known as albumin, changes to a solid. Denaturation generally cannot be reversed (you can't "unfry" an egg). However, under certain conditions, some proteins have been denatured and have returned to their original shape and biological activity when normal environmental conditions have been restored.

DNA AND RNA ARE NUCLEIC ACIDS

Nucleic acids transmit hereditary information and determine what proteins a cell manufactures. There are two classes of nucleic acids found in cells: **ribonucleic acids (RNA)** and **deoxyribonucleic acids (DNA)**. DNA comprises the genes, the hereditary material of the cell, and contains instructions for making all the proteins, as well as all the RNA, needed by the organism. RNA is required as a direct participant in the complex process in which amino acids are linked to form polypeptides. Like proteins, nucleic acids are large, complex molecules. The name *nucleic acid* reflects the fact that they are acidic and were first identified, by Friederich Miescher in 1870, in the nuclei of pus cells.

Nucleic acids consist of nucleotide subunits

Nucleic acids are polymers of **nucleotides**, molecular units that consist of (1) a five-carbon sugar, either ribose or deoxyribose, (2) one or more phosphate groups, which make the molecule acidic, and (3) a nitrogenous base, a ring compound that contains nitrogen. The nitrogenous base may be either a double-ringed purine or a single-ringed pyrimidine (Fig. 3–22).

DNA commonly contains the purines adenine (A) and guanine (G), the pyrimidines cytosine (C) and thymine (T), the sugar deoxyribose, and phosphate. RNA contains the purines adenine and guanine, and the pyrimidines cytosine and uracil (U), together with the sugar ribose, and phosphate.

The molecules of nucleic acids are made of linear chains of nucleotides, which are joined by **phosphodiester linkages**, each consisting of a phosphate group and the covalent bonds that attach it to the sugars of adjacent nucleotides (Fig. 3–23). Note that each nucleotide is defined by its particular base and that nucleotides can be joined in any sequence. A nucleic acid molecule is uniquely defined by its specific sequence of nucleotides, which constitutes a kind of code (see Chapter 12). While RNA is usually composed of one nucleotide chain, DNA consists of two nucleotide chains held together by hydrogen bonds and entwined around each other in a double helix (see Fig. 1–7).

Figure 3–22 Nucleotides. (a) The three major pyrimidine bases found in nucleotides are cytosine, thymine (in DNA only), and uracil (in RNA only). (b) The two major purine bases found in nucleotides are adenine and guanine. The hydrogens indicated by the boxes are removed when the base is attached to a sugar. (c) A nucleotide, adenosine monophosphate (AMP).

Some nucleotides are important in energy transfers and other cellular functions

In addition to their importance as subunits of DNA and RNA, nucleotides serve other vital functions in living cells. **Adenosine triphosphate (ATP)**, composed of adenine, ribose, and three phosphates (Fig. 3–24), is of major importance as the primary energy currency of all cells (see Chapter 6). The two terminal phosphate groups are joined to the nucleotide by un-

Figure 3–23 RNA. Nucleotides, each with a specific base, are joined by phosphodiester linkages. P, phosphate; S, the sugar ribose; G, guanine; C, cytosine; A, adenine; U, uracil.

Figure 3–24 ATP, a nucleotide. The two terminal phosphate groups are joined by unstable bonds (indicated by wavy lines). These bonds permit the phosphates to be transferred to other molecules, making them more reactive.

Figure 3–25 Cyclic AMP. The single phosphate is part of a ring connecting two regions of the ribose.

Figure 3–26 NAD^+ , an important hydrogen (electron) acceptor. The nicotinamide portion of the molecule accepts hydrogen and becomes reduced in the process. The resulting reduced molecule, known as NADH, is an electron donor.

stable covalent bonds, traditionally indicated by wavy lines. ATP can transfer a phosphate group to another molecule, making that molecule more reactive. In this way ATP is able to donate some of its chemical energy. Most of the readily available chemical energy of the cell is associated with the phosphate groups of ATP.

A nucleotide may be converted to an alternative form with specific cellular functions. ATP, for example, is converted to cyclic AMP (c-AMP or cyclic adenosine monophosphate) by the enzyme adenyl cyclase (Fig. 3–25). Cyclic AMP regulates certain cellular functions and is important in the mechanism by which some hormones act (see Chapters 13, 39, and 47).

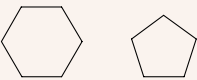

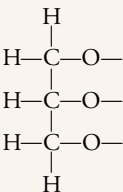

Cells contain several dinucleotides, which are of great importance in metabolic processes. For example, as discussed in Chapter 6, **nicotinamide adenine dinucleotide** (Fig. 3–26)

has a primary role in biological oxidations and reductions within cells. It can exist in an oxidized form (**NAD⁺**) that is converted to a reduced form (**NADH**) when it accepts electrons (in association with hydrogen). These electrons, along with their energy, can be transferred to other molecules.

BIOLOGICAL MOLECULES CAN BE RECOGNIZED BY THEIR KEY FEATURES

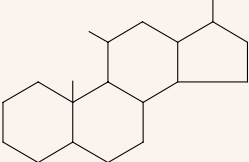

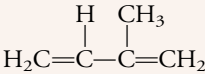

Although the fundamental classes of biological molecules may seem to form a bewildering array, one can learn to distinguish them readily by understanding their chief attributes. These are summarized in Table 3–2.

TABLE 3–2 Some of the Groups of Biologically Important Organic Compounds

Class of compounds	Component elements	Description	How to recognize	Principal function in living systems
Carbohydrates	C, H, O	Contain approximately 1 C:2 H:1 O (but make allowance for loss of oxygen and hydrogen when sugar units are linked)	Count the carbons, hydrogens, and oxygens.	Cellular fuel; energy storage; structural component of plant cell walls; component of other compounds such as nucleic acids and glycoproteins
		1. Monosaccharides (simple sugars) Mainly five-carbon (pentose) molecules such as ribose or six-carbon (hexose) molecules such as glucose and fructose	Look for the ring shapes: 	Cellular fuel; components of other compounds
		2. Disaccharides. Two sugar units linked by a glycosidic bond, e.g., maltose, sucrose	Count sugar units	Components of other compounds; form of sugar transported in plants
		3. Polysaccharides. Many sugar units linked by glycosidic bonds, e.g., glycogen, cellulose	Count sugar units	Energy storage; structural components of plant cell walls
Lipids	C, H, O	Contain much less oxygen relative to carbon and hydrogen than do carbohydrates		Energy storage; cellular fuel, structural components of cells; thermal insulation
		1. Neutral fats. Combination of glycerol with one to three fatty acids. Monoacylglycerol contains one fatty acid; diacylglycerol contains two fatty acids; triacylglycerol contains three fatty acids. If fatty acids contain double carbon-to-carbon linkages (C=C), they are unsaturated; otherwise they are saturated	Look for glycerol at one end of molecule: 	Cellular fuel; energy storage

continued

TABLE 3-2 continued

Class of compounds	Component elements	Description	How to recognize	Principal function in living systems
		<p>2. Phospholipids. Composed of glycerol attached to one or two fatty acids and to an organic base containing phosphorus</p> <p>3. Steroids. Complex molecules containing carbon atoms arranged in four attached rings. (Three rings contain six carbon atoms each, and the fourth ring contains five.)</p> <p>4. Carotenoids. Orange and yellow pigments; consist of isoprene units</p>	<p>Look for glycerol and side chain containing phosphorus and nitrogen.</p> <p>Look for four attached rings:</p>  <p>Look for isoprene units.</p> 	<p>Components of cell membranes</p> <p>Some are hormones, others include cholesterol, bile salts, vitamin D, components of cell membranes</p> <p>Retinal (important in photoreception) and vitamin A are formed from carotenoids.</p>
Proteins	C, H, O, N, usually S	One or more polypeptides (chains of amino acids) coiled or folded in characteristic shapes	Look for amino acid units joined by C—N bonds.	Serve as enzymes; structural components; muscle proteins; hemoglobin
Nucleic acids	C, H, O, N, P	Backbone composed of alternating pentose and phosphate groups, from which nitrogenous bases project. DNA contains the sugar deoxyribose and the bases guanine, cytosine, adenine, and thymine. RNA contains the sugar ribose and the bases guanine, cytosine, adenine, and uracil. Each molecular subunit, called a <i>nucleotide</i> , consists of a pentose, a phosphate, and a nitrogenous base.	Look for a pentose-phosphate backbone. DNA forms a double helix.	Storage, transmission, and expression of genetic information

SUMMARY WITH KEY TERMS

- I. The major groups of biologically important organic compounds are carbohydrates, lipids, proteins, and nucleic acids.
- II. The properties of carbon atoms make them extraordinarily versatile, able to form the backbones of the large variety of organic compounds essential to life.
 - A. Each carbon atom can form four covalent bonds with four other atoms; these can be single, double, or triple bonds.
 - B. Carbon forms covalent bonds with a greater number of different elements than does any other type of atom. Carbon atoms can form straight or branched chains or can join into rings.
- III. **Isomers** are compounds with the same molecular formula but different structures.
 - A. **Structural isomers** differ in the covalent arrangements of their atoms.
 - B. **Geometric isomers**, or *cis-trans* isomers, differ in the spatial arrangements of their atoms.
 - C. **Enantiomers** are isomers that are mirror images of each other. Cells can distinguish between these configurations.
- IV. Organic compounds are made up of specific functional groups with characteristic properties.
 - A. **Hydrocarbons** are nonpolar and hydrophobic.
 - B. Polar and ionic functional groups interact with each other and dissolve in water.
 - C. Partial charges on atoms at opposite ends of a bond are responsible for the polar property of a functional group. **Hydroxyl** and **carbonyl** groups are polar.
 - D. **Carboxyl** and **phosphate** groups are acidic, becoming negatively charged when they release hydrogen ions. The **amino** group is basic, becoming positively charged when it accepts a hydrogen ion.
- V. Long chains of similar organic compounds linked together are called **polymers**. Large polymers such as polysaccharides, proteins, and DNA are referred to as **macromolecules**.
- VI. **Carbohydrates** contain carbon, hydrogen, and oxygen in a ratio of approximately one carbon to two hydrogens to one oxygen.
 - A. **Monosaccharides** are simple sugars such as glucose, fructose, and ribose.

- B. Two monosaccharides can be joined by a glycosidic linkage, forming a **disaccharide** such as maltose or sucrose.
- C. Most carbohydrates are **polysaccharides**, long chains of repeating units of a simple sugar.
- Carbohydrates are typically stored in plants as **starch** and in animals as **glycogen**.
 - The cell walls of plants are composed mainly of the polysaccharide **cellulose**.
- VII. **Lipid** molecules are composed mainly of hydrocarbon-containing regions, with few oxygen-containing (polar or ionic) functional groups. Lipids have a greasy or oily consistency and are relatively insoluble in water.
- A. **Neutral fats** are used for fuel storage. A fat consists of a molecule of **glycerol** combined with one to three **fatty acids**.
- Monoacylglycerols**, **diacylglycerols**, and **triacylglycerols** are neutral fats containing one, two, and three fatty acids, respectively.
 - A fatty acid can be either **saturated** with hydrogen, or **unsaturated**.
- B. **Phospholipids** are structural components of cellular membranes.
- C. **Steroid** molecules contain carbon atoms arranged in four attached rings. Cholesterol, bile salts, and certain hormones are important steroids.
- VIII. **Proteins** are large, complex molecules made of simpler subunits, called **amino acids**, joined by **peptide bonds**.
- A. Proteins are the most versatile class of biological molecules, serving as **enzymes**, structural components, cellular regulators, etc.
- B. Proteins are composed of various linear sequences of 20 different amino acids. Two amino acids combine to form a **dipeptide**. A longer chain of amino acids is a **polypeptide**.
- All amino acids contain an amino group and a carboxyl group, but vary in their side chains. The side chains of amino acids dictate their chemical properties.
 - Amino acids generally exist as dipolar ions at cellular pH and serve as important biological buffers.
- C. Four levels of organization can be distinguished in protein molecules.
- Primary structure** is the linear sequence of amino acids in the polypeptide chain.
 - Secondary structure** is a regular conformation, such as an α -**helix** or a β -**pleated sheet**, due to hydrogen bonding between elements of the uniform backbone of the polypeptide.
 - Tertiary structure** is the overall shape of the polypeptide chains, as dictated by chemical properties and interactions of the side chains of specific amino acids. Hydrogen bonding, ionic bonds, hydrophobic interactions, and disulfide bridges contribute to tertiary structure.
 - Quaternary structure** is determined by the association of two or more polypeptide chains.
- IX. The **nucleic acids** DNA and RNA store and transfer information that governs the sequence of amino acids in proteins and ultimately the structure and function of the organism.
- A. Nucleic acids are composed of long chains of **nucleotide** subunits, each composed of a purine or pyrimidine nitrogenous base, a five-carbon sugar (ribose or deoxyribose), and a phosphate group.
- B. **ATP** (adenosine triphosphate) is a nucleotide of special significance in energy metabolism. NAD^+ is also involved in energy metabolism through its role as an electron (hydrogen) acceptor in biological oxidations.

POST - TEST

- Which of the following would be considered to be an inorganic form of carbon? (a) H_2CO_3 (b) C_2H_4 (c) CH_3COOH (d) b and c (e) all of the above are inorganic
- Carbon is particularly well suited to be the backbone of organic molecules because (a) it can form both covalent bonds and ionic bonds (b) its covalent bonds are very irregularly arranged in three-dimensional space (c) its covalent bonds are the strongest chemical bonds known (d) it can bond to a large number of other types of atoms (e) all of the bonds it forms are polar
- The structures depicted below are

- (a) enantiomers (b) different views of the same molecule (c) geometric (*cis-trans*) isomers (d) both geometric isomers and enantiomers (e) structural isomers
- Which of the following are generally hydrophobic? (a) polar molecules and hydrocarbons (b) ions and hydrocarbons (c) nonpolar molecules and ions (d) polar molecules and ions (e) none of the above
 - Which of the following is a nonpolar molecule? (a) water (H_2O) (b) ammonia (NH_3) (c) methane (CH_4) (d) ethane (C_2H_6) (e) more than one of the above
 - Which of the following functional groups normally acts as an acid? (a) hydroxyl (b) carbonyl (c) sulfhydryl (d) phosphate (e) amino
 - A monosaccharide designated as an aldehyde sugar contains (a) a terminal carboxyl group (b) an internal carboxyl group (c) a terminal carbonyl

- group (d) an internal carbonyl group (e) a terminal carboxyl group and an internal carbonyl group
- Structural polysaccharides typically (a) have extensive hydrogen bonding between adjacent molecules (b) are much more hydrophilic than storage polysaccharides (c) have much stronger covalent bonds than do storage polysaccharides (d) consist of alternating α -glucose and β -glucose subunits (e) form helical structures in the cell
 - Fatty acids are components of (a) phospholipids and carotenoids (b) carotenoids and triacylglycerol (c) steroids and triacylglycerol (d) phospholipids and triacylglycerol (e) carotenoids and steroids
 - Saturated fatty acids are so named because they are saturated with (a) hydrogen (b) water (c) hydroxyl groups (d) glycerol (e) double bonds
 - Which pair of amino acid side groups would be most likely to associate with each other by an ionic bond?
 - $-\text{CH}_3$
 - $-\text{CH}_2-\text{COO}^-$
 - $-\text{CH}_2-\text{CH}_2-\text{NH}_3^+$
 - $-\text{CH}_2-\text{CH}_2-\text{COO}^-$
 - $-\text{CH}_2-\text{OH}$
 - (a) 1 and 2 (b) 2 and 4 (c) 1 and 5 (d) 2 and 5 (e) 3 and 4
 - Which of the following levels of protein structure may be affected by hydrogen bonding? (a) primary and secondary (b) primary and tertiary (c) secondary, tertiary, and quaternary (d) primary, secondary, and tertiary (e) primary, secondary, tertiary, and quaternary
 - Each phosphodiester linkage in DNA or RNA includes a phosphate joined by covalent bonds to (a) two bases (b) two sugars (c) two additional phosphates (d) a sugar, a base, and a phosphate (e) a sugar and a base

REVIEW QUESTIONS

1. Marble is composed of the carbon-containing compound calcium carbonate (CaCO_3). Should calcium carbonate be considered an organic molecule? Why or why not?
2. What are some of the ways that the features of carbon-to-carbon bonds influence the stability and three-dimensional structure of organic molecules?
3. Draw pairs of simple sketches comparing two (a) structural isomers, (b) geometric isomers, and (c) enantiomers.
4. Sketch the following functional groups: methyl, amino, carbonyl, hydroxyl, carboxyl, and phosphate. Classify each as either nonpolar, polar, acidic, or basic.
5. What features related to hydrogen bonding give storage polysaccharides, such as starch and glycogen, very different properties from structural polysaccharides, such as cellulose and chitin?
6. Draw a structural formula of a simple amino acid and identify the carboxyl group, amino group, and R group.
7. How does the primary structure of a polypeptide influence its secondary and tertiary structures? How can the conformation of a protein be disrupted?
8. Compare the functions of proteins and nucleic acids.

YOU MAKE THE CONNECTION

1. Like oxygen, sulfur forms two covalent bonds. However, it is far less electronegative. In fact, it is approximately as electronegative as carbon. How would the properties of the various classes of biological molecules be altered if you were to replace all the oxygen atoms with sulfur atoms?
2. How would you reconcile the following statements? (1) All organisms share a common ancestry. (2) Individual organisms are generally biochemically unique.

CHAPTER 4

Organization of the Cell

Cells are a dramatic example of the underlying unity of all living things. When we examine a wide range of seemingly very diverse organisms, ranging from simple bacteria to the most complex plants and animals, we find striking similarities at the cell level. This is a reflection of their evolution from a common ancestor, as well as the fact that living things have many common needs. Careful studies of shared cell features help us trace the evolutionary history of various groups of organisms and furnish powerful evidence that all organisms alive today had a common origin.

Each cell is a virtual microcosm of life for it is the smallest unit that can carry out all life activities. When provided with essential nutrients and an appropriate environment, some cells can be kept alive and growing in the laboratory for many years. By contrast, no isolated cell part is capable of sustained survival. Composed of a vast array of inorganic and organic ions and molecules including water, salts, carbohydrates, lipids, proteins, and nucleic acids, most cells have all the physical and chemical components needed for their own maintenance, growth, and division. Genetic information is stored in DNA molecules and is faithfully replicated and passed on to each new generation of cells during cell division. Information in DNA codes for specific proteins that in turn determine cell structure and function. In this chapter and those that follow we will discuss how cells use many of the chemical materials introduced in Chapters 2 and 3.

Cells exchange materials and energy with the environment. All living cells need one or more sources of energy, but a cell rarely obtains energy in a form that is immediately usable. Cells convert energy from one form to another, and that energy is used to carry out various activities, ranging from mechanical work to chemical synthesis. Cells convert energy to a convenient form, usually chemical energy stored in ATP (adenosine triphosphate; see Chapter 3). Although the specifics vary, the basic strategies cells use for energy conversion are very similar. The chemical reactions that convert energy from one form to another are essentially the same in all cells, from bacteria to those of complex plants and animals.

Cells are the building blocks of complex multicellular organisms. Although cells are basically similar, they are also ex-

(Courtesy of Dr. John M. Murray, Department of Cell and Developmental Biology, University of Pennsylvania)

traordinarily versatile. They can be modified in a variety of ways to carry out specialized functions.

Biologists have long labored to understand the mechanisms of cell structure and function. The cells shown here were stained with fluorescent antibodies (specific proteins) that bound to proteins associated with DNA (*orange*) and to a protein (tubulin) in one of the cells' skeletal elements, microtubules (*green*). This type of microscopy, known as *confocal fluorescence microscopy*, shows the extensive distribution of microtubules in these cells. The cell skeleton (cytoskeleton) functions in maintaining cell shape, in cell movement, and in transport of materials within the cell. Investigation of the cytoskeleton is currently a very active and exciting area of research.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Explain why the cell is considered the basic unit of life and discuss some of the implications of the cell theory.
 2. Compare and contrast the general characteristics of prokaryotic and eukaryotic cells.
 3. Compare size relationships among different cells and cell structures.
 4. Explain why the relationship between surface area and volume of a cell is important in determining cell size limits.
 5. Describe the structure of the nucleus and relate this information to its function in eukaryotic cells.
 6. Distinguish between smooth and rough endoplasmic reticulum in terms of both structure and function and discuss the relationship between the endoplasmic reticulum and other internal membranes in the cell.
 7. Trace the path of certain proteins synthesized in the rough endoplasmic reticulum as they are subsequently processed, modified, and sorted by the Golgi complex.
 8. Describe the functions of lysosomes. Explain what can happen when they fail to carry out their functions or when they leak.
 9. Compare the functions of chloroplasts and mitochondria and discuss ATP synthesis by each of these organelles.
 10. Explain the importance of the cytoskeleton to the cell and describe the structures of the major types of fibers that make up the cytoskeleton.
 11. Relate the structural features of cilia and flagella to the way in which these organelles are able to move.
-

THE CELL IS THE BASIC UNIT OF LIFE

Two German scientists, botanist Matthias Schleiden in 1838 and zoologist Theodor Schwann in 1839, were the first to point out that all plants and animals are composed of cells. Later, Rudolph Virchow, a physician, observed cells dividing and giving rise to daughter cells. In 1855, Virchow proposed that new cells are formed only by the division of previously existing cells. In other words, cells do not arise by spontaneous generation from nonliving matter, a belief that had prevailed for centuries.

The work of Schleiden, Schwann, and Virchow gave rise to the **cell theory**, the unifying concept that cells are the basic living units of organization and function in all organisms and that all cells come from other cells. About 1880 another biologist, August Weismann, added an important corollary to Virchow's concept by pointing out that the ancestry of all the cells alive today can be traced back to ancient times. Evidence that all presently living cells have a common origin is provided by the basic similarities in their structures and in the molecules of which they are made.

CELL ORGANIZATION AND SIZE PERMIT HOMEOSTASIS

Recall from Chapter 1 that **homeostasis** is the process of maintaining an internal environment that is appropriate and supportive to life. Cells experience constant changes in their environments such as deviations in salt concentration, pH, and temperature. In order for its biochemical mechanisms to function, the cell must work continuously to restore appropriate conditions.

Organization is basically similar in all cells

Every cell must be able to keep its contents together and also keep them separated from the external environment. For this reason all cells, from bacteria to human cells, are enclosed by a structurally distinctive surface membrane commonly known as the **plasma membrane**. Cells must also be able to accumulate materials and energy stores and to exchange materials with the environment, usually in a highly regulated fashion. Therefore the plasma membrane must serve as an extremely selective barrier, making the interior of the cell an enclosed compartment with a chemical composition quite different from that outside.

Typically, cells have internal structures, called **organelles**, specialized to carry on life activities such as converting energy to usable forms, synthesizing needed compounds, and manufacturing structures essential to function and reproduction. Each cell has genetic instructions in the form of DNA, which is concentrated in a limited region of the cell.

Cell size is limited

Although their sizes vary over a wide range (Fig. 4–1), most cells are microscopic, and very small units are required to measure them and their internal structures. The basic unit of linear measurement in the metric system (see inside back cover) is the meter (m), which is just a little longer than a yard. A millimeter (mm) is 1/1000 of a meter and is about as long as the bar enclosed in parentheses (-). The micrometer (μm) is the most convenient unit for measuring cells. A bar $1\mu\text{m}$ long is far too short to be seen with the unaided eye, for it is 1/1,000,000 (one-millionth) of a meter, or 1/1000 of a millimeter, long. Most of us have difficulty thinking about units

Figure 4-1 Biological size and cell diversity. Relative size from chemical to organismic levels is most conveniently compared using a logarithmic scale (multiples of ten). The prokaryotic cells of bacteria typically range in size from less than 1 to 10 μm long; their small size enables them to grow and divide rapidly. Eukaryotic cells (cells of all other organisms) are typically 10 to 100 μm in diameter; the majority are between 10 and 30 μm . The nuclei of animal and plant cells range from about 3 to 10 μm in diameter. Mitochondria are about the size of small bacteria, whereas chloroplasts are usually larger, about 5 μm long. Ova (egg cells) are among the largest cells. Although microscopic, some nerve cells are very long, specialized to transmit messages from one part of the body to another. The cells shown here are not drawn to scale.

that are too small to see, but it is very helpful to remember that a micrometer has the same relationship to a millimeter that a millimeter has to a meter (1/1000).

As small as it is, the micrometer is actually too large to measure most cellular components. For these purposes we use the nanometer (nm), which is 1/1,000,000,000 (one-billionth) of a meter, or 1/1000 of a micrometer. To mentally move down to the world of the nanometer, recall that a millimeter is one thousandth of a meter, a micrometer is one thousandth of a millimeter, and a nanometer is one thousandth of a micrometer.

A good light microscope allows us to see most types of bacterial cells, and some specialized algae and animal cells are

large enough to be seen with the naked eye. A human egg cell, for example, is about 130 μm in diameter, or approximately the size of the period at the end of this sentence. The largest cells are birds' eggs, but they are atypical because both the yolk and the egg white consist of food reserves. The functioning part of the cell is a small mass on the surface of the yolk.

Why are most cells so small? If you consider what a cell must do to grow and survive, it may be easier to understand the reasons for its small size. A cell must take in food and other materials and must rid itself of waste products generated by metabolic reactions. Everything that enters or leaves a cell must pass through its plasma membrane. The plasma membrane contains specialized "pumps" and "gates" that selectively regu-

Figure 4-2 Surface area to volume ratio. Eight small cells have a much greater surface area (plasma membrane) in relation to their total volume than does one large cell. The volume of a cube is equal to the cube of the length of one of its sides. The volume of the large cube on the right, which is equal to the total volume of the eight small cubes on the left, is $(100\ \mu\text{m})^3 = 1,000,000\ \mu\text{m}^3$. The surface area of a cube is equal to the square of the length of one of its sides, multiplied by 6 (the number of sides). The surface area of the large cube on the right is $(100\ \mu\text{m})^2 \times 6 = 60,000\ \mu\text{m}^2$. The ratio of its surface area to its volume (surface area:volume) is 0.06. The total surface area of the eight small cubes on the left is $(50\ \mu\text{m})^2 \times 6 \times 8 = 120,000\ \mu\text{m}^2$. The ratio of their total surface area to their total volume is 0.12—double the surface-to-volume ratio of the single large cube.

late the passage of materials into and out of the cell. The plasma membrane must be large enough relative to the cell volume to keep up with the demands of regulating the passage of materials. This means that a critical factor in determining cell size is the ratio of its surface area to its volume (Fig. 4-2).

As a cell becomes larger its volume increases at a greater rate than its surface area (i.e., its plasma membrane), which effectively places an upper limit on cell size. Above some critical size, the number of molecules required by the cell could not be transported into the cell fast enough to sustain its needs. In addition, the cell would not be able to regulate its concentration of various ions or efficiently export its wastes.

Of course, not all cells are spherical or cuboidal. Some very large cells have relatively favorable ratios of surface area to volume because of their shapes. In fact, some variations in cell shape represent a strategy for increasing the ratio of surface area to volume. For example, many large plant cells are long and thin, which increases their surface-to-volume ratio. Some cells, such as epithelial cells, have finger-like projections of the plasma membrane, called *microvilli*, that significantly increase the surface area used to absorb nutrients and other materials.

Another reason that cells are small is that, once inside, molecules must be transported to the locations where they are converted into other forms. Because cells are small, the distances molecules travel within them are relatively short, which speeds up many cellular activities.

Cell size and shape are related to function

The sizes and shapes of cells are related to the functions they perform (Fig. 4-1). Some cells, such as the amoeba and the white blood cell, can change their shape as they move about. Sperm cells have long, whiplike tails, called flagella, for locomotion. Nerve cells possess long, thin extensions that permit them to transmit messages over great distances. The extensions of some nerve cells in the human body may be as long as 1 m. Other cells, such as certain epithelial cells, are almost rectangular in shape and are stacked much like building blocks to form sheetlike structures.

CELLS ARE STUDIED BY A COMBINATION OF METHODS

One of the most important tools used to study cell structures has been the microscope. In fact, cells were not described until 1665, when Robert Hooke examined a piece of cork using a microscope he had made. In his book *Micrographia*, published in 1665, Hooke drew what he saw and described many objects that he viewed through his microscope. Hooke did not actually see cells in the cork; rather, he saw the walls of dead cork cells (Fig. 4-3a). Not until much later was it realized that the interior enclosed by the walls is the important part of living cells.

Light microscopes are used to study stained or living cells

A few years after Hooke described dead cork cells, the Dutch naturalist Anton van Leeuwenhoek viewed living cells with small lenses that he made. However, he did not share his lens-making techniques, and more than a century passed before biologists realized the importance of microscopes and what they could reveal. It was not until the early 19th century that microscopes were sufficiently developed for biologists to begin their study of cells.

The **light microscope (LM)**, the type used by most students, consists of a tube with glass lenses at each end. (Because it contains several lenses, the light microscope is sometimes called a compound microscope.) Visible light passes through the specimen being observed and through the lenses. Light is refracted (bent) by the lenses, magnifying the image.

Two features of a microscope determine how clearly a small object can be viewed: magnification and resolving power. *Magnification* is the ratio of the size of the image seen with the microscope to the actual size of the object. The best light microscopes usually magnify an object no more than 1000 times. **Resolution, or resolving power**, is the capacity to distinguish fine detail in an image. This is defined as the minimum distance between two points at which they can both be seen separately rather than as a single, blurred point. Resolving power depends on the quality of the lenses and the *wave-*

Figure 4-3 Viewing cells with various types of microscopes. (a) Using a crude microscope that he constructed, Robert Hooke looked at a thin slice of cork and drew what he saw. Hooke used the term *cell* because the tissue reminded him of the small rooms that monks lived in during that period. More sophisticated microscopes and techniques permit biologists to view cells in more detail. Unstained epithelial cells from the skin of human cheek are compared using (b) bright field (transmitted light), (c) dark field, (d) phase contrast, and (e) Nomarski differential interference microscopy. The phase contrast and differential interference microscopes enhance detail by increasing the differences in optical density in different regions of the cells. (a, from Hooke's *Micrographica*, 1665; b–e, Jim Solliday/Biological Photo Service)

length of the illuminating light. As the wavelength decreases, the resolution increases. The visible light used by light microscopes has wavelengths ranging from about 400 nm (violet) to 700 nm (red); this limits the resolution of the light microscope to details no smaller than the diameter of a small bacterial cell (about 1 micrometer).

By the early 20th century, refined versions of the light microscope, as well as certain organic compounds that specifically stain different cell structures, became available. These enabled biologists to discover that cells contain a number of different internal structures, the organelles. The contribution of organic chemists in the development of biological stains was essential to this understanding, because the interior of many cells is transparent. Most of the methods used to prepare and stain cells for observation, however, also kill them in the process.

More recently, sophisticated types of light microscopes have been developed that use interfering waves of light to enhance the internal structures of cells. With *phase contrast* and *Nomarski differential interference microscopes*, some internal structures can be seen in unstained living cells (Fig. 4-3 d and

e). One of the most striking things that can be observed with these microscopes is that living cells contain numerous internal structures that are constantly changing shape and location.

Fluorescence microscopes are used to detect the locations of specific molecules in cells. Fluorescent stains (like paints that glow under black light) are molecules that absorb light energy of one wavelength and then release some of that energy as light of a longer wavelength. One such stain binds specifically to DNA molecules and emits green light after absorbing ultraviolet light. Cells can be stained, and the location of the DNA can be determined, by observing the source of the green fluorescent light within the cell. Some fluorescent stains can be chemically bonded to *antibodies*, protein molecules important in internal defense. The antibody can then bind to a highly specific region of a molecule in the cell. A single type of antibody molecule can bind to only one type of structure, such as a part of a specific protein or some of the sugars in a specific polysaccharide. Purified fluorescent antibodies known to bind to a specific protein isolated from a cell can be used to determine where that protein is located. Powerful computer imaging methods have allowed the development of the *confocal flu-*

Figure 4–4 Confocal fluorescence micrograph of cultured animal cells. The cell in the center is dividing. The DNA of the chromosomes is yellow; the microtubules (skeletal elements of the cells) are red. (Courtesy of Dr. John M. Murray, Department of Cell and Developmental Biology, University of Pennsylvania)

orescence microscope, which greatly improves the resolution of structures labeled by fluorescent dyes (Fig. 4–4 and LM in chapter introduction).

Cell biologists are developing new techniques for viewing cells, using computers, lasers, and photodetectors. Computer-based image processing synthesizes multiple images to produce three-dimensional views.

Electron microscopes provide a high resolution image that can be greatly magnified

Even with improved microscopes and techniques for staining cells, ordinary light microscopes can distinguish only the gross details of many cell parts. In most cases all that can be seen clearly is the outline of a structure and its ability to be stained by some dyes and not by others. Not until the development of the **electron microscope (EM)**, which came into wide use in the 1950s, were researchers able to study the fine details, or **ultrastructure**, of cells.

Whereas light microscopes magnify an object no more than about 1000 times, the electron microscope can magnify it 250,000 times or more. And while the best light microscopes have about 500 times more resolution than the human eye, the electron microscope multiplies the resolving power by more than 10,000 (Fig. 4–5). This is because electrons have very short wavelengths, on the order of about 0.1 to 0.2 nm. Al-

though such resolution is difficult to achieve with biological material, it can be approached when isolated molecules such as proteins or DNA are examined.

The image formed by the electron microscope cannot be seen directly. The electron beam itself consists of energized electrons, which, because of their negative charge, can be focused by electromagnets just as images are focused by glass lenses in a light microscope (Fig. 4–5). For **transmission electron microscopy (TEM)**, the specimen is embedded in plastic and then cut into extraordinarily thin sections (50 to 100 nm thick) with a glass or diamond knife. A section is then placed on a small metal grid. The electron beam passes through the specimen and then falls onto a photographic plate or a fluorescent screen that works much like a television screen. When you look at transmission electron micrographs in this chapter (and elsewhere), keep in mind that each represents only a thin cross section of a cell.

To reconstruct a three-dimensional view of the cell, it is necessary to study many consecutive sectional views (called *serial sections*) through the object. To understand the enormity of such a task, try imagining what it would be like to reconstruct the contents of your home from a set of hundreds of consecutive 5-cm sections.

Special methods using antibody molecules that have very tiny gold particles bound to them allow the detection of specific molecules in electron microscope images. The dense gold particles block the electron beam and identify the location of the proteins recognized by the antibodies as precise black spots on the electron micrograph.

In another type of electron microscope, the **scanning electron microscope (SEM)**, the electron beam does not pass through the specimen. Instead, the specimen is coated with a thin film of gold or some other metal. When the electron beam strikes various points on the surface of the specimen, secondary electrons are emitted whose intensity varies with the contour of the surface. The recorded emission patterns of the secondary electrons give a three-dimensional picture of the surface (Fig. 4–5). The SEM provides information about the shape and external features of the specimen that cannot be obtained with the TEM.

Note that the light microscope, TEM, and SEM are focused by similar principles. A beam of light or an electron beam is directed by the condenser lens onto the specimen and is magnified by the objective lens and the eyepiece in the light microscope or by the objective lens and the projector lens in the TEM. The TEM image is focused onto a fluorescent screen, and the SEM image is viewed on a type of television screen. Lenses in the electron microscopes are actually magnets that bend the beam of electrons.

Cell fractionation procedures permit study of cell components

The EM is a powerful tool for studying cell structure, but it has limitations. The methods used to prepare cells for electron microscopy kill them and may even alter their structure. Fur-

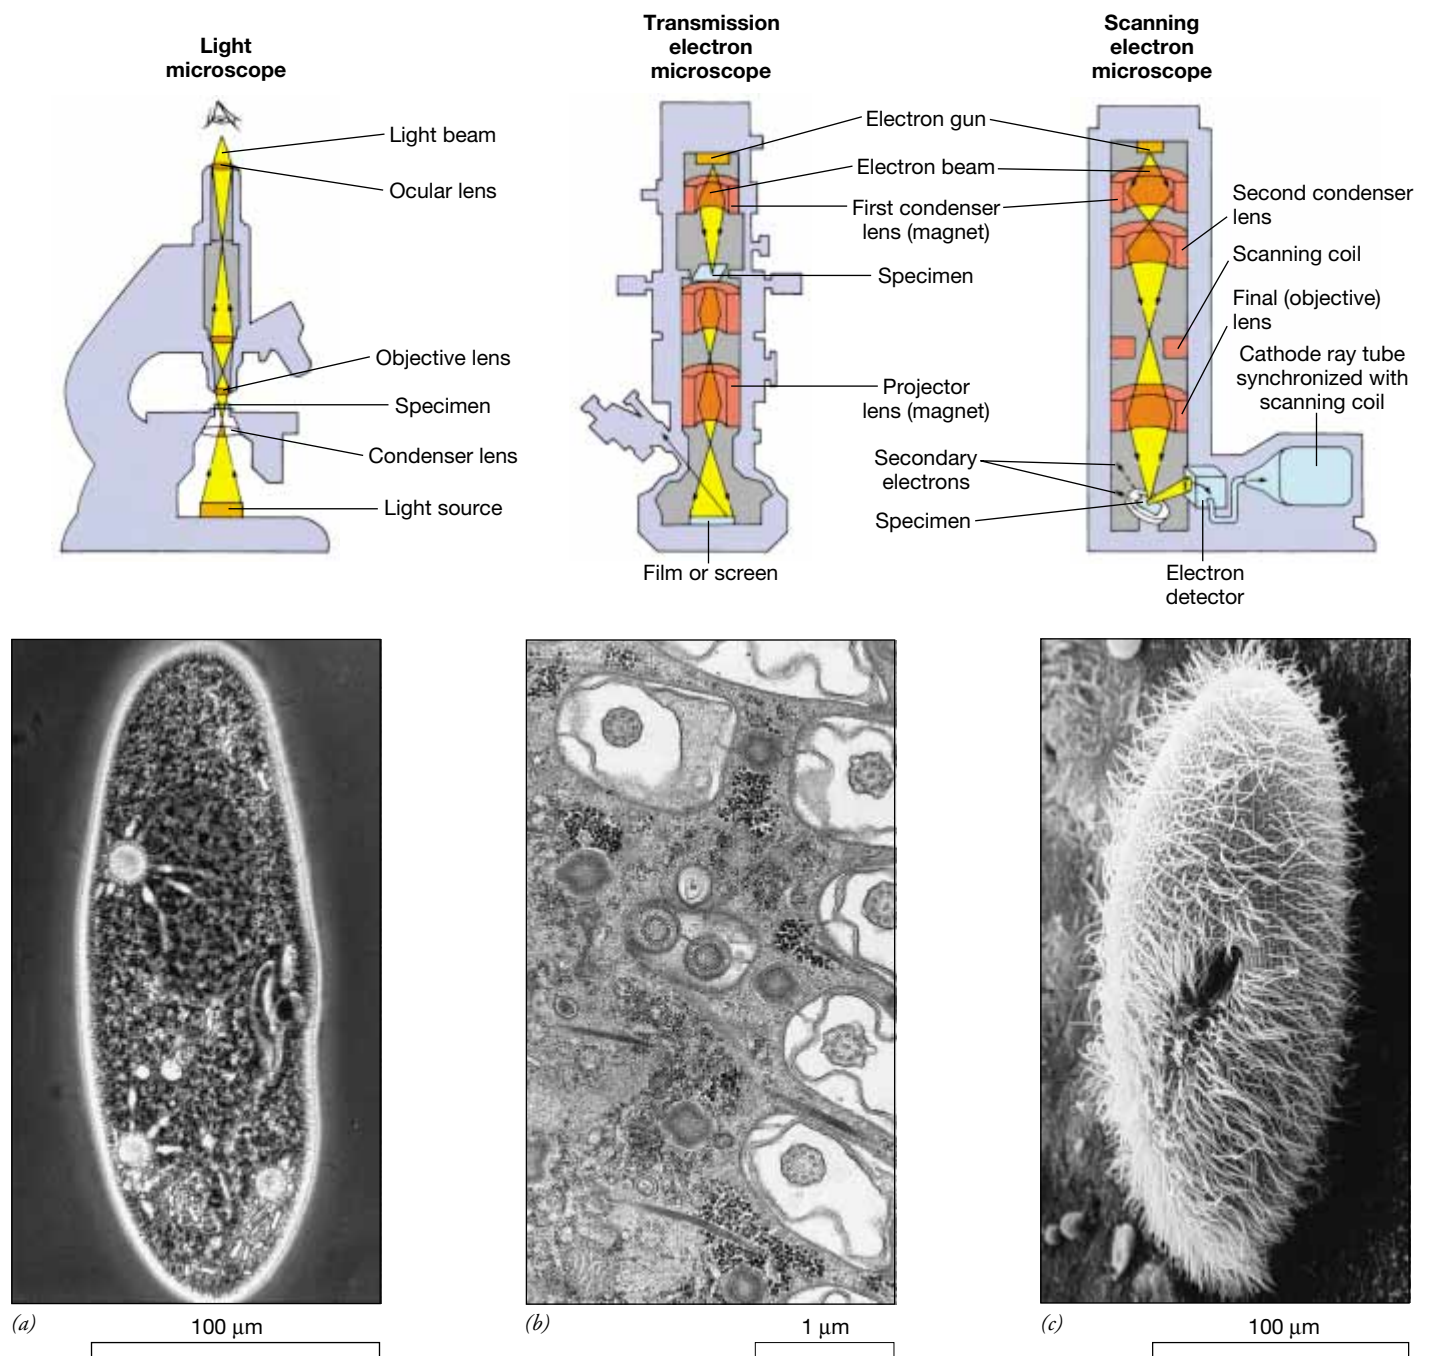

Figure 4–5 Comparison of light and electron microscopy. Distinctive images of cells, such as the protist *Paramecium* shown in the photomicrographs, are provided by three types of microscopes. (a) A phase-contrast light microscope can be used to view stained or living cells, but at relatively low resolution. (b) The transmission electron microscope (TEM) produces a high resolution image that can be greatly magnified. Because of the high magnification, only a small part of the *Paramecium* is shown in the photograph. (c) The scanning electron microscope (SEM) is used to provide a clear view of surface features. (Photos courtesy of T.K. Maugel/University of Maryland)

thermore, electron microscopy provides few clues about the functions of organelles and other cell components. To determine what organelles actually do, researchers have to be able to purify different parts of cells so that they can be studied by physical and chemical methods.

Cell fractionation procedures are methods for purifying organelles. Generally, cells are broken apart as gently as possible, and the mixture, referred to as the cell extract, is subjected to centrifugal force by spinning in a device called a **centrifuge**. An ultracentrifuge, a very powerful centrifuge, can spin at

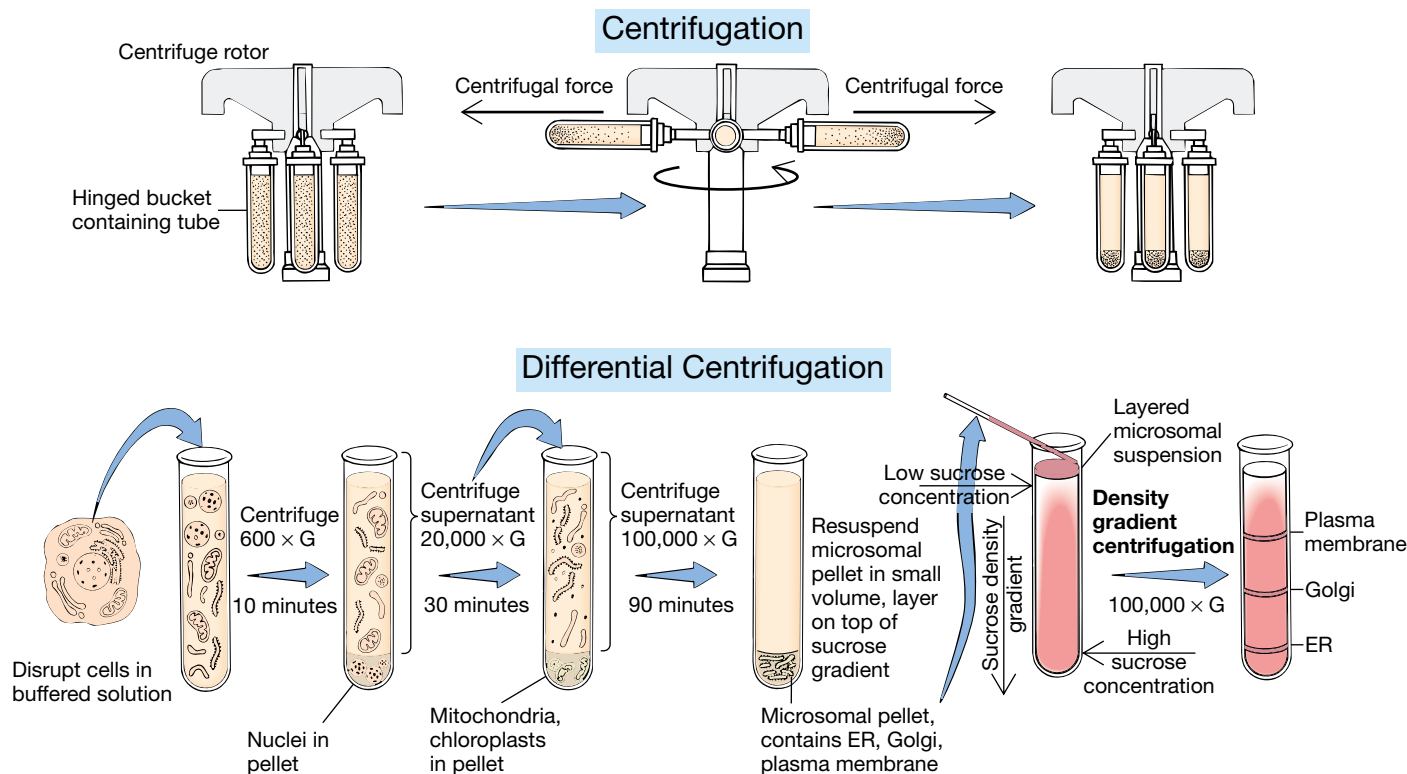

Figure 4–6 Cell fractionation. Differential centrifugation permits cell biologists to separate cell structures into various fractions by spinning the suspension at increasing revolutions per minute. Membranes and organelles from the resuspended pellets can then be further purified by density gradient centrifugation, shown as the last step in the figure.

speeds exceeding 100,000 rpm (revolutions per minute), generating a centrifugal force of 500,000 Gs (a G is equal to the force of gravity). Centrifugal force separates the extract into two fractions: a pellet and a supernatant. The *pellet*, containing heavier materials, such as nuclei, packed together, forms at the bottom of the tube. The *supernatant*, the liquid above the pellet, contains lighter particles, dissolved molecules, and ions (Fig. 4–6).

The supernatant can be centrifuged again at a higher speed to obtain a pellet that contains the next heaviest cell components, for example mitochondria and chloroplasts. In **differential centrifugation**, the supernatant is spun at successively higher speeds, permitting various cell components to be separated on the basis of their different sizes and densities.

Cell components in the resuspended pellets can be further purified by **density gradient centrifugation**. In this procedure, the resuspended pellet is placed in a layer on top of a density gradient, usually made up of a solution of sucrose and water. The concentration of sucrose (table sugar) is highest at the bottom of the tube and decreases gradually so that it is lowest at the top. Because the densities of organelles differ, each will migrate during centrifugation and form a band at the position in the gradient where its own density equals that of the sucrose solution.

Purified organelles can be examined to determine what kinds of proteins and other molecules they might contain, as well as the nature of the chemical reactions that take place within them. Today, cell biologists often use a combination of experimental approaches to study the functions of cellular structures.

PROKARYOTIC CELLS ARE STRUCTURALLY SIMPLER THAN EUKARYOTIC CELLS

Recall from Chapter 1 that two basic types of cells are known: **prokaryotic** and **eukaryotic cells**. Only bacteria have prokaryotic cells. A major difference between prokaryotic and eukaryotic cells is that the DNA of prokaryotic cells is not enclosed in a nucleus. In fact the term prokaryotic means “before the nucleus.” In the prokaryotic cell, the DNA is located in a limited region of the cell called a **nuclear area**, or **nucleoid** that is not enclosed by a membrane (Fig. 4–7). Other types of internal membrane-bounded organelles are also absent in prokaryotic cells. These cells are typically smaller than eukaryotic cells. In fact, the average prokaryotic cell is only about one-tenth the diameter of the average eukaryotic cell.

Figure 4–7 TEM of a prokaryotic cell. This bacterium, *Bacillus subtilis*, which is dividing, has a prominent cell wall surrounding the plasma membrane. The nuclear areas are clearly visible. (Courtesy of A. Ryter)

Like eukaryotic cells, prokaryotic cells have a plasma membrane that confines the contents of the cell to an internal compartment. In some prokaryotic cells the plasma membrane may be folded inward to form a complex of membranes along which the cell's energy-transforming reactions take place. Most prokaryotic cells have **cell walls**—structures that enclose the entire cell, including the plasma membrane. Many prokaryotes have **flagella** (sing., *flagellum*), long fibers that project from the surface of the cell. Flagella operate like propellers and are important in locomotion.

The dense internal material of the bacterial cell contains **ribosomes**, small complexes of RNA and protein that synthesize polypeptides (discussed later in this chapter), as well as storage granules that hold glycogen, lipid, or phosphate compounds. The ribosomes of prokaryotic cells are smaller than those found in eukaryotic cells. Prokaryotic cells are discussed in more detail in Chapter 23.

EUKARYOTIC CELLS ARE CHARACTERIZED BY MEMBRANE-BOUNDED ORGANELLES

Eukaryotic cells are characterized by highly organized membrane-bounded organelles. The most prominent of these is the **nucleus**, which contains the hereditary material, DNA. In fact, the name eukaryote means “true nucleus.” Table 4–1 summarizes the types of organelles typically found in eukaryotic cells. Some organelles may be found only in specific cells. For example, chloroplasts, structures that trap sunlight for energy conversion, are found only in cells that carry on photosynthesis, such as certain plant cells. The many specialized organelles of eukaryotic cells allow them to overcome some of the problems associated with large size, permitting eukaryotic cells to be considerably larger than prokaryotic cells.

Early biologists thought that the cell consisted of a homogeneous jelly, which they called *protoplasm*. With the elec-

tron microscope and other modern research tools, perception of the environment within the cell has been greatly expanded. We now know that the cell is highly organized and complex (Figs. 4–8 to 4–11). It has its own control center, internal transportation system, power plants, factories for making needed materials, packaging plants, and even a “self-destruct” system. Biologists refer to the part of the cell outside the nucleus as **cytoplasm** and the part of the cell within the nucleus as **nucleoplasm**. Various organelles are suspended within the fluid component of the cytoplasm, which is referred to as the **cytosol**. Therefore, the term *cytoplasm* includes both the cytosol and all the organelles other than the nucleus.

Membranes divide the cell into compartments

Membranes have unique properties that enable membranous organelles to carry out a wide variety of functions. For example, cell membranes never have free ends; therefore a membranous organelle always contains at least one enclosed internal space or compartment. These membrane-bounded compartments allow certain cell activities to be localized within specific enclosed regions of the cell. Reactants that are located in only a small part of the total cell volume are far more likely to come in contact, and the rate of the reaction can be dramatically increased. Membrane-bounded compartments keep certain reactive compounds away from other parts of the cell that might be adversely affected by them. Compartmentalizing also permits many different activities to go on simultaneously.

Membranes also allow the storage of energy. The membrane provides a barrier that is analogous to a dam on a river. A difference in the concentration of some substance on the two sides of a membrane is a form of stored energy or **potential energy** (see Chapter 6). As particles of the substance move across the membrane from the side of higher concentration to the side of lower concentration, the cell can convert some of this potential energy to the chemical energy of ATP molecules. This process of energy conversion (discussed in Chapters 7 and 8) is a basic mechanism that cells use to capture and convert energy to sustain life.

Membranes also serve as important work surfaces. For example, a number of chemical reactions in cells are carried out by enzymes that are bound to membranes. Because the enzymes that carry out successive steps of a series of reactions are organized close together on a membrane surface, certain series of chemical reactions can occur more rapidly.

In a eukaryotic cell a number of membranes are generally considered to be part of the internal membrane system, or **endomembrane system**. Look at Figures 4–8 and 4–9 and notice how membranes divide the cell into many compartments, including the cell itself (bounded by the plasma membrane), the nucleus, endoplasmic reticulum, Golgi complexes, lysosomes, and vesicles and vacuoles. (Although it is not internal,

TABLE 4–1 Eukaryotic Cell Structures and Their Functions

Structure	Description	Function
Cell Nucleus		
Nucleus	Large structure surrounded by double membrane; contains nucleolus and chromosomes	Information in DNA is transcribed in RNA synthesis; specifies cellular proteins
Nucleolus	Granular body within nucleus; consists of RNA and protein	Site of ribosomal RNA synthesis; ribosome subunit assembly
Chromosomes	Composed of a complex of DNA and protein known as chromatin; condense during cell division, becoming visible as rodlike chromosomes	Contain genes (units of hereditary information) that govern structure and activity of cell
Cytoplasmic Organelles		
Plasma membrane	Membrane boundary of cell	Encloses cellular contents; regulates movement of materials in and out of cell; helps maintain cell shape; communicates with other cells (also present in prokaryotes)
Endoplasmic reticulum (ER)	Network of internal membranes extending through cytoplasm	Synthetic site of lipids and many proteins; origin of intracellular transport vesicles carrying proteins
Smooth	Lacks ribosomes on outer surface	Lipid biosynthesis; drug detoxification
Rough	Ribosomes stud outer surface	Manufacture of many proteins destined for secretion or for incorporation into membranes
Ribosomes	Granules composed of RNA and protein; some attached to ER, some free in cytosol	Synthesize polypeptides in both prokaryotes and eukaryotes
Golgi complex	Stacks of flattened membrane sacs	Modifies proteins; packages secreted proteins; sorts other proteins to vacuoles and other organelles
Lysosomes	Membranous sacs (in animals)	Contain enzymes to break down ingested materials, secretions, wastes
Vacuoles	Membranous sacs (mostly in plants, fungi, algae)	Transport and store materials, wastes, water

the plasma membrane is also included because of its participation in the activities of the endomembrane system.)

Some organelles have direct connections between their membranes and compartments. Others transport materials in **vesicles**, small membrane-bounded sacs. Vesicles also carry materials from one organelle to another. Through a complex series of steps, a vesicle can form as a “bud” from one membrane and then be transported to another membrane to which it fuses, thus delivering its contents into another compartment. Mitochondria and chloroplasts are also separate compartments but are not generally considered part of the endomembrane system because they function independently of other membranous organelles.

The cell nucleus contains DNA

Typically, the **nucleus** is the most prominent organelle in the cell. It is usually spherical or oval and averages 5 μm in di-

ameter. Owing to its size and the fact that it often occupies a relatively fixed position near the center of the cell, some early investigators guessed long before experimental evidence was available that the nucleus served as the control center of the cell (see *Focus On: Acetabularia*). Most cells have one nucleus, although there are exceptions.

The **nuclear envelope** consists of two concentric membranes that separate the nuclear contents from the surrounding cytoplasm (Fig. 4–12). These membranes are separated by about 20–40 nm. At intervals the membranes come together to form **nuclear pores** that regulate the passage of certain materials between nucleoplasm and cytoplasm.

Most of the cell’s DNA is located inside the nucleus. Recall that the DNA molecules make up the **genes**, which contain the chemically coded instructions for producing most of the proteins needed by the cell. The nucleus controls protein synthesis by sending messenger RNA molecules to the cytoplasm (where proteins are manufactured).

TABLE 4–1 continued

Structure	Description	Function
Peroxisomes	Membranous sacs containing a variety of enzymes	Sites of many diverse metabolic reactions
Mitochondria	Sacs consisting of two membranes; inner membrane is folded to form cristae and encloses matrix	Site of most reactions of cellular respiration; transformation of energy originating from glucose or lipids into ATP energy
Plastids (e.g., chloroplasts)	Double membrane structure enclosing internal thylakoid membranes; chloroplasts contain chlorophyll in thylakoid membranes	Chlorophyll captures light energy; ATP and other energy-rich compounds are formed and then used to convert CO ₂ to glucose
Cytoskeleton		
Microtubules	Hollow tubes made of subunits of tubulin protein	Provide structural support; have role in cell and organelle movement and cell division; components of cilia, flagella, centrioles, basal bodies
Microfilaments	Solid, rodlike structures consisting of actin protein	Provide structural support; play role in cell and organelle movement and cell division
Intermediate filaments	Stable, tough fibers made of polypeptides	Help strengthen cytoskeleton; stabilize cell shape
Centrioles	Pair of hollow cylinders located near nucleus; each centriole consists of nine microtubule triplets (9 × 3 structure)	Mitotic spindle forms between centrioles during animal cell division; may anchor and organize microtubule formation in animal cells; absent in most plants
Cilia	Relatively short projections extending from surface of cell; covered by plasma membrane; made of two central and nine peripheral microtubules (9 + 2 structure)	Movement of some single-celled organisms; used to move materials on surface of some tissues
Flagella	Long projections made of two central and nine peripheral microtubules (9 + 2 structure); extend from surface of cell; covered by plasma membrane	Cellular locomotion by sperm cells and some single-celled eukaryotes

DNA is associated with proteins, forming a complex known as **chromatin**, which appears as a network of granules and strands in cells that are not dividing. Although chromatin appears disorganized, it is not. Because DNA molecules are extremely long and thin, they must be packed inside the nucleus in a very regular fashion. In dividing cells, the chromatin condenses and becomes visible as distinct threadlike structures called **chromosomes**. If the DNA in the 46 chromosomes of one human cell could be stretched end to end, it would extend for two meters.

Most nuclei have one or more compact structures called **nucleoli** (sing., *nucleolus*). A nucleolus is *not* membrane-bounded and usually stains differently from the surrounding chromatin. Each nucleolus contains a nucleolar organizer, made up of chromosomal regions containing instructions for making the type of RNA in ribosomes. This ribosomal RNA is synthesized in the nucleolus. The proteins needed to make ribosomes are synthesized in the cytoplasm and imported into

the nucleolus. Ribosomal RNA and proteins are then assembled into ribosomal subunits that leave the nucleus through the nuclear pores.

Ribosomes manufacture proteins

Ribosomes are small granules consisting of RNA and protein. Free ribosomes are suspended in the cytosol. Other ribosomes are associated with certain internal membranes within the cell. Each ribosome has two main components: a large subunit and a small subunit. Each subunit contains ribosomal RNA and several ribosomal proteins. Ribosomes, which contain the enzyme necessary to form peptide bonds, are tiny manufacturing plants that assemble proteins. Protein synthesis is discussed in detail in Chapter 12. (See *Making the Connection: Biological Molecules and Cell Control* on p. 91 for a brief overview of DNA, RNA, and protein synthesis)

(Text continues on p.87)

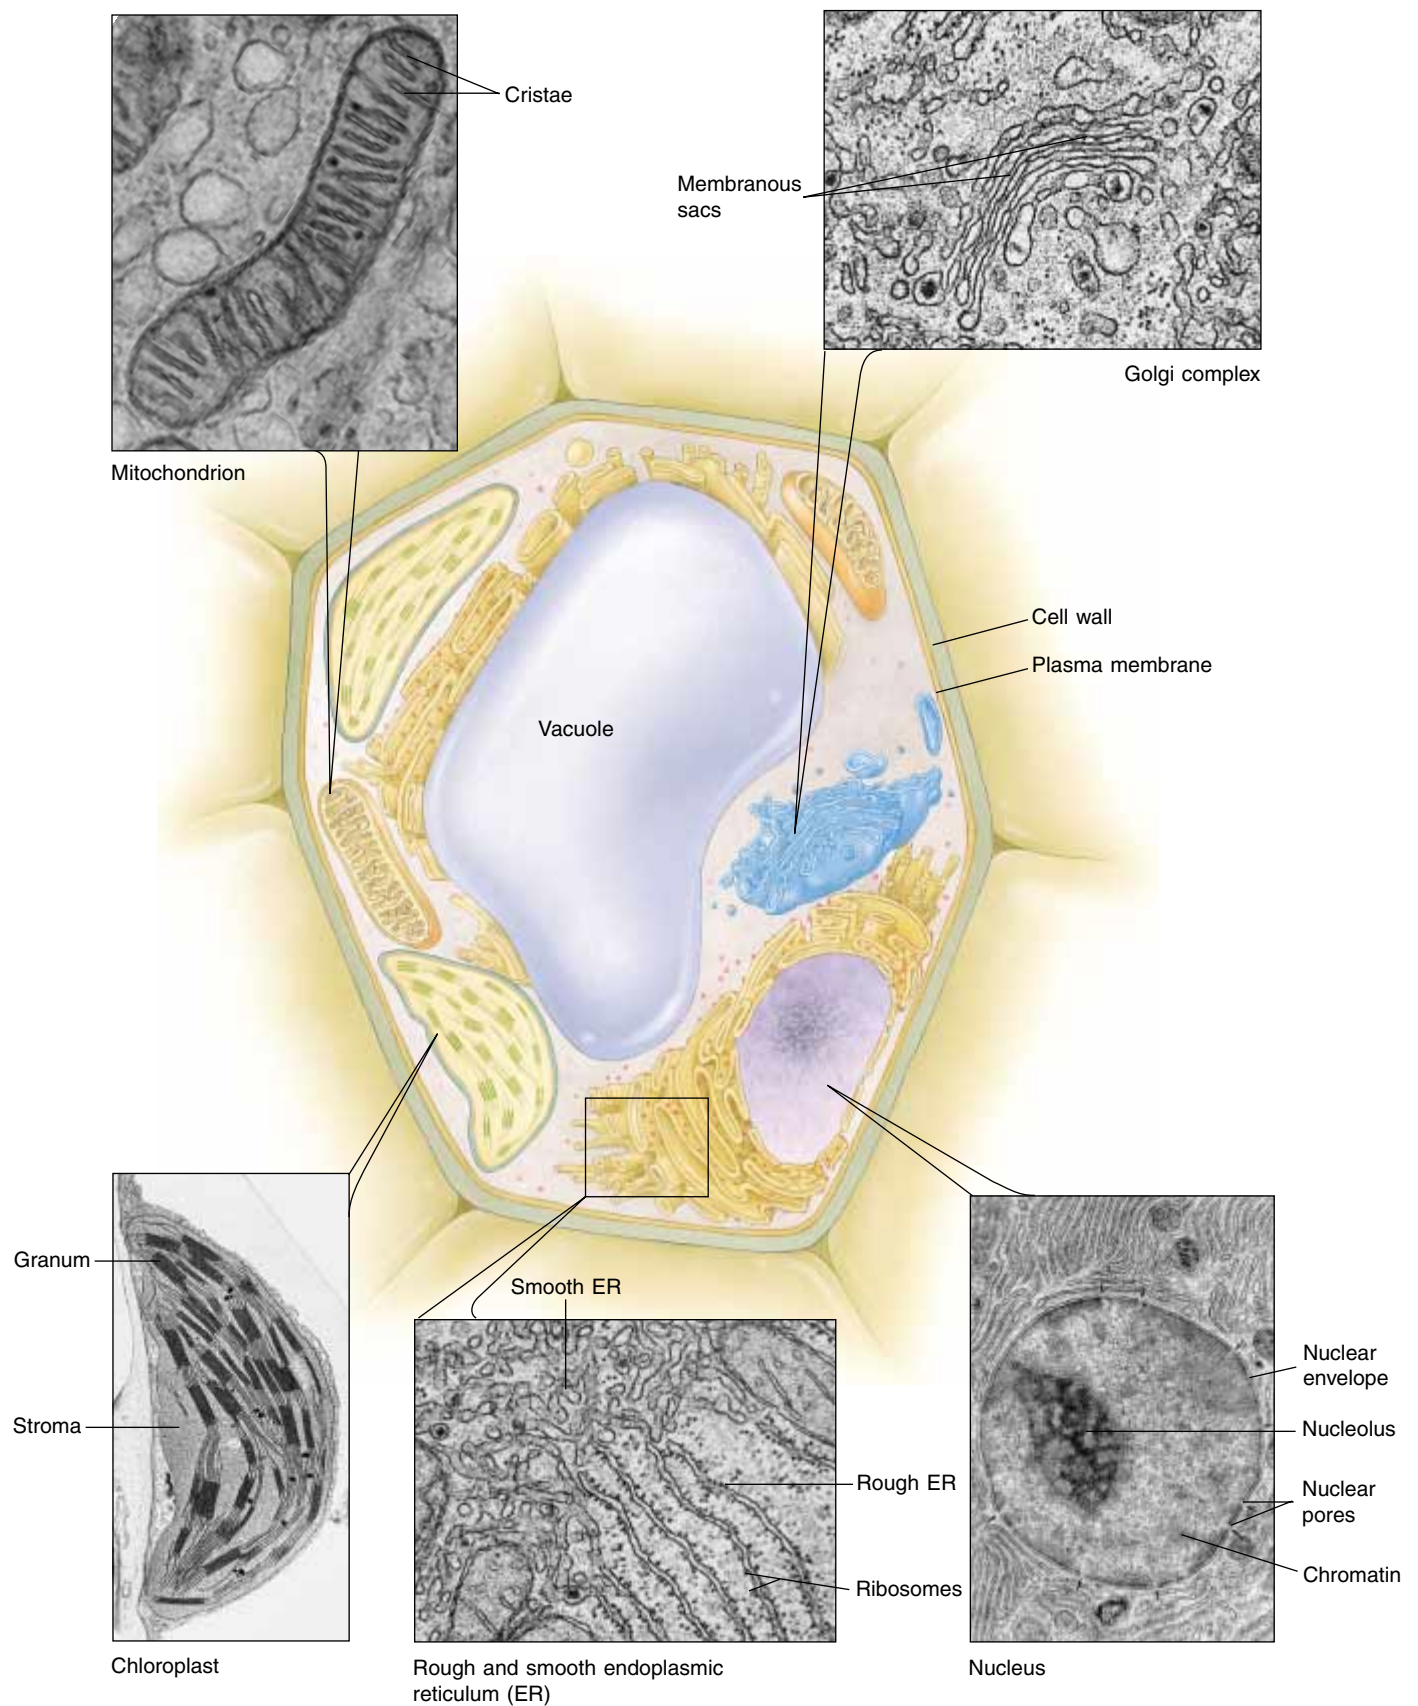

Figure 4-8 Composite diagram of a plant cell. The TEMs show certain structures or areas of the cell. Some plant cells do not have all the organelles shown. For example, cells that carry on photosynthesis contain chloroplasts, whereas root cells do not. Chloroplasts, a cell wall, and prominent vacuoles are characteristic of plant cells. Many of

the other organelles, such as the nucleus, mitochondria, and endoplasmic reticulum, are also found in protist, fungal, and animal cells. (Clockwise from top left: D.W. Fawcett; D.W. Fawcett and R. Bolender; D.W. Fawcett/Visuals Unlimited; R. Bolender and D.W. Fawcett; E.H. Newcomb and W.P. Wergin, Biological Photo Service)

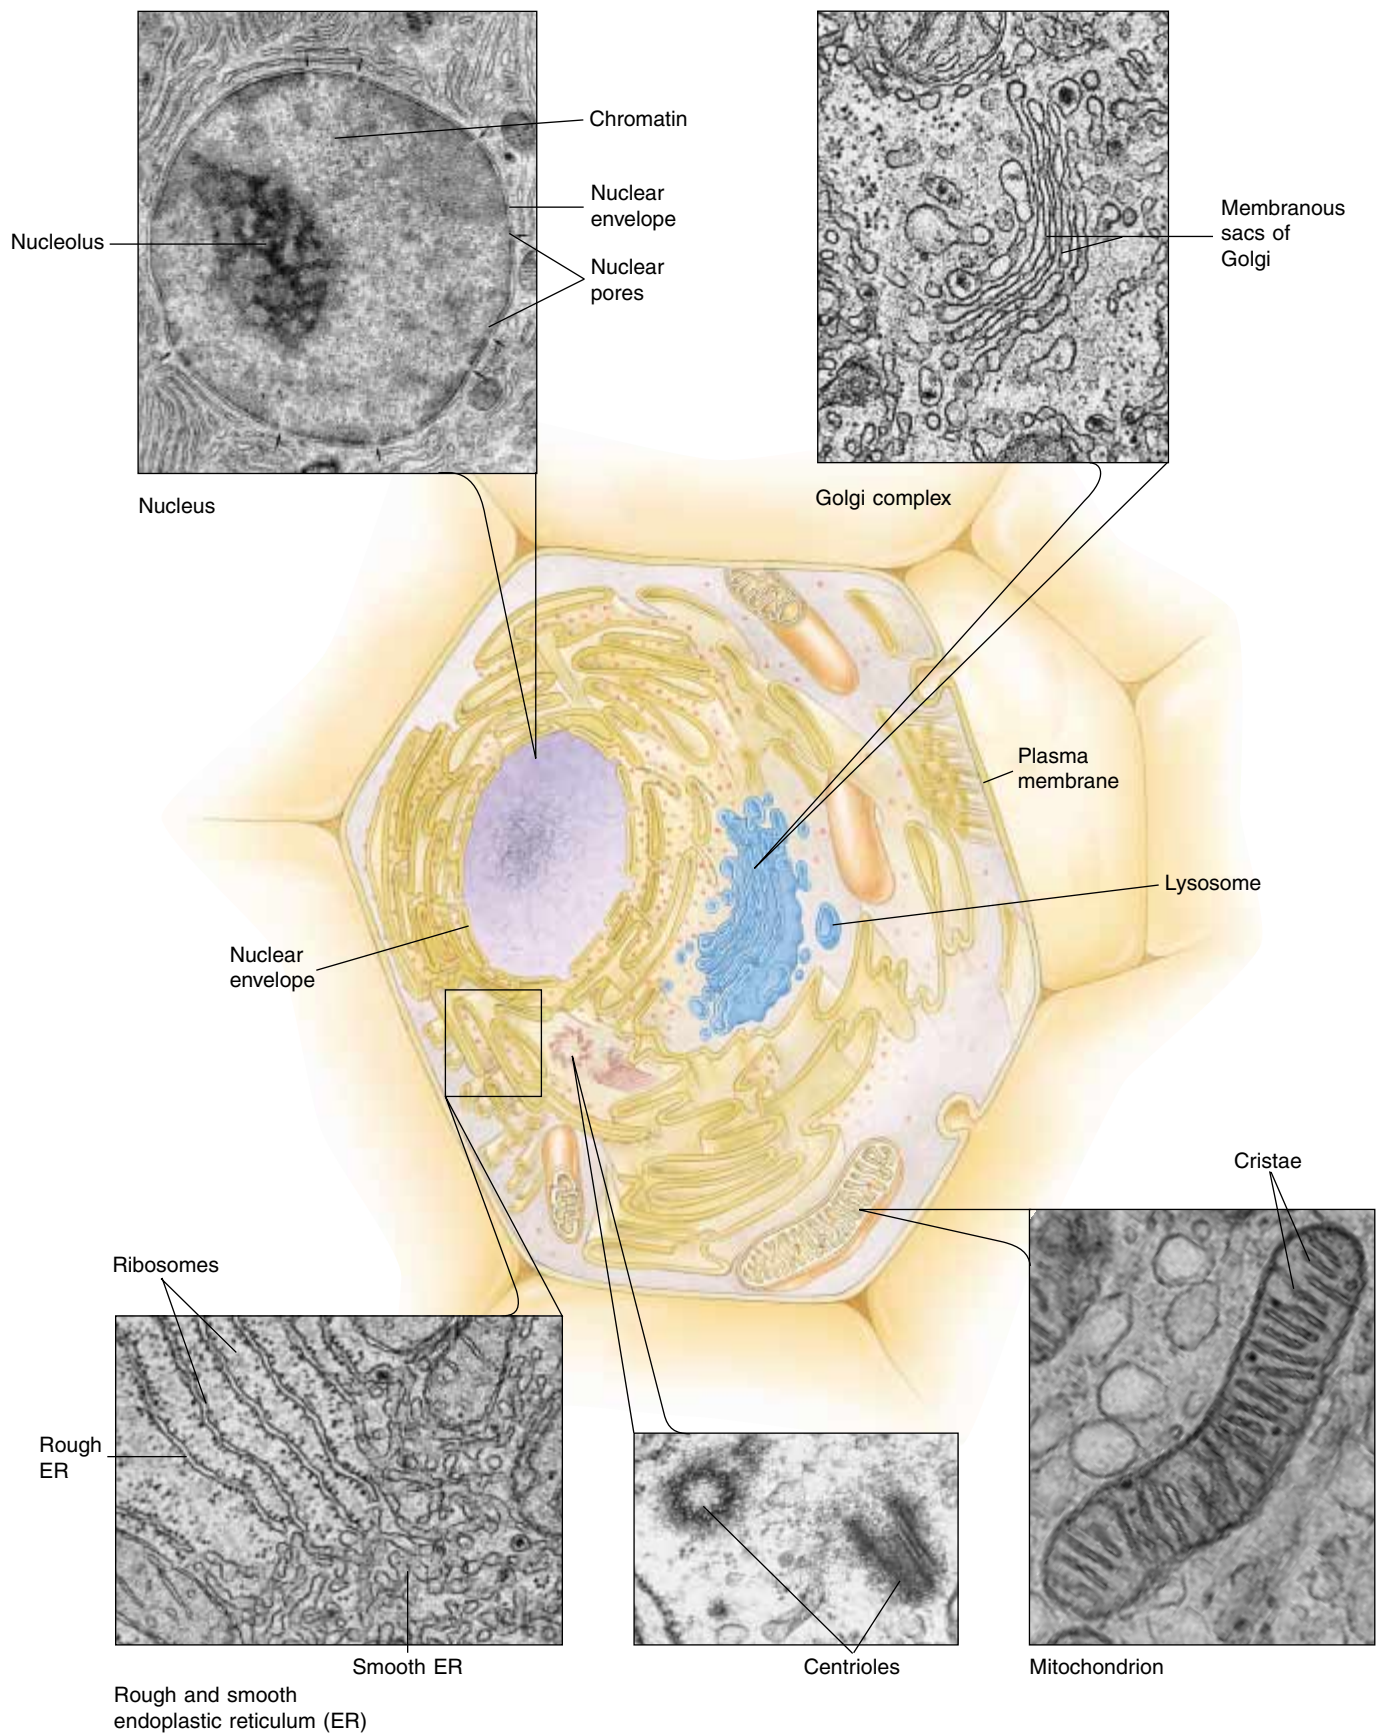

Figure 4-9 Composite diagram of an animal cell. This generalized animal cell is shown in realistic context surrounded by adjacent cells that cause it to be slightly compressed. TEMs show the structure of various organelles. Depending on the cell type, certain organelles

may be more or less prominent. (Clockwise from top left: D.W. Fawcett; D.W. Fawcett and R. Bolender; D.W. Fawcett; B.F. King, *Biological Photo Service*; R. Bolender and D.W. Fawcett/Visuals Unlimited)

(b)

Figure 4–10 TEM of a plant cell paired with interpretive drawing. Most of this cross section of a cell from the leaf of a young bean plant (*Phaseolus vulgaris*) is dominated by a vacuole. Prolamellar bodies are membranous regions typically seen in developing chloroplasts. (a, courtesy of Dr. Kenneth Miller, Brown University)

(a)

(b)

Figure 4–11 TEM of a human pancreas cell paired with interpretive drawing. Most of the structures of a typical animal cell are present. However, like most cells, this one has certain structures associated with its specialized functions. Pancreas cells such as the one shown here secrete large amounts of digestive enzymes. The large, dark, circular bodies in the TEM in (a) and the corresponding tan structures in (b) are zymogen granules containing inactive enzymes. When released from the cell, they catalyze chemical reactions such as the breakdown of peptide bonds of ingested proteins in the intestine. Most of the membranes visible in this section are part of the rough endoplasmic reticulum, an organelle specialized to manufacture protein. (a, Dr. Susumu Ito, Harvard Medical School)

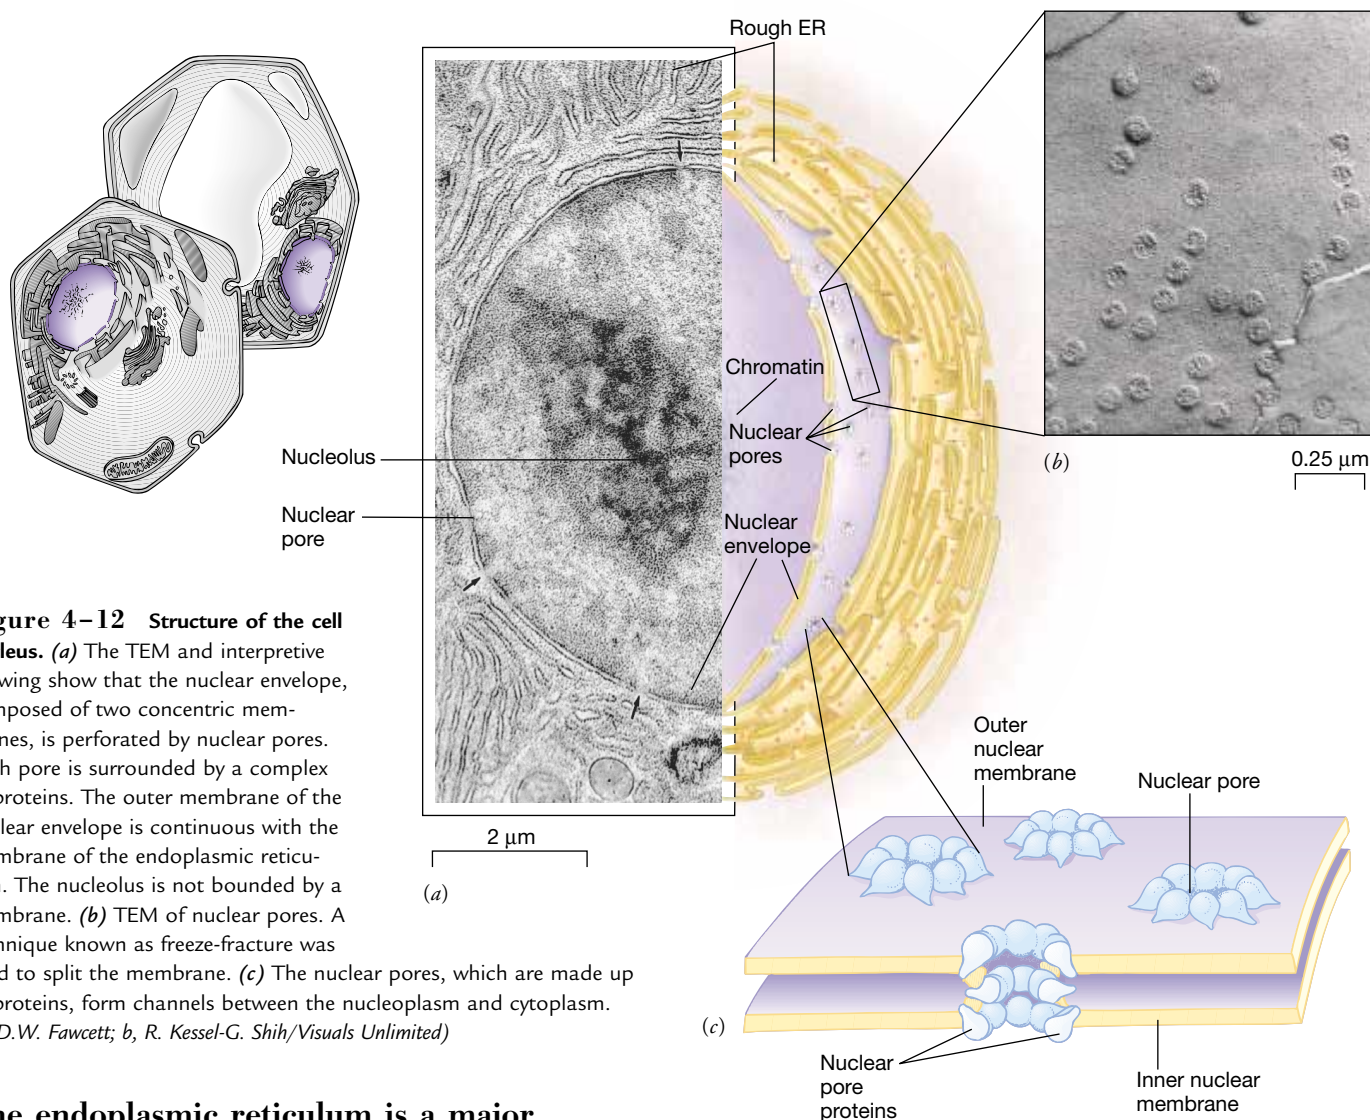

Figure 4-12 Structure of the cell nucleus. (a) The TEM and interpretive drawing show that the nuclear envelope, composed of two concentric membranes, is perforated by nuclear pores. Each pore is surrounded by a complex of proteins. The outer membrane of the nuclear envelope is continuous with the membrane of the endoplasmic reticulum. The nucleolus is not bounded by a membrane. (b) TEM of nuclear pores. A technique known as freeze-fracture was used to split the membrane. (c) The nuclear pores, which are made up of proteins, form channels between the nucleoplasm and cytoplasm. (a, D.W. Fawcett; b, R. Kessel-G. Shih/Visuals Unlimited)

The endoplasmic reticulum is a major manufacturing center

One of the most prominent features in the electron micrograph in Figure 4-11 is a maze of parallel internal membranes that encircle the nucleus and extend into many regions of the cytoplasm. This complex of membranes is the **endoplasmic reticulum (ER)**, which forms a significant part of the total volume of the cytoplasm in many cells. A higher-magnification TEM of the ER is shown in Figure 4-13. Remember that a TEM represents only a thin cross section of the cell, so there is a tendency to interpret the ER as a series of tubes. In fact, many ER membranes consist of a series of tightly packed and flattened saclike structures that form interconnected compartments within the cytoplasm.

The internal space enclosed by the membranes is called the ER **lumen**. In most cells the ER lumen forms a single internal compartment that is continuous with the outer membrane of the nuclear envelope (Fig. 4-12). The compartment formed between the two nuclear membranes is thus connected to the ER lumen. The membranes of other organelles are not directly connected to the ER and appear to form distinct and separate compartments within the cytoplasm.

The ER membranes and lumen contain a large variety of enzymes that catalyze many different types of chemical reactions. In some cases the membranes serve as a framework for systems of enzymes that carry out sequential biochemical reactions. The two surfaces of the membrane contain different sets of enzymes and represent regions of the cell with different synthetic capabilities, just as different regions of a factory are used to make different parts of a particular product. Still other enzymes are located within the ER lumen.

Two distinct regions of the ER can be distinguished in TEMs: rough ER and smooth ER. Although these regions have different functions, their membranes are connected and their internal spaces are continuous. **Rough ER** has ribosomes attached to it and consequently appears rough in electron micrographs. Notice in Figure 4-13 that one membrane face (the lumen side) appears to be bare, while the other membrane face (the cytosolic side) is studded with ribosomes that appear as dark particles.

FOCUS ON

ACETABULARIA: THE MERMAID'S WINEGLASS AND THE CONTROL OF CELL ACTIVITIES

As discussed in Chapter 1, we can learn something about the role of the nucleus by removing it from a cell and examining the consequences. When the nucleus of a single-celled amoeba is removed with a microneedle, the amoeba continues to live and move, but it ceases to grow and dies after a few days. A control amoeba, subjected to similar trauma but without removal of the nucleus, does not die. We conclude that the nucleus is necessary for the metabolic processes that provide for growth and cell reproduction.

Acetabularia Is Easy to Manipulate Because It Is a Single Giant Cell

To the romantically inclined, the little seaweed *Acetabularia* resembles a mermaid's wineglass, although the literal translation of its name, "vinegar cup," is somewhat less elegant (Fig. a).

In the 19th century, biologists discovered that this marine eukaryotic alga consists of a single cell. At about 5 cm in length, *Acetabularia* is small for a seaweed but gigantic for a cell. It consists of a root-like **holdfast**, a long cylindrical **stalk**, and a cuplike **cap**. The nucleus is found in the holdfast, about as far away from the cap as it can be.

Regeneration Experiments Demonstrated That the Cap Shape Is under the Control of Something in the Stalk or the Holdfast

If the cap of *Acetabularia* is removed experimentally, another one grows after a few weeks. Such behavior, common among simple organisms, is called **regeneration**. This fact attracted the attention of investigators, especially J. Hämmerling and J. Brachet, who became interested in whether a relationship exists between the nucleus and the physical characteristics of the alga. Because of its great size, *Acetabularia* could be subjected to surgery that would be impossible with smaller cells. During the 1930s and 1940s these researchers performed brilliant experiments that in many ways laid the foundation for much of our modern knowledge of the nucleus. Two species were used for most experiments, *A. mediterranea*, which has a smooth cap, and *A. crenulata*, which has a cap divided into a series of finger-like projections.

(a) *Acetabularia*. (a, L. Sims/Visuals Unlimited)

The kind of cap that is regenerated depends on the species of *Acetabularia* used in the experiment. As you might expect, *A. crenulata* regenerates a "cren" cap, and *A. mediterranea* regenerates a "med" cap. But it is possible to graft together two capless algae of different species. Through this union, they regenerate a common cap that has characteristics intermediate between those of the two species involved (Fig. b). Thus, it is clear that something about the lower part of the cell controls cap shape.

Stalk Exchange Experiments Indicated That Short-Term Control Can Be Exerted by the Stalk, but Long-Term Control Is in the Holdfast

It is possible to attach a section of *Acetabularia* to a holdfast that is not its own by telescoping the cell walls of the two into

one another. In this way the stalks and holdfasts of different species may be intermixed.

First, we take *A. mediterranea* and *A. crenulata* and remove their caps. Then we sever the stalks from the holdfasts. Finally, we exchange the parts (Fig. c). What happens? Not, perhaps, what you would expect! The caps that regenerate are characteristic not of the species donating the holdfasts but of those donating the stalks!

However, if the caps are removed once again, this time the caps that regenerate are characteristic of the species that donated the holdfasts. This continues to be the case no matter how many more times the regenerated caps are removed.

From all these results Hämmerling and Brachet deduced that the ultimate control of the *Acetabularia* cell is associated with the holdfast. Because there is a time lag be-

(b)

First regenerated caps

Second regenerated caps

(c)

fore the holdfast appears to take over, they hypothesized that it produces some temporary cytoplasmic messenger substance whereby it exerts its control. They further hypothesized that initially the grafted stalks still contain enough of the substance from their former holdfasts to regenerate a cap of the former shape. But this still leaves us with the question of what it is about the holdfast that accounts for its apparent control. An obvious suspect is the nucleus.

Nuclear Exchange Experiments Demonstrated That the Nucleus Is the Ultimate Source of Information for the Control of Cellular Activities

If the nucleus is removed and the cap cut off, a new cap regenerates (Fig. d). *Acetabularia*, however, can usually regenerate only

once without a nucleus. If the nucleus of another species is now inserted and the cap is cut off once again, a new cap regenerates that is characteristic of the species of the nucleus (Fig. e)! If two kinds of nuclei are inserted, the regenerated cap is intermediate in shape between those of the species that donated the nuclei.

As a result of these and other experiments, biologists began to develop certain basic ideas. The control of the cell exerted by the holdfast is attributable to the nucleus that is located there. Further, the nucleus is the apparent source of some "messenger substance" that can temporarily exert control but is limited in quantity and cannot be produced without the nucleus (Fig. f). This information helped provide a starting point for research on

the role of the nucleic acids in the control of all cells.

These ideas have been extended in our modern view of information flow and control in the cell. We now know that the nucleus of eukaryotes controls the cell's activities because it contains DNA (deoxyribonucleic acid), the ultimate source of biological information. DNA can pass on its information to successive generations because it is able to precisely replicate itself. The information in the DNA is used to specify the sequence of amino acids in all the proteins of the cell. To carry out its mission, DNA uses ribonucleic acid (RNA) as the cytoplasmic messenger substance.

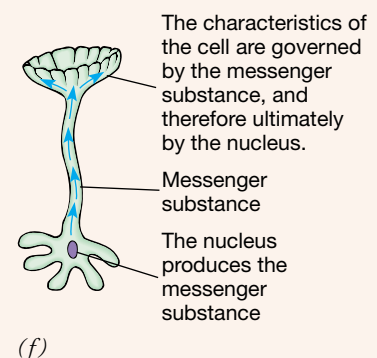

Figure 4–13 The endoplasmic reticulum (ER). The TEM shows both rough and smooth ER in a liver cell. (R. Bolender and D.W. Fawcett/Visuals Unlimited)

The ER plays a central role in the synthesis and assembly of proteins. Many proteins that are exported from the cell (such as digestive enzymes) and those destined for other organelles are synthesized on ribosomes attached to the ER membrane. Recent studies suggest that the ribosome forms a tight seal with the ER membrane. The ribosome contains a tunnel that connects to an ER pore, or *translocon*. Proteins are transported through this extended tunnel (through the ER membrane) into the ER lumen. In the ER lumen, proteins may be modified by enzymes that add complex carbohydrates or lipids to them. Other enzymes, called **chaperones**, in the ER lumen catalyze the efficient folding of proteins into proper conformations. The proteins are then transferred to other compartments by small **transport vesicles**, which bud off of the ER membrane and are then inserted into the membrane of some target compartment.

Smooth ER is more tubular and does not have ribosomes bound to it, so its outer membrane surfaces appear smooth. The smooth ER is the primary site of phospholipid, steroid, and fatty acid metabolism. While the smooth ER may be a minor membrane component in some cells, extensive amounts of smooth ER are present in others. For example, extensive smooth ER is visible in human liver cells, which synthesize

and process cholesterol and other lipids and serve as a major detoxification site. Enzymes located along the smooth ER of liver cells break down toxic chemicals such as carcinogens (cancer-causing agents). These compounds are then converted to water-soluble products that can be excreted.

The Golgi complex processes and packages proteins

The **Golgi complex** (also known as the *Golgi body* or *Golgi apparatus*) was first described in 1898 by the Italian microscopist Camillo Golgi, who found a way to specifically stain that organelle. In many cells the Golgi complex consists of stacks of flattened membranous sacs, which may be distended in certain regions because they are filled with cellular products (Fig. 4–14). Each of the flattened sacs has an internal space, or lumen. However, unlike the endoplasmic reticulum, most of these internal spaces of the Golgi complex and the membranes that form them are not continuous. Hence a Golgi complex contains a number of separate compartments, as well as some that are interconnected.

Each Golgi stack has three areas referred to as *cis* and *trans* faces, with a *medial* region between. Typically, the *cis* face is lo-

MAKING THE CONNECTION

BIOLOGICAL MOLECULES AND CELL CONTROL

How does a cell store and use genetic information? The cell stores information in the form of deoxyribonucleic acid (DNA). The DNA molecule contains a linear sequence of components called nucleotides. In all cells this sequence of nucleotides serves as a code that specifies the amino acid sequence (primary structure) in proteins. Proteins function as structural components of cells and as **enzymes**, molecules that regulate virtually every chemical reaction that takes place in the cell. By specifying the structure of enzymes and other proteins, DNA directs the metabolism of the cell.

The cell uses a second nucleic acid, ribonucleic acid (RNA), as an intermediary. The sequence of bases in DNA that codes for a specific protein is copied as a sequence of bases in a type of RNA, called **messenger RNA**. This process is known as **transcription**. In

eukaryotic cells, DNA is stored in the nucleus and transcription occurs there.

Messenger RNA leaves the nucleus and attaches to ribosomes along the rough ER (or to free ribosomes in the cytosol); two other types of RNA are also involved in protein synthesis. The complex process of assembling a chain of specific amino acids using the code in messenger RNA is called **translation**. After proteins are manufactured they may be transported to the Golgi complex where they are modified and sent on to other locations in the cell.

When a cell divides, the information stored in DNA must be reproduced and passed intact to the two daughter cells. DNA has the unique ability to make an exact duplicate of itself through a process called **replication** (see Chapter 11).

Figure 4-14 TEM and interpretive drawing of the Golgi complex. Glycoproteins are transported from the rough ER to the Golgi where they are modified. This diagram shows the passage of glycoproteins through the Golgi complex during the secretory cycle of a mucous-secreting goblet cell that lines the intestine. Mucus is a complex mixture of covalently linked proteins and carbohydrates. (D.W. Fawcett and R. Bolender)

cated nearest the nucleus and functions to receive materials from transport vesicles from the ER. The *trans* face, nearest to the plasma membrane, packages molecules in vesicles and transports them out of the Golgi.

In a cross-sectional view like that in the TEM in Figure 4–14, many of the ends of the sheetlike layers of Golgi membranes are distended, an arrangement that is characteristic of well developed Golgi complexes in many types of cells. In some animal cells the Golgi complex is often located at one side of the nucleus; in other animal and in plant cells there are many Golgi complexes, usually consisting of separate stacks of membranes dispersed throughout the cell. Cells that secrete large amounts of glycoproteins have large numbers of Golgi stacks. Golgi complexes of plant cells produce extracellular polysaccharides that are used as components of the cell wall.

The Golgi complex functions principally as an apparatus for processing, sorting, and modifying proteins. Cell biologists have studied the function of the Golgi complex by radioactively labeling newly manufactured amino acids or carbohydrates and observing their movement. Glycoproteins are first located in the rough ER and only later in the Golgi complex. The proteins are transported from the rough ER to the *cis* face of the Golgi complex in small transport vesicles formed from the ER membrane. After the glycoprotein molecules are released into the Golgi complex, they are enclosed in new vesicles that shuttle them from one compartment to another within the Golgi. While moving through the Golgi complex, proteins are modified in different ways, resulting in the formation of complex biological molecules. For example, the carbohydrate part of the glycoprotein (first added to proteins in the rough ER) may be modified.

In some cases the carbohydrate added to protein within the Golgi complex may be used as a “sorting signal” that routes the protein to a specific organelle. The glycoproteins are then packaged in secretory vesicles in the *trans* region. These vesicles pinch off from the Golgi membrane and transport their contents to a specific destination. Some vesicles fuse with the plasma membrane; the vesicle membrane becomes part of the plasma membrane and the glycoproteins are secreted from the cell. Other vesicles may store glycoproteins for secretion at a later time, while still others are routed to various organelles of the endomembrane system. In animal cells, the Golgi complex also manufactures lysosomes.

Lysosomes are compartments for digestion

Small sacs of digestive enzymes called **lysosomes** are dispersed in the cytoplasm of most eukaryotic cells (Fig. 4–15). The enzymes in these organelles break down complex molecules—lipids, proteins, carbohydrates, and nucleic acids—that originate inside or outside the cell. About 40 different digestive enzymes have been identified in lysosomes; most are active under rather acidic conditions (pH 5). The powerful enzymes and low pH maintained by the lysosome is a good example of the importance of separating functions into different compartments. Under most normal conditions, the lysosome mem-

Figure 4–15 Lysosomes. The dark vesicles in this TEM are lysosomes. These compartments separate powerful digestive enzymes from the rest of the cell. Primary lysosomes bud off from the Golgi complex. After a lysosome encounters material to be digested, it is known as a secondary lysosome. The large vesicles shown here are secondary lysosomes containing various material being digested. (Don Fawcett/Photo Researchers, Inc.)

brane confines its enzymes and their actions. Some forms of tissue damage have been related to “leaky” lysosomes.

Primary lysosomes are formed by budding from the Golgi complex. Their hydrolytic enzymes are synthesized in the rough ER. As these enzymes pass through the lumen of the ER, sugars are attached to each molecule, identifying it. This signal permits the Golgi complex to appropriately sort the enzyme to the lysosomes rather than export it from the cell.

Lysosomes degrade bacteria or debris ingested by scavenger cells. The ingested matter is enclosed in a vesicle formed from part of the plasma membrane. One or more primary lysosomes fuse with the vesicle containing the ingested material, forming a larger vesicle called a *secondary lysosome*. In the secondary lysosome the powerful enzymes come in contact with the ingested molecules and degrade them into their components.

Lysosomal enzymes are also released into the cell in some normal processes. For example, under some conditions lysosomes break down organelles so that their components can be recycled or used as an energy source. Programmed cell death, or **apoptosis**, is a normal part of development and maintenance. For example, during the metamorphosis of a tadpole to a frog, lysosomes break down the cells of the tadpole tail. And during human development, the hand is webbed until, through apoptosis, lysosomes destroy the tissue between the fingers. Cells in the upper layer of human skin and in the intestinal wall are continuously destroyed by apoptosis and replaced by new cells. Inappropriate initiation or inhibition of apoptosis

may contribute to a variety of diseases including cancer, AIDS, and Alzheimer's disease.

In certain genetic diseases of humans, known as lysosomal storage diseases, one of the normally present digestive enzymes is lacking. Its substrate (substance that the enzyme would normally break down) accumulates in the lysosomes, ultimately interfering with cellular activities. An example is Tay-Sachs disease (see Chapter 15), in which a normal lipid cannot be broken down in brain cells. The lipid accumulates in the cells, resulting in mental retardation and death.

Peroxisomes metabolize small organic compounds

Peroxisomes are membrane-bounded organelles containing enzymes that catalyze an assortment of metabolic reactions in which hydrogen is transferred from various compounds to oxygen (Fig. 4–16). During these reactions, hydrogen peroxide (H_2O_2), a substance toxic to the cell, is produced as a byproduct. Peroxisomes contain catalase, an enzyme that splits hydrogen peroxide, rendering it harmless.

Peroxisomes are found in large numbers in cells that synthesize, store, or degrade lipids. In plant seeds, specialized peroxisomes, called **glyoxysomes**, contain enzymes that convert stored fats to sugars. The sugars are used by the young plant as an energy source and as a component needed to synthesize other compounds. Animal cells lack glyoxysomes and cannot convert fatty acids into sugars.

Figure 4–16 Peroxisomes. In this TEM of a tobacco leaf cell, peroxisomes are seen in close association with chloroplasts and mitochondria. These organelles may cooperate in carrying out some metabolic processes. (E.H. Newcomb and S.E. Frederick/Biological Photo Service)

When yeast cells grow in an alcohol-rich medium, they manufacture a large number of peroxisomes. These peroxisomes contain an enzyme that degrades the alcohol. Peroxisomes in human liver and kidney cells detoxify ethanol, the alcohol in alcoholic beverages.

Vacuoles are large, fluid-filled sacs with a variety of functions

Although lysosomes have been identified in almost all kinds of eukaryotic cells, their occurrence in plant and fungal cells is open to debate. Many of the functions carried out in animal cells by lysosomes are performed in plant and fungal cells by a large, single, membrane-bounded sac referred to as the **vacuole**. The vacuolar membrane, part of the endomembrane system, is referred to as the **tonoplast**. The term *vacuole*, which means “empty,” refers to the fact that these organelles have no internal structure. Although the terms *vacuole* and *vesicle* are sometimes used interchangeably, vacuoles are usually larger structures, sometimes produced by the merging of many vesicles.

Vacuoles play a significant role in plant growth and development. Immature plant cells are generally small and contain numerous small vacuoles. As water accumulates in these vacuoles, they tend to coalesce, forming a large central vacuole. A plant cell increases in size mainly by adding water to this central vacuole.

As much as 90% of the volume of a plant cell may be occupied by a large central vacuole containing water, as well as stored food, salts, pigments, and wastes (Figs. 4–8 and 4–10). The vacuole may serve as a storage compartment for inorganic compounds and for molecules such as proteins in seeds. Plants lack organ systems for disposing of toxic metabolic waste products. Wastes may be recycled in the vacuole or they may aggregate and form small crystals inside the vacuole.

Compounds that are noxious to herbivores (animals that eat plants) may also be stored in some plant vacuoles as a means of defense. Plant vacuoles are lysosome-like in their ability to break down unneeded organelles and other cellular components.

Vacuoles have numerous other functions and are also present in many types of animal cells and in single-celled protists. Most protozoa have **food vacuoles** which fuse with lysosomes so that the food they contain can be digested (Fig. 4–17). Many protozoa also have **contractile vacuoles** which remove excess water from the cell (see Chapter 24).

Mitochondria and chloroplasts are energy-converting organelles

When a cell obtains energy from its environment, it is usually in the form of chemical energy in food molecules (such as glucose) or in the form of light energy. These types of energy must be converted to forms that can be used more conveniently by cells. Some energy conversions go on in the cytosol, but other

Figure 4–17 LM of food vacuoles. This protozoan, *Chilodonella*, has ingested many small, photosynthetic protists called diatoms (*dark areas*) that have been enclosed in vacuoles. From the number of diatoms scattered about its cell, one might judge that *Chilodonella* has a rather voracious appetite. (M.I. Walker/Photo Researchers, Inc.)

types take place in mitochondria and chloroplasts, organelles that are specialized to facilitate conversion of energy from one form to another. Chemical energy is most commonly stored in ATP. Recall from Chapter 3 that the chemical energy of ATP can be used to drive a variety of chemical reactions in the cell.

Figure 4–18 summarizes the main activities that take place in mitochondria, found in almost all eukaryotic cells (including algae and plants), and in chloroplasts, found only in algae and certain plant cells. In addition to their central roles in energy metabolism, mitochondria and chloroplasts contain small amounts of DNA, and they provide important clues about the evolution of eukaryotic cells (see *Making the Connection: Mitochondria, Chloroplasts, and Cell Evolution*).

Mitochondria make ATP through cellular respiration

Virtually all eukaryotic cells (plant, animal, fungal, and protist) contain complex organelles called **mitochondria** (sing., *mitochondrion*). These organelles are the site of **aerobic respiration**, a process that includes most of the reactions that convert the chemical energy present in certain foods to ATP (see Chapter 7). Aerobic respiration requires oxygen and results in the release of carbon atoms from food molecules as carbon dioxide (a waste product).

Mitochondria are most numerous in cells that are very active and therefore have high energy requirements. More than 1000 mitochondria have been counted in a single liver cell!

Figure 4–18 Cellular respiration and photosynthesis. In cellular respiration, which takes place in the mitochondria of virtually all eukaryotic cells, the chemical energy of glucose is converted to chemical energy in the form of ATP. Photosynthesis, which is carried out in chloroplasts in some plant and algal cells, converts light energy to ATP and other forms of chemical energy. This energy is used to synthesize glucose from carbon dioxide and water.

Figure 4-19 Mitochondria. Aerobic respiration takes place within mitochondria. Cristae are evident in the TEM as well as in the drawing; the drawing reveals the relationship between the inner and outer mitochondrial membranes. (D.W. Fawcett)

Mitochondria vary in size, ranging from 2 to 8 μm in length and are capable of changing size and shape rapidly. Mitochondria usually give rise to other mitochondria by growth and subsequent division.

Each mitochondrion is bounded by a double membrane, which forms two *different* compartments within the organelle: the intermembrane space and the matrix (Fig. 4-19; see Chapter 7 for more detailed descriptions of mitochondrial structure). The **intermembrane space** is the compartment formed between the outer and inner mitochondrial membranes. The **matrix**, the compartment enclosed by the inner mitochondrial membrane, contains enzymes that break down food molecules and convert their energy to other forms of chemical energy.

The **outer mitochondrial membrane** is smooth and allows many small molecules to pass through it. By contrast, the **inner mitochondrial membrane** has numerous folds and strictly regulates the types of molecules that can move across it. The folds, called **cristae** (sing., *crista*), extend into the ma-

trix, the space enclosed by the inner mitochondrial membrane. Cristae greatly increase the surface area of the membrane, providing a surface for the chemical reactions that transform the chemical energy in food molecules into the energy of ATP. The membrane contains the complex series of enzymes and other proteins needed for these reactions.

In a mammalian cell, each mitochondrion has 5–10 identical, circular molecules of DNA, accounting for up to 1% of the total DNA in the cell. In 1988 two research teams independently linked mutations in mitochondrial DNA with certain genetic diseases. Douglas C. Wallace at Emory University reported that an inherited mutation in a mitochondrial gene was associated with a form of young-adult blindness. Ian J. Holt and his colleagues at the Institute of Neurology in London linked mitochondrial mutations to progressive muscle disorders. Investigators have found evidence for links between mitochondrial mutations and several other diseases, including some cases of Alzheimer's disease and type 2 diabetes.

Chloroplasts convert light energy to chemical energy through photosynthesis

Certain plant and algal cells carry out a complex set of energy conversion reactions known as *photosynthesis* (see Chapters 1 and 8). **Chloroplasts** are organelles that contain **chlorophyll**, a green pigment that traps light energy for photosynthesis. Chloroplasts also contain a variety of yellow and orange, light-absorbing pigments known as **carotenoids** (see Chapter 3). A unicellular alga may have only a single large chloroplast, whereas a leaf cell may have 20 to 100. Chloroplasts tend to be somewhat larger than mitochondria, with lengths typically ranging from about 5 to 10 μm or longer.

Chloroplasts are typically complex disc-shaped structures and, like mitochondria, have a complex system of folded membranes (Fig. 4-20; see Chapter 8 for more detailed descriptions of structure). Two membranes, separated by a small space, separate the chloroplast from the cytosol. The inner membrane encloses a fluid-filled space called the **stroma**, which contains enzymes responsible for producing carbohydrates from carbon dioxide and water, using energy trapped from sunlight. The inner chloroplast membrane may fold inward to form a system of internal membranes, consisting of an interconnected set of flat, disc-like sacs called **thylakoids**. The thylakoids are arranged in stacks called **grana** (sing., *granum*).

The thylakoid membranes enclose a third, innermost compartment within the chloroplast, called the **thylakoid interior space**. The thylakoid membranes, in which chlorophyll is found, are similar to the inner mitochondrial membranes in that they are involved in the formation of ATP. Energy trapped from sunlight by the chlorophyll molecules is used to excite electrons; the energy in these excited electrons is then used to form ATP and other molecules that can transfer chemical energy. This chemical energy is used to produce carbohydrates from carbon dioxide and water in the stroma.

Chloroplasts belong to a group of organelles known as **plastids** that produce and store food materials in cells of plants

MAKING THE CONNECTION

MITOCHONDRIA, CHLOROPLASTS, AND CELL EVOLUTION

What is the evolutionary relationship between prokaryotic cells and the more complex cells of eukaryotes? Mitochondria and chloroplasts have provided valuable insights because these organelles have been shown to have many prokaryote features. For example, although most of the DNA in eukaryotic cells resides in the nucleus, both mitochondria and chloroplasts (as well as other plastids) have DNA molecules in their inner compartments. These DNA molecules code for a small number of the proteins found in these organelles. These proteins are synthesized on mitochondrial or chloroplast ribosomes, which are similar to the ribosomes of prokaryotes. The majority of the mitochondrial and chloroplast proteins, however, are controlled by nuclear genes, manufactured on free ribosomes outside the organelles, and then transported to their appropriate locations within.

The existence of a separate set of ribosomes and DNA molecules in mitochondria and chloroplasts and their similarity in size

to many bacteria, along with other prokaryote-like characteristics, provide support for the **endosymbiont theory** (see Chapter 20). According to this theory mitochondria and chloroplasts evolved from prokaryotic organisms that took up residence inside larger cells, and eventually lost the ability to function as autonomous organisms.

Evolutionary biologists are currently sequencing mitochondrial genes from protists in order to determine the mitochondrion's evolution from bacterium to highly specialized organelle. Evidence suggests that during this process, some genes moved from the early mitochondrion to the nucleus. One such gene codes for a protein known as chaperonin 60 that helps other proteins fold appropriately. Protists that have retained this gene in their mitochondria are thought to have evolved earlier than those in which the chaperonin 60 gene is found in the nucleus.

and algae. All plastids develop from **proplastids**, precursor organelles found in less specialized plant cells, particularly in growing, undeveloped tissues. Depending on the special functions a cell will eventually have, its proplastids can mature into a variety of specialized mature plastids. These are extremely

versatile organelles; in fact, under certain conditions even mature plastids can convert from one form to another.

Chloroplasts are produced when proplastids are stimulated by exposure to light. **Chromoplasts** contain pigments that give certain flowers and fruits their characteristic colors; these at-

Figure 4–20 The chloroplast, organelle of photosynthesis. The TEM shows part of a chloroplast from a corn leaf cell. Chlorophyll and other photosynthetic pigments are found in the thylakoid membranes. Grana in one chloroplast have been cut open to show the thylakoid space. The inner chloroplast membrane may or may not be continuous with the thylakoid membrane (as shown). (E.H. Newcomb and W.P. Wergin/Biological Photo Service)

tract animals as pollinators or as seed dispersers. **Leukoplasts** are unpigmented plastids; they include **amyloplasts** (see Fig. 3–8), which store starch in the cells of many seeds, roots, and tubers (e.g., potatoes).

EUKARYOTIC CELLS CONTAIN A CYTOSKELETON

We have seen that there are many different sizes and shapes of cells. When we watch cells growing in the laboratory, we see that they may change shape and in many cases move about. The shapes of cells and their ability to move are determined in large part by the **cytoskeleton**, a dense network of protein fibers (Fig. 4–21). In addition to providing mechanical support, the cytoskeleton functions in transport of materials within the cell and in cell division.

The cytoskeleton is highly dynamic and constantly changing. Its framework is made of three types of protein filaments: **microtubules**, **microfilaments** (also known as actin filaments), and **intermediate filaments**. Both microfilaments and

Figure 4–21 The cytoskeleton. Eukaryotic cells contain a cytoskeleton consisting of networks of several types of fibers, including microtubules, microfilaments, and intermediate filaments. The cytoskeleton contributes to the shape of the cell, anchors organelles, and sometimes rapidly changes shape during cellular locomotion.

microtubules are fibers formed from beadlike, globular protein subunits, which can be rapidly assembled and disassembled. Intermediate filaments are made from fibrous protein subunits and are more stable than microtubules and microfilaments.

Microtubules are hollow cylinders

Microtubules, the thickest filaments of the cytoskeleton, are about 25 nm in diameter and up to several micrometers in length. In addition to playing a structural role in the formation of the cytoskeleton, these extremely adaptable structures are involved in the movement of chromosomes during cell division. They serve as tracks for several other kinds of intracellular movement and are the major structural components of cilia and flagella—specialized structures used in some cell movements.

Microtubules consist of two very similar proteins: α and β **tubulin**. These proteins combine to form a dimer (recall from Chapter 3 that a dimer forms from the association of two similar, simpler units, referred to as monomers). In 1998, biophysicists Kenneth Downing and Eva Nogales reported in the journal *Nature* that, using electron microscopy, they were able to determine the three-dimensional structure of tubulin. A microtubule elongates by the addition of tubulin dimers (Fig. 4–22). The energy for microtubule elongation is provided by GTP, a molecule similar to ATP. Downing and Nogales found that both α and β tubulin have GTP-binding sites. However, only the GTP bound to β tubulin breaks down to GDP. Each microtubule has polarity, and its two ends are referred to as *plus* and *minus*. The plus end elongates more rapidly. Microtubules can be disassembled by the removal of dimers, which can then be recycled to form microtubules in other parts of the cell.

For microtubules to act as a structural framework or participate in cell movement, they must be anchored to other parts of the cell. In nondividing cells, the minus ends of microtubules appear to extend from regions called **microtubule-organizing centers (MTOC)**. In most eukaryotic cells, the main MTOC is in the **centrosome**, a structure that is important in cell division. In almost all animal cells, the centrosome contains two structures called **centrioles** (Fig. 4–23). These structures, which are at right angles to each other, are known as 9×3 *structures*; they consist of nine sets of three microtubules arranged to form a hollow cylinder. The centrioles are duplicated before cell division and may play a role in some types of microtubule assembly. Most plant cells have a microtubule-organizing center but lack centrioles. This suggests either that centrioles are not essential to most microtubule assembly processes or that alternative assembly mechanisms are possible.

The ability of microtubules to assemble and disassemble rapidly can be seen during cell division, when much of the cytoskeleton appears to break down (see Chapter 9). Many of the tubulin subunits organize into a structure called the **spindle**, which serves as a framework for the orderly distribution of chromosomes when the cell divides.

(a)

50 μm

Figure 4–22 Organization of microtubules. (a) Microtubules are manufactured in the cell by adding dimers of α -tubulin and β -tubulin to an end of the hollow cylinder. Notice that the cylinder has polarity. The end shown at the top of the figure is the fast-growing or plus end; the opposite end is the minus end. Each turn of the spiral requires 13 dimers. (b) Confocal fluorescence LM showing microtubules in green. A microtubule-organizing center (pink dot) is visible near most of the cell nuclei (blue). (b, Nancy Kedersha)

Several **microtubule-associated proteins (MAPs)** have been identified and classified into two groups: fibrous MAPs and motors. *Fibrous MAPs* cross-link microtubules so that they form bundles. Such bundles help form the shapes of many types of cells. *Motors* use ATP energy to produce movement. George Langford of Dartmouth College and other investigators are studying the mechanisms by which the cell moves organelles and other materials within the cell. Nerve cells typically have long extensions called axons that transmit signals to

Centrioles

0.25 mm

Figure 4–23 Centrioles. The TEM is paired with an interpretive drawing. The centrioles are positioned at right angles to each other, near the nucleus of a nondividing animal cell. Note the 9×3 arrangement of microtubules. The centriole on the left has been cut longitudinally and the one on the right transversely. (B.F. King/Biological Photo Service)

other nerve cells, muscle cells, or cells that produce hormones. Because of its length and availability and because other cells have similar mechanisms, investigators have used the axon as a model system to study transport of organelles within the cell. Mitochondria, transport and secretory vesicles, and other organelles attach to microtubules that serve as tracks along which organelles can be moved to different cellular locations.

One motor protein, named *kinesin*, moves organelles toward the plus end of a microtubule (Fig. 4–24). *Dynein*, another motor protein, transports organelles in the opposite direction, toward the minus end. This is referred to as retrograde transport. In 1997, Waterman Storer of the University of Pennsylvania and his colleagues reported that dynein is essential but not sufficient for retrograde transport. These investigators determined that a protein complex called dynactin is required.

Figure 4-24 Hypothetical model of a kinesin motor. A kinesin molecule attaches to a specific receptor on the vesicle. Energy from ATP allows the kinesin molecule to change its conformation and “walk” along the microtubule, carrying the vesicle along.

Dynactin binds to both microtubules and dynein and appears to function in transport, linking the organelle, microtubule, and dynein.

Cilia and flagella are composed of microtubules

Projecting from surfaces of many cells are thin, movable structures important in cell movement. If a cell has one, or only a few, of these appendages and if they are relatively long (up to 1 mm or longer) relative to the size of the cell, they are called

flagella (sing., *flagellum*). If the cell has many short (typically 2–10 μm long) appendages, they are called **cilia** (sing., *cilium*). Both cilia and flagella are used by cells to move through a watery environment or to pass liquids and particles across the cell surface. These structures are commonly found on unicellular and small multicellular organisms. In animals and certain plants, flagella serve as the tails of sperm cells. In animals cilia commonly occur on the surfaces of cells that line internal ducts of the body (e.g., respiratory passageways).

Eukaryotic cilia and flagella are structurally alike. Each consists of a slender, cylindrical stalk covered by an extension of the plasma membrane. The core of the stalk contains a group of microtubules arranged so that there are nine attached pairs of tubules around the circumference and two unpaired microtubules in the center (Fig. 4-25). This $9 + 2$ arrangement of microtubules is characteristic of virtually all eukaryotic cilia and flagella, another example of the unity of organisms that reflects their common origin.

The microtubules move by sliding in pairs past each other. The sliding force is generated by dynein proteins, which are attached to the microtubules like small arms. These proteins use the energy from ATP to power the cilia or flagella. The dynein proteins (arms) on one pair of tubules change their shape and “walk” along the adjacent pair. Thus, the microtubules on one side of a cilium or a flagellum extend farther toward the tip than those on the other side. This sliding of microtubules translates into a bending motion (Fig. 4-25*b*). Cilia typically move like oars, alternating power and recovery strokes and exerting a force that is parallel to the cell surface. A flagellum moves like a whip, exerting a force perpendicular to the cell surface.

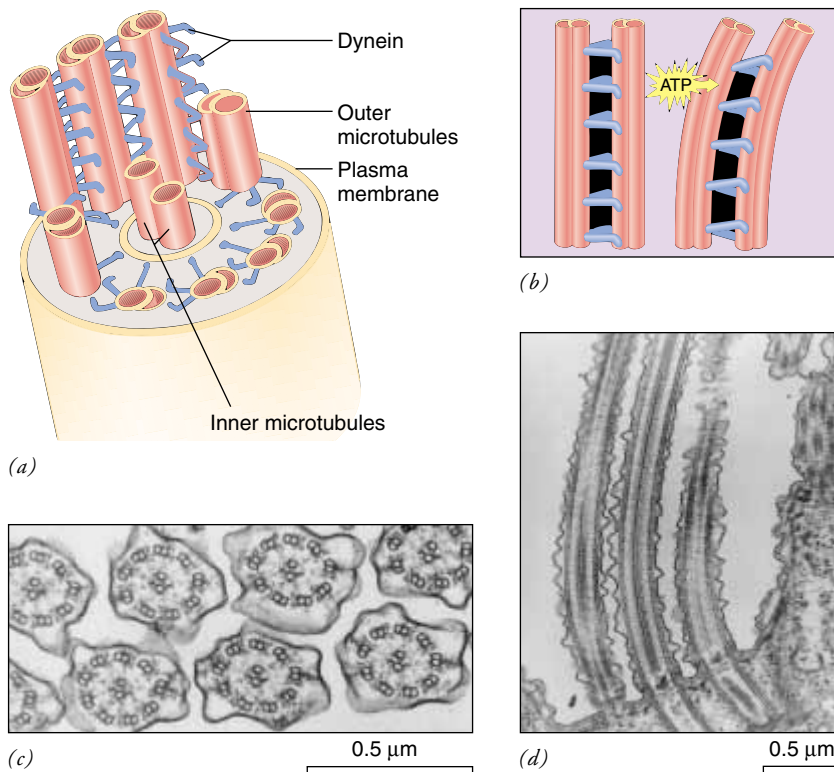

Figure 4-25 Structure of cilia. A cilium (or flagellum) contains microtubules in a $9 + 2$ arrangement. (a) This three-dimensional representation shows nine attached microtubule pairs (doublets) arranged in a cylinder, with two unattached microtubules in the center. The “arms” are made of dynein, a motor protein that uses energy from ATP to bend the cilia by “walking” up and down the neighboring pair of microtubules. The dynein arms, shown widely spaced for clarity, are actually much closer together along the longitudinal axis. (b) The dynein arms move the microtubules by forming and breaking cross bridges on the adjacent microtubules, so that one tubule “walks” along its neighbor. (c) TEM of cross sections through cilia showing the $9 + 2$ arrangement of microtubules. (d) TEM of a longitudinal section of three cilia of the protist *Tetrahymena*, an organism often used in genetic research. Some of the interior microtubules are visible. (c, d, W.L. Dentler/Biological Photo Service)

Each cilium or flagellum is anchored in the cell by a **basal body**, which has nine sets of three microtubules in a cylindrical array (a 9×3 structure). The basal body appears to be the organizing structure for the cilium or flagellum when it first begins to form. However, experiments have shown that as growth proceeds, the tubulin subunits are added much faster to the tips of the microtubules than to the base. Basal bodies and centrioles appear to be functionally related as well as structurally similar. In fact, centrioles are typically found in the cells of organisms that are capable of producing flagellated or ciliated cells; these include animals, certain protists, and a few plants. Both basal bodies and centrioles give rise to new basal bodies and centrioles.

Microfilaments consist of intertwined strings of actin

Microfilaments, also called actin filaments, are flexible, solid fibers about 7 nm in diameter. Each microfilament consists of two intertwined strings of beadlike **actin** molecules (Fig.

(a)

100 μm

(b)

Figure 4–26 Microfilaments. (a) Many bundles of aggregated microfilaments (green) are evident in this confocal fluorescence LM of fibroblasts (cells found in connective tissue). (b) An individual microfilament consists of two intertwined strings of beadlike actin molecules. (a, Nancy Kedersha/ImmunoGen, Inc.)

4–26). Actin molecules cross-link with one another and with other proteins to form bundles of fibers that provide mechanical support for various cell structures. In many cells, a network of microfilaments can be seen just inside the plasma membrane.

In muscle cells, actin is associated with another protein, myosin, to form fibers that generate the forces involved in muscle contraction (see Chapter 38). In nonmuscle cells, actin can also associate with myosin, forming contractile structures that are involved in various cell movements. Actin filaments themselves cannot contract, but they can generate movement by rapidly assembling and disassembling. Actin filaments associated with myosin are involved in transient functions, such as cell division in animals, in which contraction of a ring of actin associated with myosin causes the constriction of the cell to form two daughter cells (see Chapter 9). Certain organelles in the giant axons of the squid move along microfilaments. A type of myosin appears to be the motor for this transport.

Many types of cells have **microvilli**, projections of the plasma membrane that increase the surface area of the cell for transporting materials across the plasma membrane. Microvilli contain bundles of microfilaments, and they extend and retract as a result of the building and breaking down of these microfilaments.

Intermediate filaments help stabilize cell shape

Intermediate filaments are very stable, tough fibers made of polypeptides that can vary widely in size among different cell types and different species of animals. Typically, they are 8 to 10 nm in diameter. These fibers are thought to help strengthen the cytoskeleton, stabilizing cell shape. They are abundant in parts of a cell that may be subject to mechanical stress. It is not clear whether intermediate filaments are involved in cellular functions beyond their structural role.

The assembly of intermediate filaments is probably irreversible; unpolymerized subunits are not abundant in cells. Cells may be able to regulate the length of intermediate filaments, however, by use of enzymes that break down their polypeptides into smaller fragments.

Intermediate filaments form a sheath called the **nuclear lamina**, just inside the nuclear envelope. These filaments are important in the disorganization and reorganization of the nucleus during cell division.

AN EXTRACELLULAR MATRIX SURROUNDS MOST CELLS

Most eukaryotic cells are surrounded by a **glycocalyx**, or **cell coat**, formed by polysaccharide side chains of proteins and lipids that are part of the plasma membrane. Certain mole-

Figure 4–27 Extracellular matrix (ECM). Fibronectins, glycoproteins of the ECM, bind to integrins and other receptors in the plasma membrane.

cules of the cell coat permit cells to recognize one another, make contact, and in some cases to form associations. Other molecules of the cell coat contribute to the mechanical strength of multicellular tissues.

Many animal cells are also surrounded by an **extracellular matrix (ECM)**, consisting of a gel of carbohydrates and fibrous proteins (Fig. 4–27). The main structural protein in the ECM is **collagen**, which forms very tough fibers. Certain glycoproteins of the ECM, called **fibronectins**, bind to protein receptors that extend from the plasma membrane. The main membrane receptors for the ECM are **integrins**. These proteins have a variety of functions, including anchoring the external ECM to the microfilaments of the internal cytoskeleton. Binding of proteins to integrins also appears to be important in cell movement and in organizing the cytoskeleton so that cells assume a definite structure.

Most bacteria, fungi, and plant cells are surrounded by a **cell wall** and proteins. Plant cells are surrounded by thick cell walls that contain multiple layers of the polysaccharide **cellulose** (see Fig. 3–9). Other polysaccharides in the plant cell wall form cross links between the bundles of cellulose fibers. Each cellulose fiber layer runs in a different direction from the adjacent layer, giving the cell wall great mechanical strength.

A growing plant cell secretes a thin, flexible **primary cell wall**, which can stretch and expand as the cell increases its size (Fig. 4–28). After the cell stops growing, either new wall material is secreted that thickens and solidifies the primary wall or multiple layers of a **secondary cell wall** with a different chemical composition are formed between the primary wall and the plasma membrane. Wood is made mainly of secondary cell walls. Between the primary cell walls of adjacent cells lies the

middle lamella, a layer of gluelike polysaccharides called **pectins**. The middle lamella causes the cells to adhere tightly to one another.

Figure 4–28 Plant cell walls. The cell walls of two adjacent plant cells are labeled in this TEM. The cells are cemented together by the middle lamella, a layer of gluelike polysaccharides called pectins. A growing plant cell first secretes a thin primary wall that is flexible and can stretch as the cell grows. The thicker layers of the secondary wall are secreted inside the primary wall after the cell stops growing. (Biophoto Associates)

SUMMARY WITH SELECTED KEY TERMS

- I. The **cell** is considered the basic unit of life because it is the smallest self-sufficient unit of living material.
- II. The **cell theory** states that organisms are composed of cells and that all cells arise by division of preexisting cells.
- III. Every cell is surrounded by a **plasma membrane** that forms a cytoplasmic compartment, inside of which are found the contents of the cell.
 - A. All cells have genetic material in the form of **DNA**.
 - B. Cells have internal structures called **organelles**.
 - C. A critical factor in determining cell size is the ratio of the plasma membrane (surface area) to the cell's volume; the plasma membrane must be large enough to regulate the passage of materials into and out of the cell.
 - D. Cell size and shape are related to function and are limited by the need to maintain homeostasis.
- IV. Biologists have learned much about cellular structure by studying cells with **light microscopes** and **electron microscopes** and with a variety of chemical methods.
 - A. The electron microscope has superior **resolving power**, enabling investigators to see details of cell structures not observable with conventional microscopes.
 - B. Cell biologists use **cell fractionation** techniques and other biochemical methods to gain information about the function of cellular structures.
- V. **Prokaryotic cells** are bounded by a plasma membrane and have a **nuclear area**, but a membrane-bounded nucleus is absent; these cells have little or no internal membrane organization. Prokaryotes typically have a **cell wall** and **ribosomes** and may have **flagella** (sing., **flagellum**).
- VI. **Eukaryotic cells** have a membrane-bounded **nucleus** and **cytoplasm**, which is organized into organelles; the fluid component of the cytoplasm is the **cytosol**.
 - A. Plant cells differ from animal cells in that they possess rigid cell walls, **plastids**, and large **vacuoles**; cells of most plants lack centrioles.
 - B. Membranes divide the cell into membrane-bounded compartments that allow cells to conduct specialized activities within small areas of the cytoplasm, concentrate molecules, and organize metabolic reactions. A network of membranes forms the **endomembrane system**. Small membrane-bounded sacs, called **vesicles**, transport materials between compartments.
 - C. The nucleus, the control center of the cell, contains genetic information in the form of DNA.
 1. The nucleus is bounded by a **nuclear envelope** consisting of a double membrane perforated with **nuclear pores** that communicate with the cytoplasm.
 2. DNA in the nucleus associates with protein to form **chromatin**. During cell division, chromatin condenses and the chromosomes become visible.
 3. The **nucleolus** is a region in the nucleus that is the site of ribosomal RNA synthesis and ribosome assembly.
 - D. The **endoplasmic reticulum (ER)** is a network of folded internal membranes with many functions.
 1. **Rough ER** is studded along its outer walls with ribosomes, which manufacture proteins. Proteins synthesized on rough ER can be transferred to other cell membranes or secreted from the cells by **transport vesicles**, which are formed by membrane budding.
 2. **Smooth ER** is the site of lipid synthesis and detoxifying enzymes.
- E. The **Golgi complex** consists of stacks of flattened membranous sacs that process, sort, and modify proteins synthesized on the ER. It adds carbohydrates and lipids to proteins and can route proteins, by way of **secretory vesicles**, to the plasma membrane for export from the cell, or to other destinations. The Golgi complex also manufactures lysosomes.
- F. **Lysosomes** function in intracellular digestion; they contain enzymes that break down both worn-out cell structures and substances taken into cells.
- G. **Peroxisomes** are membrane-bounded sacs that contain enzymes that catalyze a variety of reactions in which hydrogen peroxide is formed as a byproduct. Peroxisomes contain catalase, an enzyme that splits hydrogen peroxide.
- H. Vacuoles are important in plant growth and development. Many protists have **food vacuoles** and **contractile vacuoles**. Vacuoles may be formed by the merging of many vesicles.
- I. **Mitochondria**, the sites of aerobic respiration, are double-membrane organelles in which the inner membrane is folded, forming **cristae** that increase the surface area of the membrane. The cristae and the compartment enclosed by the inner membrane, the **matrix**, contain enzymes for the reactions of cellular respiration.
- J. Cells of algae and plants contain plastids; **chloroplasts**, the sites of photosynthesis, are double-membraned plastids. Typically, the inner membrane encloses a fluid-filled space, the **stroma**, and stacks, called **grana**, of disclike sacs, the **thylakoids**. **Chlorophyll**, the green pigment that traps light energy during **photosynthesis**, is found in the thylakoid membranes.
- VII. The **cytoskeleton** is a dynamic internal framework made of at least three types of fibers: microtubules, microfilaments, and intermediate filaments. The cytoskeleton provides structural support and functions in various types of cell movement, including transport of materials in the cell.
 - A. **Microtubules** are hollow cylinders assembled from subunits of the protein **tubulin**.
 1. In cells that are not dividing, the minus ends of microtubules appear to be anchored in **microtubule-organizing centers (MTOCs)**. The main MTOC is the **centrosome**. In most animal cells the centrosome contains two **centrioles**. Each centriole has a 9×3 arrangement of microtubules.
 2. **Microtubule-associated proteins (MAPs)** include fibrous MAPs and motors. Two motor proteins are kinesin and dynein.
 3. **Cilia** and flagella are important in cell movement. Each consists of a $9 + 2$ arrangement of microtubules, and each is anchored in the cell by a **basal body** that has a 9×3 organization of microtubules.
 - B. **Microfilaments**, or **actin filaments**, formed from subunits of the protein actin, are important in cell movement.
 - C. **Intermediate filaments** are stable structures formed from several different types of protein; they are thought to stabilize cell shape.
- VIII. Most cells are surrounded by a **glycocalyx**, or **cell coat**, formed by polysaccharides extending from the plasma membrane.
 - A. Many animal cells are also surrounded by an **extracellular matrix (ECM)** consisting of carbohydrates and protein. **Fibronectins** are glycoproteins of the ECM that bind to **integrins**—receptor proteins in the plasma membrane.
 - B. Most bacteria, fungi, and plant cells are surrounded by a cell wall made of carbohydrates and protein. Plant cells secrete cellulose and other polysaccharides to form rigid cell walls.

POST-TEST

- The ability of a microscope to reveal fine detail is known as (a) magnification (b) resolving power (c) cell fractionation (d) scanning electron microscopy (e) phase contrast
- A plasma membrane is characteristic of (a) all cells (b) prokaryotic cells only (c) eukaryotic cells only (d) animal cells only (e) eukaryotic cells except for plant cells
- Detailed information about the shape and external features of a specimen can best be obtained by using a (a) differential centrifuge (b) fluorescence microscope (c) transmission electron microscope (d) scanning electron microscope (e) light microscope
- In eukaryotic cells DNA may be found in (a) chromosomes (b) chromatin (c) mitochondria (d) answers a, b, and c are correct (e) answers a and b only are correct
- Which of the following structures would NOT be found in prokaryotic cells? (a) cell wall (b) ribosomes (c) nuclear area (d) nucleus (e) flagellum
- Which of the following is most closely associated with protein synthesis? (a) ribosomes (b) smooth ER (c) mitochondria (d) microfilaments (e) lysosomes
- Which of the following is most closely associated with the breakdown of ingested material? (a) ribosomes (b) smooth ER (c) mitochondria (d) microfilaments (e) lysosomes
- Which of the following is most closely associated with photosynthesis? (a) basal bodies (b) smooth ER (c) cristae (d) thylakoids (e) MTOCs
- A 9 + 2 arrangement of microtubules best describes (a) cilia (b) centrosomes (c) basal bodies (d) microfilaments (e) microvilli
- Which sequence most accurately describes information flow in the eukaryotic cell? (a) DNA in nucleus → messenger RNA → ribosomes → protein synthesis (b) DNA in nucleus → ribosomal RNA → mitochondria → protein synthesis (c) RNA in nucleus → messenger DNA → ribosomes → protein synthesis (d) DNA in nucleus → messenger RNA → Golgi complex → protein synthesis (e) DNA in nucleus → messenger RNA → smooth ER → protein synthesis
- Which sequence most accurately describes glycoprotein processing in the eukaryotic cell? (a) smooth ER → transport vesicle → *cis* region of Golgi → *trans* region of Golgi → plasma membrane or other organelle (b) rough ER → transport vesicle → *cis* region of Golgi → *trans* region of Golgi → plasma membrane or other organelle (c) rough ER → transport vesicle → *trans* region of Golgi → *cis* region of Golgi → plasma membrane or other organelle (d) rough ER → nucleus → *cis* region of Golgi → *trans* region of Golgi → plasma membrane or other organelle (e) smooth ER → transport vesicle → *cis* region of Golgi → chloroplast
- Which of the following are part of the cytoskeleton? (a) microfilaments (b) lysosomes (c) peroxisomes (d) ribosomes (e) endoplasmic reticulum
- Which of the following function in cell movement? (a) microtubules (b) cristae (c) grana (d) smooth ER (e) rough ER

REVIEW QUESTIONS

- Describe the basic needs of all living things and explain how a cell is able to meet these needs. Why is the cell theory important to an understanding of how living things function?
- Compare and contrast prokaryotic and eukaryotic cells.
- Draw a chloroplast and a mitochondrion. Label the membranes and their compartments.
- Describe the functions of each of the following
 - ribosomes
 - smooth endoplasmic reticulum
 - Golgi complex
 - microtubules
- Trace the path of a protein from its site of synthesis to its final destination for the following
 - a secreted protein
 - a protein found inside a lysosome
 - a protein associated with the plasma membrane
- Contrast microfilaments and microtubules. Compare their structures and the different roles they play in cell structure and function.
- Why are lysosomes sometimes referred to as the “self-destruct system” of the cell?
- Describe plant cell walls. How are they formed?
- Label the diagrams of the animal and plant cell. How is the structure of each organelle related to its function? Use Figures 4–8 and 4–9 to check your answers.

YOU MAKE THE CONNECTION

1. Why does a eukaryotic cell need both membranous organelles and fibrous cytoskeletal components?
2. Describe three examples illustrating the correlation between cell structure and function. (*Hint*: Think of mitochondrial structure.)
3. The *Acetabularia* experiments described in this chapter suggest that DNA is much more stable in the cell than messenger RNA. Is this advantageous or disadvantageous to the cell? Why? How can *Acetabularia* live for a few days after its nucleus is removed?

CHAPTER 5

Biological Membranes

To carry out the many chemical reactions necessary to sustain life, a cell must maintain an appropriate internal environment. The plasma membrane that surrounds every cell physically separates the cell from the outside world and defines the cell as a distinct entity. The plasma membrane helps maintain a life-supporting internal environment by regulating the passage of materials into and out of the cell. Many biologists view the evolution of biological membranes as an essential step in the origin of life. One can argue further that membranes made the evolution of complex cells possible because the extensive internal membranes of eukaryotes form multiple compartments with unique environments for highly specialized activities.

Cell biologists have found that biological membranes are not inanimate walls; they are complex and dynamic structures made from lipid and protein molecules that are in constant motion. The unusual properties of membranes allow them to perform many functions in addition to defining the cell as a compartment and regulating passage of materials. These functions include participating in many chemical reactions, transmitting signals and information between the environment and the interior of the cell, and acting as an essential part of energy transfer and storage systems (see Chapters 7 and 8).

One exciting area of cell membrane research focuses on membrane proteins. Many proteins associated with the plasma membrane are enzymes. Others function in transport of materials or in transfer of information. Still others are important in connecting cells to one another to form tissues. Investigators are studying how membrane proteins function in health and disease. The human skin cells shown in the photograph were grown in culture and stained with fluorescent antibodies. Membrane proteins known as cadherins are seen as green belts around each cell in this sheet of cells. These proteins are responsible for calcium-dependent adhesion between cells that form sheets. An absence of these proteins has been observed when cells become malignant. (In the cells shown in the photograph, the nuclei appear as blue spheres; myosin in the cell appears red.)

(Nancy Kedersha)

In this chapter, we first consider what is known about the composition and structure of biological membranes. We also consider how information can cross the plasma membrane through a signal relay system. We then survey how various materials, ranging from simple to complex molecules, and even particles, move across membranes. Finally, specialized structures that permit interactions between membranes of different cells are examined. Although most of our discussion centers on the structure and functions of plasma membranes, most of the concepts are also applicable to other membranes of the cell.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Evaluate the importance of membranes to the cell, emphasizing their various functions.
2. Make a detailed sketch of the fluid mosaic model of cell membrane structure.
3. Explain how the properties of the lipid bilayer are responsible for many of the physical properties of a cell membrane.
4. Explain how the various classes of membrane proteins associate with the lipid bilayer and discuss the different roles of membrane proteins.
5. Contrast the physical processes of simple diffusion and osmosis with the carrier-mediated physiological processes by which materials are transported across cell membranes.
6. Solve simple problems involving osmosis; for example, predict whether cells will swell or shrink under various osmotic conditions.
7. Summarize the main ways that small hydrophilic molecules can move across membranes.
8. Differentiate between the processes of facilitated diffusion and active transport and discuss the ways in which energy is supplied to active transport systems.
9. Compare endocytotic and exocytotic transport mechanisms.
10. Describe the structures and compare the functions of desmosomes, tight junctions, gap junctions, and plasmodesmata.

BIOLOGICAL MEMBRANES ARE LIPID BILAYERS WITH ASSOCIATED PROTEINS

Long before the development of the electron microscope, it was known that membranes are composed of both lipids and proteins. Work by researchers in the 1920s and 1930s had provided clues that the core of cell membranes is composed of lipids, mostly phospholipids (see Chapter 3).

Phospholipids form bilayers in water

Phospholipids are primarily responsible for the physical properties of biological membranes. This is because certain phospholipids have unique attributes, including features that allow them to form bilayered structures. A phospholipid contains two fatty acid chains linked to two of the three carbons of a glycerol molecule. The fatty acid chains make up the nonpolar, hydrophobic (“water-fearing”) portion of the phospholipid. Bonded to the third carbon of the glycerol is a negatively charged, hydrophilic (“water-loving”) phosphate group, which in turn is linked to a polar, hydrophilic organic group. Molecules of this type, which have distinct hydrophobic and hydrophilic regions, are called **amphipathic** molecules. All lipids that make up the core of biological membranes have amphipathic characteristics.

Because one end of each phospholipid associates freely with water and the opposite end does not, the most stable orientation for them to assume in water results in the formation of a bilayer structure (Fig. 5–1). This arrangement allows the hydrophilic heads of the phospholipids to be in contact with the aqueous medium, while their oily tails, the hydrophobic fatty acid chains, are buried in the interior of the structure away from the water molecules.

Amphipathic properties alone do not predict the ability of lipids to associate as a bilayer. Shape is also important. Phospholipids tend to have uniform widths; their roughly cylindrical shapes, together with their amphipathic properties, are responsible for bilayer formation. In summary, phospholipids form bilayers because the molecules have (1) two distinct re-

gions, one strongly hydrophobic and the other strongly hydrophilic (making them strongly amphipathic), and (2) cylindrical shapes that allow them to associate with water most easily as a bilayer structure.

Many common detergents are amphipathic molecules, each containing a single hydrocarbon chain (like a fatty acid) at one end and a hydrophilic region at the other. These molecules are roughly cone-shaped, with the hydrophilic end forming the broad base and the hydrocarbon tail leading to the point. Because of their shapes, these molecules do not associate as bilayers but instead tend to form spherical structures in water (Fig. 5–1). Detergents are able to “solubilize” oil because the oil molecules associate with the hydrophobic interiors of the spheres.

Current data support a fluid mosaic model of membrane structure

By examining the plasma membrane of the mammalian red blood cell and comparing the surface area of the membrane

Figure 5–1 Lipid membranes. The ability of lipids to associate in water depends on their amphipathic properties and their shapes. (a) Detergent molecules are roughly cone-shaped amphipathic molecules that associate in water as spherical structures. (b) Phospholipids associate as bilayers in water because they are roughly cylindrical amphipathic molecules. The hydrophobic fatty acid chains associate with each other and are not exposed to the water. The hydrophilic phospholipid heads are in contact with the water.

Figure 5-2 Two models of membrane structure. (a) According to the Davson-Danielli model, the membrane is a sandwich of phospholipids spread between two layers of protein. Although accepted for more than 20 years, this model was shown to be incorrect. (b) According to the fluid mosaic model, a cell membrane is made up of a fluid lipid bilayer with a constantly changing "mosaic pattern" of associated proteins.

with the total number of lipid molecules per cell, early investigators were able to calculate that the phospholipids are probably arranged so that the membrane is no more than two phospholipid molecules thick. These findings, together with other data, led H. Davson and J.F. Danielli in 1935 to propose a model in which they envisioned a membrane as a kind of "sandwich" consisting of a *lipid bilayer* (a double layer of lipid) between two protein layers (Fig. 5-2a). This very useful model had a great influence on the direction of membrane research for over 20 years. Models are very important in the scientific process; good ones not only explain the available data, but are testable. That is, scientists can use the model to help them develop hypotheses that can be tested experimentally (see Chapter 1).

With the development of the electron microscope in the

1950s, cell biologists were able to see the plasma membrane for the first time. One of their most striking observations was how uniform and thin the membranes are. The plasma membrane is no more than 10 nanometers thick. The electron microscope revealed a three-layered structure, something like a railroad track, with two dark layers separated by a lighter layer (Fig. 5-3). Their findings seemed to support the protein-lipid-protein sandwich model.

During the 1960s, a paradox emerged regarding arrangement of the proteins. It was widely assumed that membrane proteins were very uniform and had shapes that would allow them to lie like thin sheets on the membrane surface. When proteins from membranes were purified by cell fractionation, however, they were found to be far from uniform; in fact, they varied widely in composition and size. Some proteins were

Figure 5-3 TEM of the plasma membrane of a mammalian red blood cell. The plasma membrane separates the cytoplasm (darker region) from the external environment (lighter region). The hydrophilic heads of the phospholipids are seen as the parallel dark lines, while the hydrophobic tails are visible as the light zone between them. (Omikron/Photo Researchers, Inc.)

much larger than investigators had imagined. How could these proteins be arranged to fit within a surface layer of a membrane less than 10 nanometers thick? At first, some investigators attempted to address these objections by modifying the model with the hypothesis that the proteins on the membrane surfaces were a flattened, extended form, perhaps a β -pleated sheet (see Chapter 3).

Other cell biologists found that instead of having sheet-like structures, many membrane proteins are rounded in shape, or globular. Studies of a number of individual membrane proteins showed that one region (or domain) of the molecule could always be found on one side of the bilayer, while another part of the protein might be located on the opposite side. It appeared that, rather than forming a thin surface layer, many membrane proteins extend completely through the lipid bilayer. Thus, membranes appear to contain many different types of proteins of different shapes and sizes that are associated with the bilayer in a mosaic pattern.

In 1972, S.J. Singer and G.L. Nicolson proposed a model of membrane structure that represented a synthesis of the known properties of biological membranes. According to their **fluid mosaic model**, a cell membrane consists of a fluid bilayer of phospholipid molecules in which the proteins are embedded or otherwise associated, much like the tiles in a mosaic picture. This mosaic pattern is not static, however, because the positions of the proteins are constantly changing as they move about like icebergs in a fluid sea of phospholipids. This model has provided great impetus to research; it has been repeatedly tested and has been shown to accurately predict the properties of many kinds of cell membranes. Figure 5–2*b* depicts the plasma membrane of a eukaryotic cell; prokaryotic plasma membranes are discussed in Chapter 23.

Biological membranes are two-dimensional fluids

An important physical property of phospholipid bilayers is that they behave as *liquid crystals*. The bilayers are crystal-like in that the lipid molecules form an ordered array with the heads on the outside and fatty acid chains on the inside; they are liq-

Figure 5–4 Membrane fluidity. The ordered arrangement of phospholipid molecules makes the cell membrane a fluid crystal. However, the hydrocarbon chains are in constant motion, allowing each molecule to move laterally on the same side of the bilayer.

uid-like in that, despite the orderly arrangement of the molecules, their hydrocarbon chains are in constant motion. Thus molecules are free to rotate and can move laterally within their single layer (Fig. 5–4). Such movement gives the bilayer the property of a *two-dimensional fluid*. Under normal conditions this means that a single phospholipid molecule can travel laterally across the surface of a eukaryotic cell in seconds.

The fluid-like qualities of lipid bilayers also allow molecules embedded in them to move along the plane of the membrane (as long as they are not anchored in some way). This was elegantly demonstrated by David Frye and Michael Edidin in 1970. They conducted experiments in which they followed the movement of membrane proteins on the surface of two cells that had been joined together (Fig. 5–5). When the plasma membranes of a mouse cell and a human cell are fused, within minutes at least some of the membrane proteins from each cell migrate and become randomly distributed over the single continuous plasma membrane that surrounds the joined cells. The experiments of Frye and Edidin demonstrated that the fluidity of the lipids in the membrane allows many of the proteins to move, producing an ever-changing configuration.

If a membrane is to function properly, its lipids must be in a state of optimal fluidity. The structure of a membrane is weakened if its lipids are too fluid. On the other hand, it has been shown that many membrane functions, such as the trans-

Figure 5–5 Mobility of membrane proteins. An elegant series of experiments by Frye and Edidin demonstrated that at least some membrane proteins are highly mobile entities in a two-dimensional fluid. Membrane proteins of mouse cells and human cells were labeled with fluorescent dye markers in two different colors. When the plasma membranes of a mouse cell and a human cell were fused, mouse proteins were observed migrating to the human side and human proteins to the mouse side. After a short time mouse and human proteins became randomly distributed on the cell surface.

port of certain substances, are inhibited or cease if the lipid bilayer is too rigid. At normal temperatures, cell membranes are fluid. However, the motion of the fatty acid chains is slowed at low temperatures. If the temperature decreases to a critical point, the membrane is converted to a more solid gel state.

Certain properties of membrane lipids have significant effects on the fluidity of the bilayer. Recall from Chapter 3 that molecules are free to rotate around single carbon-to-carbon covalent bonds. Because most of the bonds in hydrocarbon chains are single bonds, the chains themselves can undergo very rapid twisting motions that increase as the temperature increases.

The fluid state of the membrane depends on its component lipids. You have probably noticed that when melted butter is left at room temperature, it solidifies. Vegetable oils, however, remain liquid at room temperature. Recall from our discussion of fats in Chapter 3 that butter is a saturated fat, so it has no double bonds in its fatty acids. In contrast, a vegetable oil may be polyunsaturated with two or more double bonds in its fatty acid chains. Double bonds produce “bends” in the molecules that prevent the hydrocarbon chains from coming close together. In this way unsaturated fats lower the temperature at which oil or membrane lipids solidify.

Many organisms have regulatory mechanisms that allow them to maintain their membranes in an optimally fluid state. For example, some organisms that are unable to maintain a constant internal temperature can compensate for temperature changes by altering the fatty acid content of their membrane lipids. When grown at colder temperatures, such organisms are found to have relatively high proportions of unsaturated fatty acids in their membrane lipids.

Some membrane lipids have the ability to help stabilize membrane fluidity within certain limits. One such “fluidity buffer” is cholesterol, a steroid found in animal cell membranes. A cholesterol molecule is largely hydrophobic, but is slightly amphipathic due to the presence of a single hydroxyl group (see Fig. 3–13*a*). This hydroxyl group associates with the hydrophilic heads of the phospholipids; the hydrophobic remainder of the cholesterol molecule fits between the fatty acid hydrocarbon chains (Fig. 5–6).

Figure 5–6 Structure of the cell membrane according to the fluid mosaic model. Although the lipid bilayer consists mainly of phospholipids, other lipids such as cholesterol are present. Peripheral proteins are loosely associated with the bilayer, while integral proteins are tightly bound. The integral proteins shown here are transmembrane proteins that extend through the bilayer. They have hydrophilic regions on both sides of the bilayer, connected by a membrane-spanning α -helix with hydrophobic amino acid side chains (not shown). Glycolipids (carbohydrates attached to lipids) and glycoproteins (carbohydrates attached to proteins) are exposed on the extracellular surface; they play roles in cell recognition and adhesion.

At low temperatures the cholesterol molecules act as “spacers” between the hydrocarbon chains, restricting molecular interactions that would promote solidifying. Cholesterol also helps prevent the membrane from becoming weakened or unstable at higher temperatures. This is because the cholesterol molecules interact strongly with the portions of the hydrocarbon chains closest to the phospholipid head. This interaction restricts motion in these regions. Plant cells have steroids other than cholesterol that carry out similar functions.

Biological membranes fuse and form closed vesicles

Lipid bilayers, particularly those in the liquid-crystalline state, have additional important physical properties. Bilayers tend to resist forming free ends; as a result, they are self-sealing and under most conditions spontaneously round up to form closed vesicles. Fluid bilayers are also flexible, allowing cell membranes to change shape without breaking. Finally, under appropriate conditions lipid bilayers have the ability to fuse with other bilayers.

Membrane fusion is an important cellular process. Recall from Chapter 4 that when a vesicle fuses with another membrane, both membrane bilayers and their compartments become continuous. Various transport and secretory vesicles form from and also merge with membranes of the ER and Golgi complex, allowing materials to be transferred from one compartment to another. A secretory vesicle can fuse with the plasma membrane when a product is secreted from the cell. This process, known as exocytosis, will be discussed later in this chapter. In endocytosis, large molecules are brought into the cell from the outside by the formation of vesicles from the plasma membrane.

Membrane proteins include integral and peripheral proteins

The two major classes of membrane proteins, integral proteins and peripheral proteins, are defined by how tightly they are associated with the lipid bilayer (Fig. 5–6). **Integral membrane proteins** are firmly bound to the membrane. Cell biologists usually can release them only by disrupting the bilayer with detergents. These proteins are amphipathic. Their hydrophilic regions extend out of the cell or into the cytoplasm, while their hydrophobic regions interact with the tails of the membrane phospholipids.

Some integral proteins do not extend all the way through the membrane. Many others, called **transmembrane proteins**, extend completely through the membrane. Some span the membrane only once, while others wind back and forth as many as 24 times. The most common kind of transmembrane protein is an α -helix (see Chapter 3) with hydrophobic amino acid side chains projecting out from the helix into the hydrophobic region of the lipid bilayer (Fig. 5–6).

Peripheral membrane proteins are not embedded in the lipid bilayer. They are located on the inner or outer surfaces of the plasma membrane, usually bound to exposed regions of integral proteins by noncovalent interactions. Peripheral proteins can be easily removed from the membrane without disrupting the structure of the bilayer.

Proteins are oriented asymmetrically across the bilayer

One of the most remarkable demonstrations that proteins are actually embedded in the lipid bilayer comes from freeze-fracture electron microscopy (Fig. 5–7), which enables investiga-

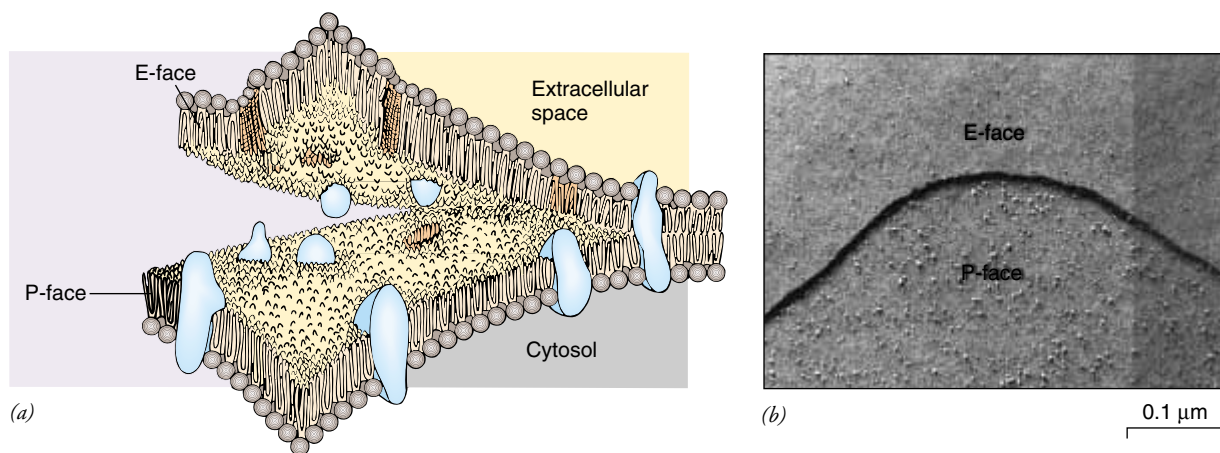

Figure 5–7 Asymmetry of the plasma membrane. (a) In the freeze-fracture method, the path of membrane cleavage is along the hydrophobic interior of the lipid bilayer, resulting in two complementary fracture faces: (1) an inner half-membrane presenting the P-face (or protoplasmic face), from which project the majority of the membrane proteins, and (2) a relatively smooth, outer half-membrane presenting the E-face (or external face), which shows fewer protein particles. In a good fracture, particles are visible on both of the inside faces of the fractured membrane, as shown here. These particles are transmembrane proteins inserted into the lipid bilayer. Freeze-fractured bilayers of lipids alone do not have particles on the fracture planes. (b) A freeze-fracture TEM. Notice the greater number of proteins on the P-face of the membrane. (b, D.W. Fawcett)

tors to literally see the membrane from “inside out.” When cellular membranes are examined in this way, numerous particles are observed on the fracture faces. These particles are clearly integral membrane proteins because they are never seen in freeze-fractured artificial lipid bilayers. These findings profoundly influenced Singer and Nicolson in their development of the fluid mosaic model.

When the two sides of a membrane are compared (as in Fig. 5–7), large numbers of particles are found on one side and very few on the other. This does not necessarily mean that there are more proteins on one side of the membrane than on the other but rather that most are more firmly attached to a given side. Thus, the protein molecules are *asymmetrically oriented*. Each side of a membrane has different characteristics because each type of protein is oriented in the bilayer in only one way. Proteins are not randomly placed into membranes; asymmetry is produced by the highly specific way in which each protein is inserted into the bilayer.

Membrane proteins that will become part of the inner surface of the plasma membrane are manufactured by free ribo-

somes and move to the membrane through the cytoplasm. Membrane proteins that will be associated with the cell’s outer surface are manufactured like proteins destined to be exported from the cell. As discussed in Chapter 4, these proteins are initially formed by ribosomes on the rough endoplasmic reticulum (ER). They pass through the ER membrane into the lumen, where sugars are added, making them glycoproteins. Only a part of each protein passes through the ER membrane, so each completed protein has some regions that are located in the ER lumen and other regions that remain in the cytosol. Enzymes that attach the sugars to certain amino acids on the protein are found only in the lumen of the ER. Thus, carbohydrates can be added only to the parts of proteins that are located in that compartment.

Follow the vesicle budding and membrane fusion events that are part of the transport process from top to bottom in Figure 5–8. You can see that the same region of the protein that protruded into the ER lumen is also transferred to the lumen of the Golgi complex. There additional enzymes further modify the carbohydrate chains. Within the Golgi complex,

Figure 5–8 Formation of plasma membrane. The surface of the rough ER membrane that faces the lumen of the rough ER also faces the lumen of the Golgi complex and vesicles. When a vesicle fuses with the plasma membrane its inner surface becomes the extracellular surface of the plasma membrane. Note that the orientation of a protein in the plasma membrane is also a consequence of the pathway of its synthesis and transport in the cell. Carbohydrates added to proteins in the ER and then modified in the Golgi complex are associated with the extracellular surface of the plasma membrane.

the glycoprotein is sorted and directed to the plasma membrane. The modified region of the protein remains inside a membrane compartment of a secretory vesicle as it buds from the Golgi complex. When the secretory vesicle fuses with the plasma membrane, the carbohydrate chain becomes the part of the membrane protein that extends to the exterior of the cell surface.

ER lumen → transport vesicle → vesicles in Golgi (transport to successive compartments) → secretory vesicle → plasma membrane

Membrane proteins function in transport, information transfer, and as enzymes

Why should a membrane such as the plasma membrane illustrated in Figure 5–6 require so many different proteins? This diversity reflects the number of activities that take place in or on the membrane. Generally, plasma membrane proteins fall into several broad functional groups (Fig. 5–9). Some membrane proteins form junctions between adjacent cells (discussed later in this chapter). Others attach to cytoskeletal elements. For example, the integrins described in Chapter 4 serve as receptors, or docking sites, for proteins of the extracellular matrix and also bind to microfilaments inside the cell.

A number of membrane proteins are involved in the transport of molecules across the membrane. Some form channels that selectively allow the passage of certain ions or molecules. Other proteins form pumps that use ATP to actively transport solutes across the membrane. Some membrane proteins are enzymes that catalyze reactions that take place near the cell surface. In some membranes, for example the mitochondrial or chloroplast membranes, a sequence of enzymes may be organized to regulate a series of reactions such as occurs in cellular respiration or photosynthesis. Some membrane proteins transmit signals to neighboring cells. Membrane proteins can serve as receptors that function in cell recognition, permitting cells to identify each other for such diverse activities as joining cells to form a tissue or for internal defense.

Figure 5–9 Functions of membrane proteins. (a) Cell adhesion proteins attach membranes of adjacent cells and may serve as anchoring points for networks of cytoskeletal elements. (b) Some membrane proteins, for example integrins, anchor the cell to the extracellular matrix and also connect to microtubules within the cell. (c) Transport proteins form channels that allow selective passage of ions or molecules. (d) Some transport proteins pump solutes across the membrane, a process that requires a direct input of energy. (e) Membrane-bound enzymes catalyze reactions that take place within or along the surface of the membrane. (f) Some receptor proteins function in cell recognition. For example, the cells of every human have distinctive MHC receptors that identify them as part of the body; cells of bacteria have different surface proteins that are recognized as foreign and stimulate immune defenses that destroy the bacteria. (g) Some receptors bind with signal molecules such as hormones and transmit information into the cell by signal transduction.

Many receptor proteins receive information from the environment, for example from hormones, and transmit it to the cell interior (see *Making the Connection: Information Transfer across the Plasma Membrane*). Signal molecules may transmit information by **signal transduction**. In this process, the receptor converts an extracellular signal into an intracellular signal that affects some function of the cell.

Each component of a signal transduction system acts as a relay “switch,” which can be in an activated (“on”) state or an inactive (“off”) state. The first component may be a receptor, a transmembrane protein with a domain exposed on the extracellular surface. In a typical sequence of events, the binding of the external signal activates the receptor by changing its shape. The activated receptor then changes the conformation of a second protein, which then becomes activated. Ultimately these interactions result in the activation of a specific enzyme bound to the membrane, which may activate intracellular enzymes or catalyze the production of large numbers of intracellular signal molecules. In this way the original signal received by the receptor protein is amplified many times, and the metabolism of the cell may be profoundly altered.

CELL MEMBRANES ARE SELECTIVELY PERMEABLE

Whether a membrane permits a substance to pass through it depends on the size and charge of the substance and on the composition of the membrane. A membrane is said to be *permeable* to a given substance if it permits that substance to pass through, and *impermeable* if it does not. A **selectively permeable membrane** allows some but not other substances to pass through it readily. In general, biological membranes are most permeable to small molecules and to lipid-soluble substances able to pass through the hydrophobic interior of the bilayer.

Although they are polar (and therefore not lipid-soluble), water molecules can rapidly cross a fluid lipid bilayer. They can pass through a membrane because they are small enough to pass through gaps that occur as a fatty acid chain momentarily moves out of the way. Gases such as oxygen, carbon dioxide, and nitrogen; small polar molecules like glycerol; plus larger, nonpolar (hydrophobic) substances such as hydrocarbons also move through the lipid bilayer rapidly. Slightly larger polar molecules, such as glucose, and charged ions of any size pass through the bilayer much more slowly.

Although the bilayer is relatively impermeable to ions, cells must be able to move ions, as well as large and small polar molecules such as amino acids and sugars, across membranes. The permeability of membranes to those substances is due primarily to the activities of specialized membrane proteins. Biological membranes surrounding cells, nuclei, vacuoles, mitochondria, chloroplasts, and other organelles are selectively permeable to different types of molecules.

In response to varying environmental conditions or cellu-

lar needs, a plasma membrane may be a barrier to a particular substance at one time and actively promote its passage at another time. By regulating chemical traffic in this way, a cell can exert some control over its own internal ionic and molecular composition, which can be very different from that on the outside. In the nonliving world, materials move passively by physical processes such as diffusion. In living organisms, some particles can diffuse across the bilayer, while other materials can be moved rapidly by physiological processes such as active transport, exocytosis, and endocytosis (discussed later in this chapter). Physiological transport mechanisms require a direct expenditure of metabolic energy by the cell.

Random motion of particles leads to diffusion

Some substances pass into or out of cells and move about within cells by simple **diffusion**, a physical process based on random motion. All atoms and molecules possess kinetic energy, or energy of motion, at temperatures above absolute zero (0° Kelvin, -273° Celsius, or -459.4°F). Matter may exist as a solid, liquid, or gas, depending on the freedom of movement of its constituent particles. The particles of a solid are closely packed, and the forces of attraction between them allow them to vibrate but not to move around. In a liquid the particles are farther apart; the attractions are weaker, and the particles move about with considerable freedom. In a gas the particles are so far apart that intermolecular forces are negligible; molecular movement is restricted only by the walls of the container that encloses the gas. This means that atoms and molecules in liquids and gases move in a kind of “random walk,” changing directions as they collide.

Although the movement of the individual particles is undirected and unpredictable, we can nevertheless make predictions about the behavior of groups of particles. If the particles (atoms, ions, or molecules) are not evenly distributed, then at least two regions exist, one with a higher concentration of particles and the other with a lower concentration. Such a difference in the concentration of a substance from one place to another is a **concentration gradient**.

In the phenomenon of diffusion, the random motion of particles results in their net movement “down” their own concentration gradient (from the region of higher concentration to the one of lower concentration). This does not mean that individual particles are prohibited from moving “against” the gradient. However, because there are initially more particles in the region of high concentration, it logically follows that more particles move randomly from there into the low-concentration region than vice versa.

Diffusion can occur rapidly over very short distances. The rate of diffusion is determined by the movement of the particles, which in turn is a function of their size and shape, their electrical charges, and the temperature. As the temperature rises, particles move faster and the rate of diffusion increases.

Particles of different substances in a mixture diffuse independently of each other. If particles are not added to or re-

MAKING THE CONNECTION

INFORMATION TRANSFER ACROSS THE PLASMA MEMBRANE

How can an extracellular hormone or other regulatory molecule transmit information to the cell interior without physically crossing the plasma membrane? Most signal molecules rely on systems of interacting integral membrane proteins to transmit the information by signal transduction. After the **ligand**, a signaling molecule such as a hormone or other regulatory molecule, binds to the membrane receptor, the signal is relayed through a sequence of proteins (see figure). The signaling molecule is sometimes referred to as the first messenger. Often the pathway involves **protein kinases**, enzymes that transfer phosphate groups from ATP to certain proteins. The phosphorylated protein is activated and affects some metabolic activity or brings about some structural change.

Some ligand-receptor complexes bind to and activate certain integral membrane proteins, referred to as **G proteins**. In 1994 Dr. Alfred G. Gilman and Dr. Martin Rodbell were awarded a Nobel Prize for their research on G proteins. These proteins were so named because the active form is bound to GTP, or guanosine triphosphate, a molecule similar to ATP but containing the base guanine instead of adenine. G proteins catalyze the hydrolysis of GTP to GDP, a process that releases energy.

In a complex sequence of events, a G protein relays the message from the receptor to an enzyme such as adenylyl cyclase that catalyzes the production of a **second messenger**, often cyclic AMP. Typically, the second messenger activates protein kinases, enzymes that activate certain proteins by phosphorylating them. This sequence of reactions, beginning with the binding of the signaling molecule to the receptor, leads to a change in some cell function.

G proteins are involved in a number of important signal transductions, including the action of many hormones (see Chapter 47). Some G proteins regulate channels that allow ions to cross the plasma membrane, and still others play important roles in the senses of sight, smell, and taste (see Chapter 41).

Ras proteins, a group of GTP-binding proteins that function somewhat like G proteins, are thought to be important in signal transduction necessary for many cell activities. Fibroblasts (a type of connective tissue cell) require the presence of two growth factors (epidermal growth factor and platelet-derived growth factor) for DNA synthesis. However, when investigators inactivated Ras proteins by injecting antibodies to them into the fibroblasts, the growth factors were no longer effective. Data from this and similar experiments led to the conclusion that Ras is important in signal transduction involving growth factors. Ras links growth factor receptors with a class of enzymes known as serine kinases.

Cell biologists have demonstrated that when certain ligands bind to integrins (transmembrane proteins that connect the cell to the extracellular matrix) in the plasma membrane, certain signal transduction pathways are activated. Growth factors also turn on signaling pathways, and it is thought that growth factors and certain molecules of the extracellular matrix may modulate each other's messages. Integrins also respond to information received from inside the cell. This inside-out signaling affects how selective integrins are about the molecules to which they bind and how strongly they bind to them.

moved from the system, a state of **equilibrium**, a condition of no net change in the system, is ultimately reached. At equilibrium the particles are uniformly distributed.

More commonly in organisms, equilibrium is never attained. For example, carbon dioxide continually forms within a human cell as sugars and other molecules are metabolized during the process of aerobic respiration. Carbon dioxide readily diffuses across the plasma membrane but then is rapidly removed by the blood. This limits the opportunity for the molecules to reenter the cell, so a sharp concentration gradient of carbon dioxide molecules always exists across the membrane. Two special cases of diffusion are dialysis and osmosis.

Dialysis is the diffusion of a solute across a selectively permeable membrane

To demonstrate **dialysis**, one can fill a cellophane bag¹ with a sugar solution and immerse it in a beaker of pure water (Fig. 5–10). If the cellophane membrane is permeable to sugar as

well as to water, both sugar and water molecules will pass through it and the concentrations of sugar molecules in the water on the two sides of the membrane will eventually become equal. Subsequently, both solute and water molecules will continue to cross the membrane, but there will be no net change in their concentrations.

The principle of dialysis has many practical applications. For example, a dialysis machine can be used to cleanse the blood of wastes when the kidneys do not function properly. Waste products in the form of small molecules diffuse readily across the artificial membrane in the dialysis apparatus. Wastes can thus be removed from the blood, while blood cells, blood proteins, and other large molecules are retained.

¹Cellophane is often used as an “artificial membrane.” It is made from cellulose and can be formed into a thin sheet that allows the passage of water molecules. Such membranes can be constructed with varying permeability to different solutes, and can be very different from biological membranes in their permeability. (When cellophane is used to package foods, it is coated to make it impermeable to air and water.)

Transfer of information across the plasma membrane. (a) A signal molecule binds with a receptor in the plasma membrane. (b) The signal molecule-receptor complex activates a G protein. (c) G protein activates an enzyme that catalyzes the production of a second messenger such as cyclic AMP (cAMP). (d) cAMP then activates one or more enzymes such as protein kinases. The enzymes may phosphorylate proteins, which then alter the activity of the cell in some way.

(d)

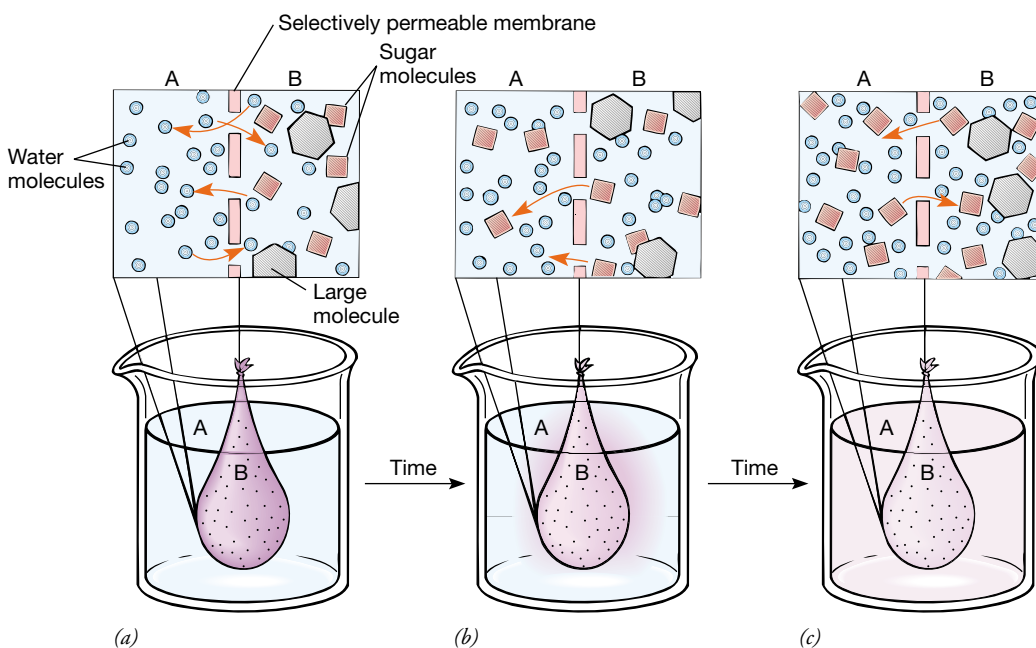

Figure 5-10 Dialysis. (a) A cellophane bag, filled with a mixture of sugar, water, and large molecules such as proteins, is immersed in a beaker of pure water. The cellophane acts as a selectively permeable membrane, permitting passage of the sugar and water molecules (arrows), but preventing passage of larger molecules. (b) The arrows indicate net movement of sugar molecules through the membrane into the water of the beaker. (c) Eventually the sugar becomes distributed equally between the two compartments. Although sugar and water molecules continue to diffuse back and forth (arrows), net movement is zero.

Osmosis is the diffusion of water (solvent) across a selectively permeable membrane

The selective permeability of cell membranes results in another special kind of diffusion called **osmosis**. This process involves the movement of *solvent* (in this case, water) molecules through a selectively permeable membrane. The water molecules pass freely in both directions, but, as in all types of diffusion, *net* movement is from the region where the water molecules are more concentrated to the region where they are less concentrated. Most solute molecules cannot diffuse freely through selectively permeable membranes of the cell.

The principles involved in osmosis can be illustrated using an apparatus called a U-tube (Fig. 5–11). The U-tube is divided into two sections by a selectively permeable membrane that allows solvent (water) molecules to pass freely but excludes solute molecules (e.g., sugar, salt). A water/solute solution is placed on one side, and pure water is placed on the other. The side containing the solute dissolved in the water has a lower effective concentration of water than the pure water side. This is because the solute particles, which are charged (ionic) or polar, interact with the partial electrical charges on the polar water molecules. Many of the water molecules are thus “bound up” and no longer free to diffuse across the membrane.

Because of the difference in effective water concentration, there is net movement of water molecules from the pure water side (with a high effective concentration of water) to the water/solute side (with a lower effective concentration of water). As a result, the fluid level drops on the pure water side and rises on the water/solute side. Because the solute molecules do not diffuse across the membrane, equilibrium is never attained. Net movement of water continues, and the fluid level continues to rise on the side containing the solute. The weight of the rising column of fluid eventually exerts enough pressure to stop further changes in fluid levels, although water molecules continue to pass through the selectively permeable membrane in both directions.

We define the **osmotic pressure** of a solution as the tendency of water to move into that solution by osmosis. In our U-tube example, we could measure the osmotic pressure by inserting a piston on the water/solute side of the tube and measuring how much pressure must be exerted by the piston to prevent the rise of fluid on that side of the tube. A solution with a high solute concentration has a low effective water concentration and a high osmotic pressure; conversely, a solution with a low solute concentration has a high effective concentration of water and a low osmotic pressure.

Two solutions may be isotonic to each other, or one may be relatively hypertonic and the other relatively hypotonic

Dissolved in the fluid compartment of every living cell are salts, sugars, and other substances that give that fluid a certain osmotic pressure. When a cell is placed in a fluid with exactly the same osmotic pressure, no net movement of water mole-

Figure 5–11 Osmosis. The U-tube contains pure water on the right and water plus a solute on the left, separated by a selectively permeable membrane. Water molecules are able to cross the membrane in both directions (red arrows). Solute molecules are unable to cross (green arrows). The fluid level rises on the left and falls on the right because net movement of water (black arrow) is to the left. The force that must be exerted by the piston in order to prevent the rise in fluid level is equal to the osmotic pressure of the solution.

cules occurs, either into or out of the cell. The cell neither swells nor shrinks. Such a fluid is said to be **isotonic**, of equal solute concentration, to the fluid within the cell (Table 5–1). Normally, our blood plasma (the fluid component of blood) and all our other body fluids are isotonic to our cells; they contain a concentration of water equal to that in the cells. A solution of 0.9% sodium chloride (sometimes called *physiological saline*) is isotonic to the cells of humans and other mammals. Human red blood cells placed in 0.9% sodium chloride neither shrink nor swell (Fig. 5–12a).

If the surrounding fluid has a concentration of dissolved substances greater than the concentration within the cell, it has a higher osmotic pressure than the cell and is said to be **hypertonic** to the cell. Because the hypertonic solution has a

TABLE 5-1 Osmotic Terminology

Solute Concentration in Solution A	Solute Concentration in Solution B	Tonicity	Direction of Net Movement of Water
Greater	Less	A hypertonic to B B hypotonic to A	B to A
Less	Greater	B hypertonic to A A hypotonic to B	A to B
Equal	Equal	A and B are isotonic to each other	No net movement

lower effective water concentration, a cell placed in such a solution shrinks as it loses water by osmosis. Human red blood cells placed in a solution of 1.3% sodium chloride shrink and are said to be *crenated* (Fig. 5-12*b*). If a cell that has a cell wall is placed in a hypertonic medium, it loses water to its surroundings. Its contents shrink, and the plasma membrane separates from the cell wall, a process known as **plasmolysis** (Fig. 5-13). Plasmolysis occurs in plants when the soil or water around them contains high concentrations of salts or fertilizers.

If the surrounding fluid contains a lower concentration of dissolved materials than does the cell, it has a lower osmotic pressure and is said to be **hypotonic** to the cell; water then enters the cell and causes it to swell. Red blood cells placed in a solution of 0.6% sodium chloride gain water, swell (Fig. 5-12*c*), and may eventually burst. Many cells that normally live in hypotonic environments have adaptations to prevent excessive water accumulation. For example, certain protists such as *Paramecium* have a contractile vacuole that they use to expel excess water.

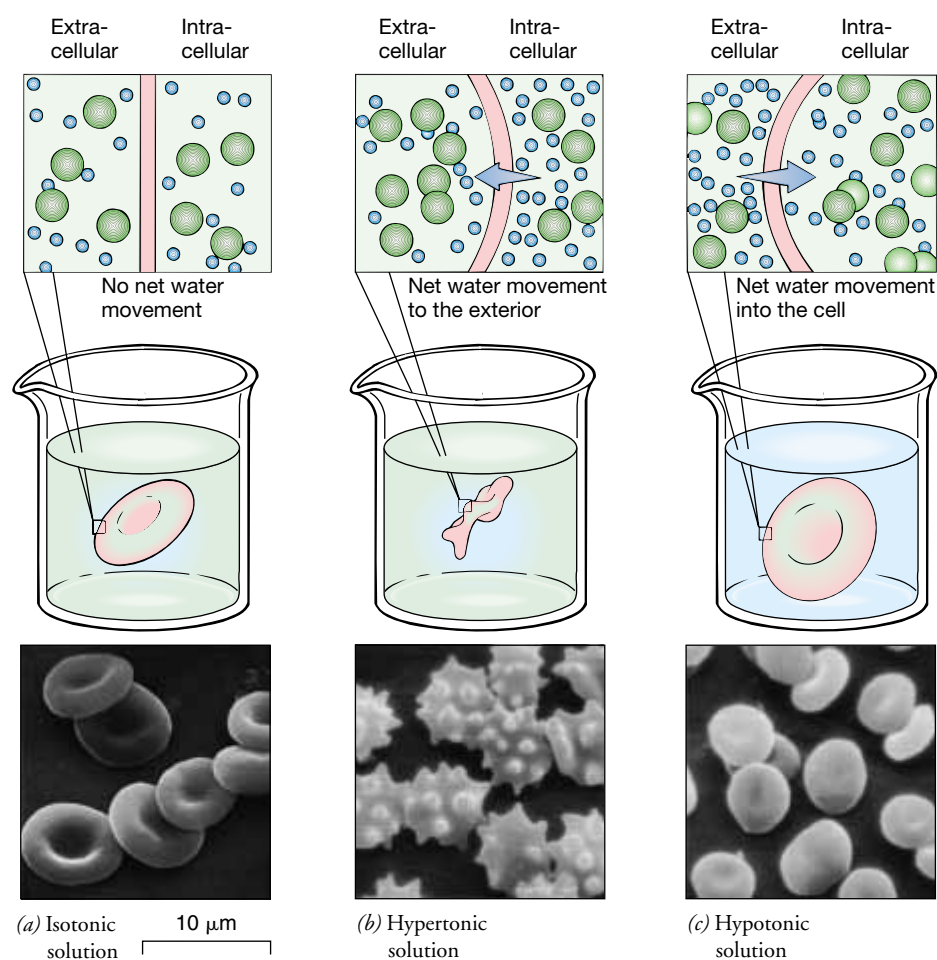

Figure 5-12 How cells respond to osmotic pressure differences. (a) When a cell is placed in an isotonic solution, water molecules pass in and out of the cell, but the net movement is zero. (b) When a cell is placed in a hypertonic solution, there is a net movement of water out of the cell (arrow), and the cell becomes dehydrated, crenated (shrunken), and may die. (c) When a cell is placed in a hypotonic solution, there is a net movement of water molecules into the cell (arrow), causing the cell to swell or even burst. (SEMs of human red blood cells courtesy of Dr. R.F. Baker, University of Southern California Medical School)

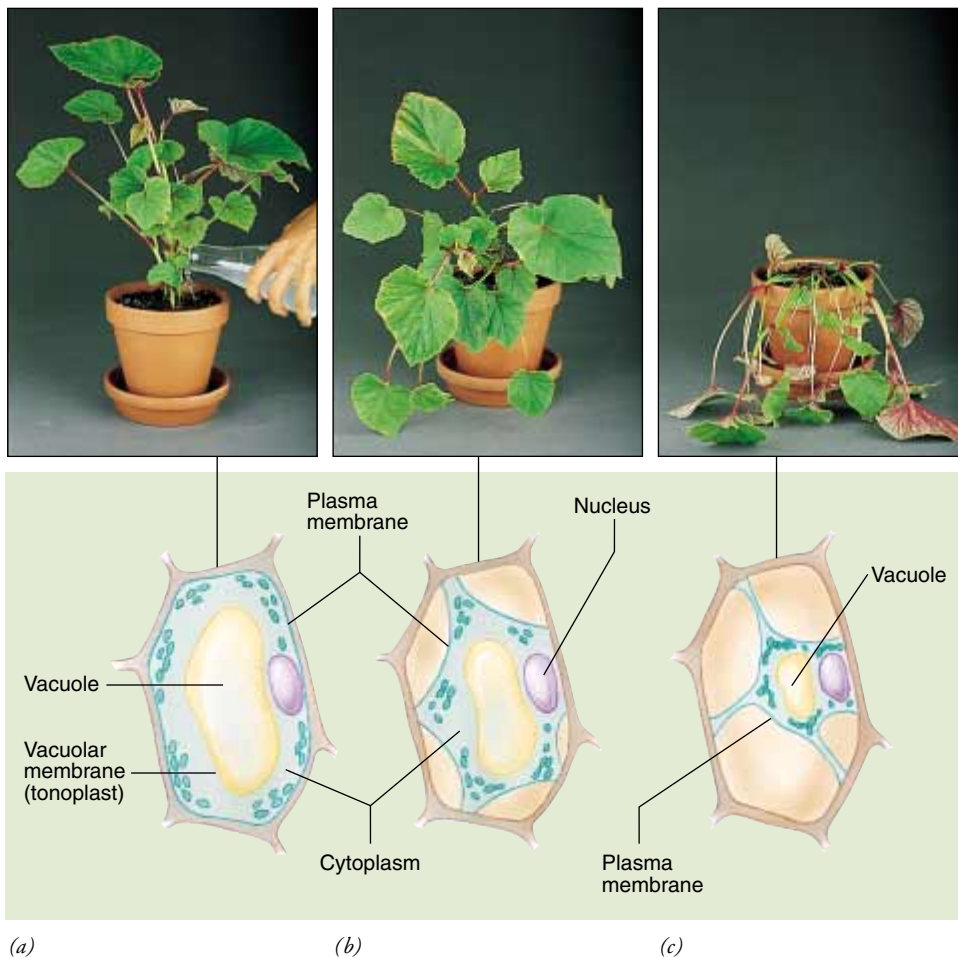

Figure 5-13 Plasmolysis. (a) In hypotonic surroundings, the vacuole of a plant cell fills, but the rigid cell walls prevent the cell from expanding. The cells of this healthy begonia plant are turgid. (b), (c) When the begonia plant is exposed to a hypertonic solution, its cells become plasmolyzed as they lose water. The plant wilts and eventually dies. (Dennis Drenner)

Turgor pressure is the internal hydrostatic pressure usually present in walled cells

The relatively rigid cell walls of plant cells, algae, bacteria, and fungi enable these cells to withstand, without bursting, an external medium that is very dilute, containing only a very low concentration of solutes. Because of the substances dissolved in the cytoplasm, the cells are hypertonic to the outside medium (conversely, the outside medium is hypotonic to the cytoplasm). Water moves into the cells by osmosis, filling their central vacuoles and distending the cells. The cells swell, building up a pressure, termed **turgor pressure**, against the rigid cell walls (Fig. 5-13a). The cell walls can be stretched only very slightly, and a steady state is reached when their resistance to stretching prevents any further increase in cell size and thereby halts the net movement of water molecules into the cells (although, of course, molecules continue to move back and forth across the plasma membrane). Turgor pressure in the cells is an important factor in providing support for the body of nonwoody plants. Thus, lettuce becomes limp in a salty salad dressing and a picked flower wilts from lack of water.

Carrier-mediated transport of solutes requires special integral membrane proteins

A lipid bilayer is relatively impermeable to most large polar molecules. This is advantageous to cells for a number of reasons. Most of the compounds required in metabolism are polar, and the impermeability of the plasma membrane prevents their loss by diffusion. A lipid bilayer is also impermeable to ions, which play important roles in many physiological processes. Some ions, such as calcium ions, are used as intracellular signals, and changes in their cytoplasmic concentration trigger changes in a number of cellular processes (such as muscle contraction; see Chapter 38). As a cell controls the influx and efflux of ions, it is able to directly or indirectly control many metabolic activities (see *Focus On: How the Patch Clamp Technique Has Revolutionized the Study of Ion Channels*).

Cells also must continually acquire essential polar nutrient molecules such as glucose and amino acids. To transport ions and nutrients through membranes, systems of carrier proteins apparently evolved very early in the origin of cells. This transfer of solutes by proteins located within the membrane is

FOCUS ON

HOW THE PATCH CLAMP TECHNIQUE HAS REVOLUTIONIZED THE STUDY OF ION CHANNELS

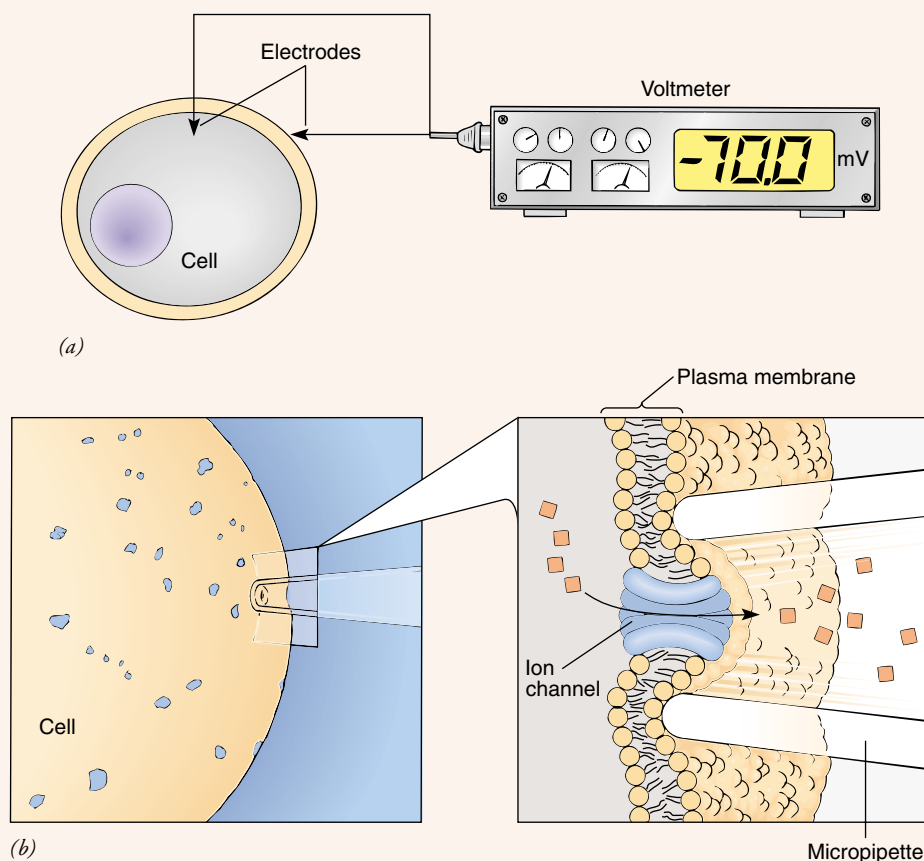

Because of their electrical charges, which provide a basis for various interactions, ions play an essential role in most cellular processes. Their electrical charges, however, prevent them from crossing a lipid bilayer by simple diffusion. For this reason, every membrane of every cell contains numerous ion carriers, or *ion channels*. Some ion channels, referred to as “ion pumps,” require a direct input of metabolic energy, while others provide for facilitated diffusion.

Movement of ions across a membrane can result in a charge difference (electrochemical gradient). If the cell is large enough, this charge difference (usually expressed in millivolts, mV) can be measured

by using two microelectrodes connected to an extremely sensitive oscilloscope or voltmeter (see figure). One of the microelectrodes is inserted into the cell and the other is placed just outside the plasma membrane. Although valuable, these techniques have serious limitations, for they cannot be used on smaller cells and do not provide information on the function of individual ion channels.

In the mid-1970s Erwin Neher and Bert Sakmann developed a method, known as the **patch clamp technique**, that allows researchers to study single ion channels of very small cells. In this technique, a micropipette is tightly sealed to a patch of membrane so small that it generally con-

tains only a single ion channel. The flow of ions through the channel can be measured using an extremely sensitive recording device. This basic technique has been modified in many ways and has been applied to studies of the roles of ion channels in a wide range of cellular processes in both plants and animals. For example, studies of single ion channels enabled researchers to demonstrate that the genetic disease cystic fibrosis (see Chapter 15) is caused by a defect in a specific type of chloride ion channel. Because of the far-reaching implications of their work, Neher and Sakmann were awarded a Nobel Prize in 1991.

Patch clamp technique. (a) The difference in electrical charge across a membrane can be measured using microelectrodes and a voltmeter. (b) A micropipette can be used to form a tight seal with a patch of plasma membrane. The membrane can be pulled away from the rest of the cell, and the flow of ions through a single ion channel can be studied.

termed **carrier-mediated transport**. The two forms of carrier-mediated transport—facilitated diffusion and carrier-mediated active transport—differ in their capabilities and energy sources.

Facilitated diffusion occurs down a concentration gradient

In all processes in which substances move across membranes by passive diffusion, the net transfer of those molecules from one side to the other occurs as a result of a concentration gradient. If the membrane is permeable to a substance, there is net movement from the side of the membrane where it is more highly concentrated to the side where it is less concentrated. Such a gradient across the membrane is actually a form of stored energy. A concentration gradient can be established as a result of certain processes taking place in the cell. The stored energy of the concentration gradient is released when molecules move from a region of high concentration to one of low concentration; movement down a concentration gradient is therefore spontaneous. (These types of energy and spontaneous processes are discussed in greater detail in Chapter 6.)

In the type of transport known as **facilitated diffusion**, the membrane may be made permeable to a solute, such as an ion or a polar molecule, by a specific *carrier* or *transport protein* (Fig. 5–14). An important example of a carrier that works by facilitated diffusion is glucose permease, a transmembrane protein that transports glucose into red blood cells. These cells keep the internal concentration of glucose low by immediately adding a phosphate group to entering glucose molecules, converting them to highly charged glucose phosphates that cannot pass back through the membrane. Because glucose phosphate is a different molecule, it does not contribute to the glucose concentration gradient. Thus a steep concentration gradient for glucose is continually maintained, and glucose

Figure 5–14 Facilitated diffusion. A transport protein in the membrane binds a solute particle. The transport protein changes its shape, opening a channel through the membrane. A specific solute can be transported from the inside of the cell to the outside or from the outside to the inside, but net movement is always from a region of higher solute concentration to a region of lower concentration. The potential energy of a concentration gradient is needed.

rapidly diffuses into the cell, only to be immediately changed to the phosphorylated form.

The mechanism of facilitated diffusion for glucose has been studied by using **liposomes**, artificial vesicles surrounded by phospholipid bilayers. The phospholipid membrane of a liposome does not permit the passage of glucose unless researchers introduce the transport protein glucose permease to the membrane. Glucose permease and similar transport proteins temporarily bind to the molecules they transport. This mechanism appears to be similar to the way an enzyme binds with its substrate, the molecule it regulates (see Chapter 6). And as in enzyme action, binding apparently changes the shape of the carrier. This allows the glucose molecule to be released on the inside of the cell. According to this model, when the glucose is released into the cytoplasm, the transport protein reverts to its original structure and is available to bind another glucose molecule on the outside of the cell.

Another similarity to enzyme action is that transport proteins become saturated when the transported molecule is at high concentration. This may be because there are a finite number of transport molecules available; when the concentrations of solute molecules to be transported reaches a certain level, all of the transport molecules are working.

Some carrier-mediated active transport systems “pump” substances against their concentration gradients

Although adequate amounts of some substances can be transported across cell membranes by diffusion, a cell often needs to move solutes against a concentration gradient. Many substances are required by the cell in concentrations higher than those outside the cell. These molecules are moved across cellular membranes by **carrier-mediated active transport** mechanisms. Because this active transport requires that particles be “pumped” from a region of low concentration to a region of high concentration (i.e., *against a concentration gradient*), transport must be coupled to an energy source such as ATP.

One of the most striking examples of an active transport mechanism is the **sodium-potassium pump** found in virtually all animal cells (Fig. 5–15). The pump is a group of specific proteins in the plasma membrane that uses energy in the form of ATP to exchange sodium ions on the inside of the cell for potassium ions on the outside of the cell. The exchange is unequal, so that usually only two potassium ions are imported inside for every three sodium ions exported. Because these particular concentration gradients involve ions, an electrical potential (separation of electrical charges) is generated across the membrane, and we say that the membrane is polarized.

Both sodium and potassium ions are positively charged, but because there are fewer potassium ions inside relative to the sodium ions outside, the inside of the cell is negatively charged relative to the outside. The action of sodium-potassium pumps helps maintain a charge separation across the plasma membrane. Because there is both a concentration difference and an electrical charge difference on the two sides of

Figure 5–15 The sodium-potassium pump. (a) The sodium-potassium pump is an active transport system that requires energy from ATP. Each complete pumping cycle uses one molecule of ATP; three sodium ions are exported, and two potassium ions are imported. (b) A model illustrating the sodium-potassium pumping cycle. (1) Three sodium ions bind to the transport protein. (2) A phosphate group is transferred from ATP to the transport protein. (3) The transport protein undergoes a conformational change, releasing three sodium ions outside the cell. (4) Two potassium ions bind to the transport protein. (5) The phosphate is released. (6) The transport protein returns to its original shape: two potassium ions are released inside the cell.

the membrane, this gradient is referred to as an *electrochemical* gradient. Such gradients also store energy (like water stored behind a dam) that can be used to drive other transport systems. So important is the electrochemical gradient produced by these pumps that some cells (e.g., nerve cells) expend 70% of their total energy just to power this one transport system.

Sodium-potassium pumps (as well as all other ATP-driven pumps) are transmembrane proteins that extend entirely through the membrane. By undergoing a series of con-

formational changes (that is, changes in shape), the pumps are able to exchange sodium for potassium across the plasma membrane. Unlike facilitated diffusion, at least one of the conformational changes in the pump cycle requires energy, which is provided by ATP. The shape of the pump protein changes as a phosphate group (from ATP) first binds to it and is subsequently removed later in the pump cycle.

The use of electrochemical potentials for energy storage is not confined to the plasma membrane of animal cells. Plant

and fungal cells use ATP-driven plasma membrane pumps to transfer protons from the cytoplasm of their cells to the outside. Removal of positively charged protons from the cytoplasm of these cells results in a large difference in the concentration of protons, such that the outside of the cells is relatively positively charged and the inside of the plasma membrane is relatively negatively charged. The energy stored in these electrochemical gradients can be made available to do certain kinds of cell work.

Other proton pumps can be used in “reverse” to synthesize ATP. As we will discuss in Chapters 7 and 8, bacteria, mitochondria, and chloroplasts use energy from food or from light to establish proton concentration gradients. When the protons diffuse through the proton carriers from a region of high proton concentration to one of low concentration, ATP is synthesized. These electrochemical gradients form the basis for the major energy-conversion system in virtually all cells.

Ion pumps have other important roles. For example, they are instrumental in the ability of an animal cell to equalize the osmotic pressures of its cytoplasm and its external environment. If an animal cell does not control its internal osmotic pressure, its contents will become hypertonic relative to the exterior. Water will enter the cell by osmosis, causing it to swell and possibly burst (see Fig. 5–12*c*). By controlling the ion distribution across the membrane, the cell is able to indirectly control the movement of water, for when ions are pumped out of the cell, water leaves by osmosis.

Linked cotransport systems indirectly provide energy for active transport

The electrochemical concentration gradients generated by the sodium-potassium pump (and other pumps) provide sufficient energy to power the active transport of other essential substances. In these systems a transport protein can **cotransport** the required molecules *against* their concentration gradient, while sodium, potassium, or hydrogen ions move *down* their gradient. Energy from ATP is used indirectly in this process, for it produces the ion gradient; the energy of this gradient is then used to drive the active transport of a required substance against its gradient.

In some cells more than one system may work to transport a given substance. For example, the transport of glucose from the intestine to the blood occurs through a thin sheet of epithelial cells that line the intestine. The surface that is exposed to the intestine has many **microvilli** (sing., *microvillus*), finger-like extensions that effectively increase the surface area of the membrane available for absorption. The glucose transport protein on that region of the cell surface is part of an active transport system for glucose that is “driven” by the cotransport of sodium. The sodium concentration inside the cell is kept low by an ATP-requiring sodium-potassium pump that transports sodium out of the cell and into the blood. Because of its high concentration inside the cell (relative to the blood),

glucose can be transported to the blood by facilitated diffusion.

What are the signals that target each transport protein to its appropriate region? Some of the current research in cell biology focuses on understanding mechanisms such as those that allow the cell to place different transport proteins in separate regions of the same plasma membrane.

Facilitated diffusion is powered by a concentration gradient; active transport requires another energy source

It is a common misconception that diffusion, whether simple or facilitated, is somehow “free of cost” and that only active transport mechanisms require energy. Because diffusion always involves net movement of a substance down its concentration gradient, we say that the concentration gradient “powers” the process. However, energy is required to do the work of establishing and maintaining the gradient. Think back to the example of facilitated diffusion of glucose. The cell maintains a steep concentration gradient (high outside, low inside) by phosphorylating the glucose molecules once they enter the cell. One ATP molecule is spent for every glucose molecule phosphorylated (not to mention such additional costs as the energy required to make the enzymes that carry out the reaction).

An active transport system can work *against* a concentration gradient, pumping materials from a region of low concentration to a region of high concentration. The energy stored in the concentration gradient is not only unavailable to the system, but actually works against it. For this reason some other source of energy must be provided. As we have seen, in many cases ATP energy is used directly. In a cotransport system, energy is provided by a concentration gradient for some other substance (e.g., an ion). Of course, ATP energy is required indirectly to power the pump that produces the ion gradient.

To summarize, both diffusion and active transport require energy. The energy for diffusion is provided by a concentration gradient for the substance being transported. Active transport requires some other, usually more direct, expenditure of metabolic energy.

In exocytosis and endocytosis large particles are transported by vesicles or vacuoles

In both simple and facilitated diffusion, and in carrier-mediated active transport, individual molecules and ions pass through the plasma membrane. Larger quantities of material, such as particles of food or even whole cells, must also be moved into or out of cells. Such work requires that cells expend energy directly, making it a form of active transport.

In **exocytosis**, a cell ejects waste products or specific secretion products such as hormones by the fusion of a vesicle with the plasma membrane (Fig. 5–16). Exocytosis results in the incorporation of the membrane of the secretory vesicle into

Figure 5-16 Exocytosis. (a) A vesicle approaches the plasma membrane, fuses with it, and releases its contents outside the cell. (b) TEM showing exocytosis of the protein components of milk by a mammary gland cell. (b, A. Ichikawa/from D.W. Fawcett)

the plasma membrane, as well as the release of the contents of the vesicle from the cell. This is also the primary mechanism by which plasma membranes grow larger.

In **endocytosis**, materials are taken into the cell. Several types of endocytotic mechanisms operate in biological systems including phagocytosis, pinocytosis, and receptor-mediated endocytosis. In **phagocytosis** (literally, “cell-eating”), the cell ingests large solid particles such as bacteria or food (Fig. 5-17). Phagocytosis is a mechanism used by certain protists and by several types of vertebrate white blood cells to ingest particles, some of which are as large as an entire bacterium. During ingestion, folds of the plasma membrane enclose the particle, which has bound to the surface of the cell, forming a large membranous sac, or vacuole. When the membrane has encircled the particle, it fuses at the point of contact. The vacuole then fuses with lysosomes, and the ingested material is degraded.

In the form of endocytosis known as **pinocytosis** (“cell-drinking”), the cell takes in dissolved materials. Tiny droplets of fluid are trapped by folds in the plasma membrane (Fig. 5-18), which pinch off into the cytosol as tiny vesicles. The liquid contents of these vesicles are then slowly transferred into the cytosol; the vesicles may become progressively smaller, to the point that they appear to vanish.

In a third type of endocytosis, called **receptor-mediated endocytosis**, specific molecules combine with *receptor proteins* embedded in the plasma membrane. A molecule that binds specifically to a receptor is called a **ligand**. The receptors are concentrated in *coated pits*, depressed regions on the cytoplasmic surface of the plasma membrane. Each pit is coated by a layer of a protein, called *clathrin*, found just below the plasma membrane. After a ligand binds with a receptor, the coated pit forms a *coated vesicle* by endocytosis.

Cholesterol in the blood is taken up by animal cells by receptor-mediated endocytosis. Much of the receptor-mediated endocytosis pathway was detailed through studies by M. Brown and J. Goldstein of the receptor for low-density lipoprotein (LDL), a primary cholesterol carrier in blood. In 1986 these investigators were awarded the Nobel Prize for their pioneering work. Their findings have important medical implications because cholesterol that remains in the blood instead of entering the cells can become deposited in the artery walls, increasing the risk of heart attack.

In Figure 5-19 the uptake of a low-density lipoprotein (LDL) particle is shown. Seconds after the vesicle moves into the cytoplasm, the coating dissociates from it, leaving an uncoated vesicle, called an *endosome*, free in the cytoplasm. The endosome typically forms two vesicles. One contains the

Figure 5-17 Phagocytosis. In this type of endocytosis, a cell ingests relatively large solid particles. (a) Steps of endocytosis: (1) Folds of the plasma membrane surround the particle to be ingested, forming a small vacuole around it. (2) The vacuole then pinches off inside the cell. (3) Lysosomes may fuse with the vacuole and pour their potent enzymes onto the ingested material. (b) The white blood cell (known as a neutrophil) shown in this TEM is phagocytizing bacteria. The vacuoles contain bacteria that have already been phagocytized, while other bacteria are still outside the cell. The granules in the cytosol contain digestive enzymes. (D.W. Fawcett)

Figure 5-18 Pinocytosis or “cell-drinking.” (a) Tiny droplets of fluid are trapped by folds of the plasma membrane. These pinch off (b) into the cytosol as small fluid-filled vesicles. The contents of these vesicles are then slowly transferred to the cytosol.

Figure 5–19 Receptor-mediated endocytosis. (a) Uptake of low-density lipoprotein (LDL) particles which transport cholesterol in the blood: (1) LDL attaches to specific receptors in coated pits on the plasma membrane. (2) Endocytosis results in the formation of a coated vesicle in the cytosol. (3) Seconds later the coat is removed. The vesicle is now called an endosome. The receptors are returned to the plasma membrane and recycled. The vesicle containing LDL particles fuses with lysosomes to form a secondary lysosome. Hydrolytic enzymes then release the cholesterol from the particles for use by the cell. (b–e) Series of TEMs showing the formation of a coated vesicle from a coated pit. (b–e, from Perry, M.M., and A.B. Gilbert, *J. Cell. Sci.* 39:257–272, 1979)

receptors, the other the LDL particle. The receptors are returned to the plasma membrane where they are recycled. The remaining vesicle fuses with a lysosome and its contents are then digested and released into the cytosol.

Ligand binds to receptors in coated pits of plasma membrane
 → coated vesicle forms by endocytosis → coating detaches from vesicle → endosome divides:
 → One vesicle returns receptors to plasma membrane where they are recycled
 → Other portion of endosome fuses with lysosome → contents are digested and released into the cytosol

The recycling of LDL receptors to the plasma membrane through vesicles illustrates a problem common to all cells that employ endocytotic and exocytotic mechanisms. In cells that are constantly involved in secretion, an equivalent amount of membrane must be returned to the interior of the cell for each vesicle that fuses with the plasma membrane; if it is not, the cell surface will keep expanding even though the growth of the cell itself may be arrested. A similar situation exists for cells that use endocytosis. A macrophage, for example, ingests the

equivalent of its entire surface membrane in about 30 minutes, requiring an equivalent amount of recycling or new membrane synthesis for the cell to maintain its surface area.

JUNCTIONS ARE SPECIALIZED CONTACTS BETWEEN CELLS

Cells in close contact with each other typically develop specialized intercellular junctions that involve their plasma membranes as well as other components. These structures may allow neighboring cells to form strong connections with each other, prevent passage of materials, or establish rapid communication between adjacent cells. In animals there are three common types of intercellular contacts: desmosomes, tight junctions, and gap junctions. Plant cells are connected by plasmodesmata.

Desmosomes are points of attachment between some animal cells

Adjacent epithelial cells, such as those found in the outer layer of the skin, are so tightly bound to each other that strong mechanical forces are required to separate them. They are held together by anchoring junctions called **desmosomes** (Fig. 5–20). Each desmosome includes components of two adjacent cells. It is made up of regions of dense material associated with the cytosolic sides of the two plasma membranes, plus protein filaments that cross the narrow intercellular space between them.

Desmosomes are anchored to systems of intermediate filaments inside the cells. Thus the intermediate filament networks of adjacent cells are connected so that mechanical stresses are distributed throughout the tissue. The function of the desmosomes appears to be purely mechanical; they hold cells together at one point like a rivet or a spot weld. As a result, cells can form strong sheets, and substances can still pass freely through the spaces between the plasma membranes.

Tight junctions seal off intercellular spaces between some animal cells

Tight junctions are literally areas of tight connections between the membranes of adjacent cells. These connections are so tight that no space remains between the cells; substances cannot leak between the cells. TEMs of tight junctions show that in the region of the junction the membranes of the two cells are in actual contact with each other, held together by proteins linking the two cells (Fig. 5–21).

Cells connected by tight junctions seal off body cavities. For example, tight junctions between cells lining the intestine prevent substances in the intestine from entering the body or the blood by passing around the cells. The sheet of cells thus

Figure 5–20 Desmosomes. The dense structure in the TEM is a desmosome. Each desmosome consists of a pair of button-like discs associated with the plasma membranes of adjacent cells, plus the intercellular protein filaments that connect them. Intermediate filaments in the cells are attached to the discs and are connected to other desmosomes. (D.W. Fawcett)

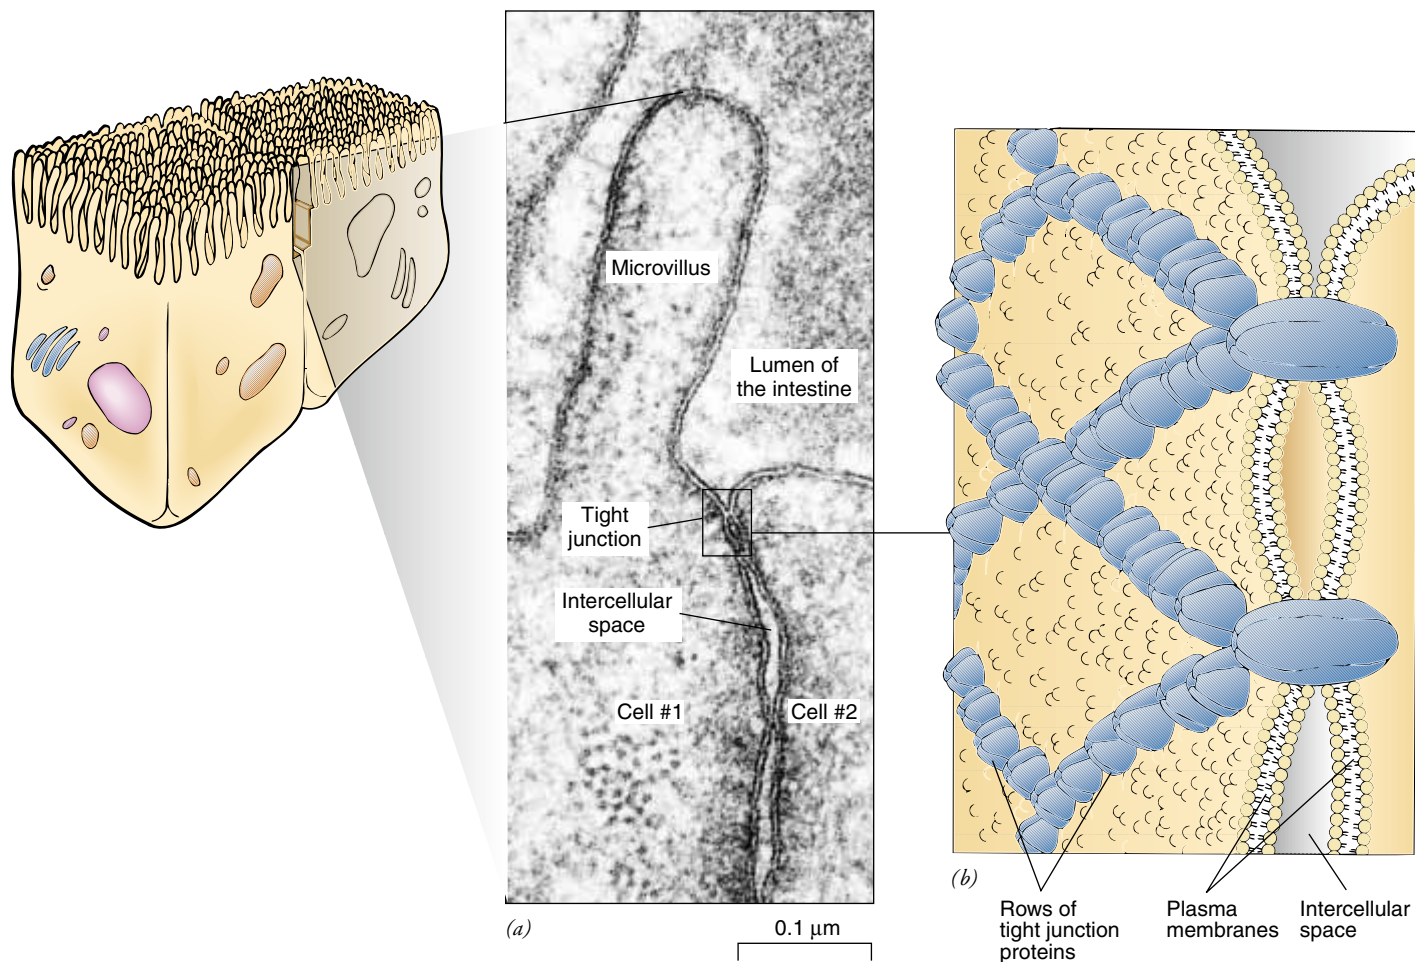

Figure 5-21 Tight junctions. These junctions prevent passage of materials through spaces between cells. Tight junctions occur at the points of contact between two cells and extend completely around the cells. *(a)* This TEM shows points of fusion between the plasma membranes of adjacent cells lining the intestine. One tight junction is marked by the box. *(b)* The diagram shows that a tight junction is formed by linkages between rows of proteins of adjacent cells. These proteins are tightly packed in rows that seal off the intercellular space. *(a, G.E. Palade)*

acts as a selective barrier. Food substances must be transported across the plasma membranes and through the intestinal cells before they enter the blood. This arrangement helps prevent toxins and other unwanted materials from entering the blood.

Gap junctions permit transfer of small molecules and ions

A third type of intercellular connection in animal cells, the **gap junction**, is like the desmosome in that it bridges the space between cells; however, the space it spans is somewhat narrower (Fig. 5-22). Gap junctions also differ in that they not only connect the membranes, but also contain channels connecting the cytoplasm of adjacent cells. A gap junction consists of a hexagonal array of proteins (connexin) forming a clus-

ter of channels, each of which is about 1 to 2 nanometers in diameter. Small inorganic molecules (e.g., ions) and some biological molecules (e.g., derivatives of ATP) can pass through the pores, but larger molecules are excluded. When appropriate marker substances are injected into one of a group of cells connected by gap junctions, the marker passes rapidly into the adjacent cells but does not enter the space between the cells.

Cells are able to control the passage of materials through gap junctions by opening and closing the pores (Fig. 5-22*d*). There is evidence that the open and closed states are regulated mainly by the intracellular concentrations of certain ions.

Gap junctions provide for rapid chemical and electrical communications between cells. Cells in the pancreas, for example, are linked together by gap junctions in such a way that if one of a group of cells is stimulated to secrete insulin, the

Figure 5–22 Gap junctions. These connections permit transfer of small molecules and ions between adjacent cells. (a) A TEM of a gap junction (between the arrows). (b) Model of a gap junction based on electron-microscopic and x-ray diffraction data. The two membranes contain cylinders composed of six protein subunits arranged to form a pore. Two cylinders from opposite membranes are joined to form a pore about 1.5 to 2.0 nanometers in diameter connecting the cytoplasmic compartments of the two cells. (c) Freeze-fracture replica of the P-face of a gap junction between two ovarian cells of a mouse, showing the numerous protein particles present. (d) Model illustrating how a gap junction pore might open and close. (a, D.W. Fawcett; c, E. Anderson, *J. Morph.* 156:339–366, 1978)

signal is passed through the junctions to the other cells in the cluster, ensuring a coordinated response to the initial signal. Gap junctions allow some nerve cells to be electrically coupled. Heart muscle cells are linked by gap junctions that permit the flow of ions necessary to synchronize contractions.

Plasmodesmata allow movement of certain molecules and ions between plant cells

Plant cells do not need desmosomes for strength because they have cell walls. However, these same walls would isolate the cells, preventing them from communicating. For this reason, plant cells require connections that are functionally equivalent

to the gap junctions of some animal cells. **Plasmodesmata** (sing., *plasmodesma*) are 20- to 40-nanometer-wide channels through adjacent cell walls connecting the cytoplasm of neighboring cells (Fig. 5–23). The plasma membranes of adjacent cells are therefore continuous with each other through the plasmodesmata. Most plasmodesmata contain a cylindrical membranous structure, called the *desmotubule*, which also runs through the opening and connects the endoplasmic reticulum of the two adjacent cells.

Plasmodesmata generally allow molecules and ions, but not organelles, to pass through the openings from cell to cell. The movement of ions through the plasmodesmata allows for a very slow type of electrical signaling in plants.

Figure 5-23 Plasmodesmata. TEM and line art of cytoplasmic channels through the cell walls of adjacent plant cells that allow passage of water, ions, and small molecules (*wide arrows*). The channels are lined with the fused plasma membranes of the two adjacent cells. (E.H. Newcomb, Biological Photo Service)

S U M M A R Y W I T H K E Y T E R M S

- I. Cell membranes are complex structures that (1) physically separate the interior of the cell from the extracellular environment and (2) form compartments within the cells of eukaryotes that allow them to perform complex functions. Membranes have many different structural and functional roles.
 - A. They regulate the passage of materials.
 - B. They receive information that permits the cell to sense changes in its environment and respond to them.

- C. They contain specialized structures that allow specific contacts and communications with other cells.
 - D. They participate in and serve as surfaces for biochemical reactions.
- II. According to the **fluid mosaic model**, membranes consist of a fluid phospholipid bilayer in which a variety of proteins are embedded.
 - A. The phospholipid molecules are **amphipathic**: they have hydrophobic and hydrophilic regions.
 - B. The lipid bilayer is arranged in such a way that the hydrophilic

heads of the phospholipids are at the two surfaces of the bilayer and their hydrophobic fatty acid chains are in the interior.

- C. In almost all biological membranes, the lipids of the bilayer are in a fluid or liquid-crystalline state, which allows the molecules to move rapidly in the plane of the membrane.
 - D. **Integral membrane proteins** are embedded in the bilayer with their hydrophilic surfaces exposed to the aqueous environment and their hydrophobic surfaces in contact with the hydrophobic interior of the bilayer. **Transmembrane proteins** are integral proteins that extend completely through the membrane.
 - E. **Peripheral membrane proteins** are associated with the surface of the bilayer, usually bound to integral proteins, and are easily removed without disrupting the structure of the membrane.
 - F. Membrane proteins, lipids, and carbohydrates are asymmetrically positioned with respect to the bilayer so that one side of the membrane has a different composition and structure than the other.
 - G. Many materials are transported from one part of the cell to another in vesicles that bud from various cell membranes and then fuse with some other membrane.
 - H. Membrane proteins have various functions including transport of materials, acting as enzymes or receptors, and structurally linking cells together.
 - I. In **signal transduction**, a receptor converts an extracellular signal into an intracellular signal that causes some change in the cell.
 1. Signal transduction typically involves a sequence of molecules that relay information from one to another.
 2. The pathway often involves protein kinases, enzymes that phosphorylate specific proteins.
- III. Biological membranes are **selectively permeable membranes**; that is, they allow the passage of some substances but not others.
- A. Some molecules pass through membranes by simple **diffusion**.
 1. Diffusion is the net movement of a substance down its concentration gradient (from a region of greater concentration to one of lower concentration).
 2. **Dialysis** is the diffusion of a solute across a membrane.
 3. **Osmosis** is a kind of diffusion in which molecules of water pass through a selectively permeable membrane from a region where water has a higher effective concentration to a region where its effective concentration is lower.
 4. The **osmotic pressure** of a solution is determined by its concentration of dissolved substances (solute). Cells regulate their internal osmotic pressures to prevent shrinking or bursting.
 5. An **isotonic** solution has an equal solute concentration to another fluid, e.g., the fluid within the cell. When placed in a **hypertonic** solution, one that has a greater solute concentration than the cell, cells lose water to the surroundings and undergo **plasmolysis**, a process in which the plasma membrane separates from the cell wall. When cells are placed in a **hypotonic** solution, one with a lower concentration of dissolved materials relative to the cell, water enters the cells and causes them to swell.
 6. Plant cells can withstand high internal hydrostatic pressure because their cell walls prevent them from expanding and bursting. When water moves into cells by osmosis, it fills the central vacuoles. The cells swell, building up **turgor pressure** against the rigid cell walls.
 - B. In **carrier-mediated transport** special membrane proteins move ions or molecules across a membrane.
 1. Some substances pass through membranes by **facilitated diffusion**, a form of carrier-mediated transport that uses the energy of a concentration gradient for the substance being transported and cannot work against the gradient.
 2. In **carrier-mediated active transport** the cell expends metabolic energy to move ions or molecules across a membrane *against* a concentration gradient. The **sodium-potassium pump** uses ATP to pump sodium ions out of the cell and potassium ions into the cell.
 - C. In **cotransport** an ATP-powered pump such as the sodium-potassium pump transports ions or some other solute and indirectly powers the active transport of other solutes by maintaining a concentration gradient.
 - D. In **exocytosis**, the cell ejects waste products or secretes substances such as hormones or mucus by fusion of a vesicle with the plasma membrane.
 - E. In **endocytosis** materials such as food may be moved into the cell; a portion of the plasma membrane envelops the material, enclosing it in a vesicle or vacuole that is then released inside the cell.
 1. In **phagocytosis**, the plasma membrane encloses a particle such as a bacterium or protist, forms a vacuole around it, and moves it into the cell.
 2. In **pinocytosis**, the cell takes in dissolved materials by forming tiny vesicles around droplets of fluid trapped by folds of the plasma membrane.
 3. In **receptor-mediated endocytosis**, **ligands** bind to specific receptors in coated pits along the plasma membrane. These pits, coated by the protein clathrin, form coated vesicles by endocytosis.
- IV. Plasma membranes of many eukaryotic cells contain specialized structures that permit contact and communication with other cells.
- A. **Desmosomes** weld adjacent animal cells together to form strong tissues.
 - B. **Tight junctions** seal membranes of adjacent animal cells together, preventing substances from passing between cells.
 - C. **Gap junctions** are protein complexes that form channels in membranes, allowing communication between the cytoplasm of adjacent animal cells.
 - D. **Plasmodesmata** are channels connecting adjacent plant cells. Openings in the cell walls allow the plasma membranes and cytoplasm to be continuous, thus permitting certain molecules and ions to pass from cell to cell.

POST - TEST

1. Lipids that make up the core of biological membranes (a) are amphipathic (b) have hydrophobic and hydrophilic regions (c) are typically in a fluid state (d) answers a, b, and c are correct (e) answers a and c only
2. According to the fluid mosaic model, membranes consist of (a) a lipid-protein sandwich (b) mainly phospholipids with scattered nucleic acids (c) a fluid phospholipid bilayer in which proteins are embedded (d) a fluid phospholipid bilayer in which carbohydrates are embedded (e) none of the preceding is correct
3. Transmembrane proteins (a) are peripheral proteins (b) are integral proteins (c) extend completely through the membrane (d) answers a, b, and c are correct (e) answers b and c only
4. Which of the following is *not* a function of the plasma membrane? (a) transports materials (b) helps to structurally link cells together (c) manufactures proteins (d) anchors the cell to the extracellular matrix (e) has receptors that relay signals
5. Which of the following processes require(s) the cell to expend metabolic energy directly (e.g., from ATP)? (a) active transport (b) facilitated diffusion (c) dialysis (d) osmosis (e) diffusion
6. Which of the following are examples of carrier-mediated transport? (a) active transport (b) facilitated diffusion (c) dialysis (d) answers a, b, and c are correct (e) answers a and b only
7. Transport of sodium by sodium-potassium pumps is an example of (a) active transport (b) pinocytosis (c) dialysis (d) exocytosis (e) facilitated diffusion
8. The cell takes in dissolved materials by forming tiny vesicles around fluid droplets trapped by folds of the plasma membrane. This process is (a) ac-

- tive transport (b) pinocytosis (c) receptor-mediated endocytosis (d) exocytosis (e) facilitated diffusion
- When plant cells are in a hypotonic medium, they (a) undergo plasmolysis (b) build up turgor pressure (c) wilt (d) answers a, b, and c are correct (e) answers a and c only are correct
 - Which sequence most accurately describes receptor-mediated endocytosis? (a) ligand binds to receptors in coated vesicle → vesicle enters cytosol by cotransport mechanisms → clathrin accumulates around vesicle (b) ligand binds to receptors in coated pit → pit forms coated vesicle by endocytosis → clathrin coating detaches from vesicle (c) ATP binds to receptors in coated vesicle → vesicle enters cytosol by facilitated diffusion → protein coat dissolves (d) ligand binds to receptors in coated pit → pit forms coated vesicle by phagocytosis → coating detaches from vesicle (e) clathrin binds to receptors in coated pit → pit forms coated vesicle by endocytosis → protein coating forms around vesicle
 - In signal transduction (a) an extracellular signal is converted to an intracellular signal (b) a signal is relayed through a series of molecules in the membrane (c) the metabolism of the cell is always inhibited (d) answers a, b, and c are correct (e) answers a and b only
 - Anchoring junctions that hold cells together at one point like a spot weld are (a) tight junctions (b) microfilaments (c) desmosomes (d) gap junctions (e) plasmodesmata
 - Junctions that permit the transfer of water, ions, and molecules between adjacent plant cells are (a) tight junctions (b) microfilaments (c) desmosomes (d) gap junctions (e) plasmodesmata

REVIEW QUESTIONS

- What molecules are responsible for the physical properties of a cell membrane?
- Illustrate how a transmembrane protein might be positioned in a lipid bilayer. How do the hydrophilic and hydrophobic regions of the protein affect its orientation?
- Describe the pathway used by cells to place carbohydrates on plasma membrane proteins. Explain why this pathway results in the carbohydrate groups being on only one side of the lipid bilayer.
- What is the source of energy for diffusion? State a rule for predicting the movement of particles along their concentration gradient. Is the rule different for facilitated diffusion compared with simple diffusion?
- Distinguish between osmosis and dialysis.
- Predict the consequences if a plant cell were to be placed in a relatively (a) isotonic, (b) hypertonic, or (c) hypotonic environment. Would you have to modify any of your predictions for an animal cell?
- What are some of the functions of the plasma membrane? Discuss the nature of the proteins that carry out those functions and explain how their properties make them especially adapted for their functions.
- Identify a common energy source for active transport. In what ways are facilitated diffusion and carrier-mediated active transport similar? In what ways do they differ?
- Draw a diagram illustrating how membrane lipid bilayers fuse during the processes of exocytosis and endocytosis. Is one the exact reverse of the other? Why or why not?
- Discriminate between the processes of phagocytosis and pinocytosis.
- How are desmosomes and tight junctions functionally similar? How do they differ? Do they share any structural similarities?
- What is the justification for considering gap junctions and plasmodesmata to be functionally similar? How do they differ structurally?
- Label the diagram of a typical plasma membrane. Use Figure 5–6 to check your answer.

YOU MAKE THE CONNECTION

- Why can't larger polar molecules and ions cross a lipid bilayer? Would it be advantageous to the cell if they could?
- Most cells do not actively transport water, yet water is essential to life. How, then, are cells able to control their water content?
- You prepare a salad with dressing in the morning but find that it is limp and unappetizing by lunch time. Why?
- Most adjacent living cells in a plant are connected by plasmodesmata. On the other hand, only certain adjacent animal cells are associated through gap junctions. Why?

Nabil Elkareh is a retail pharmacist in Orlando, Florida. Born in Beirut, Lebanon, Nabil came to Dallas, Texas in 1986 to visit a brother. He decided to stay because of the war back home and switched his tourist visa to a student visa. He enrolled at North Texas State University as a biology major. After two years, Nabil applied his biology credits to the pharmacy program. He completed his B.S. in Pharmacy in his fifth year. Nabil has always been fascinated by the way chemicals interact with the human body, and he now enjoys counseling patients about the interactions of their prescriptions. Nabil takes seriously his role as the responsible link between doctor and patient.

Did you know what you wanted to major in at the time you enrolled?

Yes, I had already made up my mind about pharmacy, but I was also interested in the medical field. So, I started out as a biology major until I could decide on my professional track.

Did you go through a five-year pharmacy program then? Did this include some clinical experience?

Yes. I applied my two years of biology toward a pharmacy degree, and then spent the next three years in pharmacy school. The requirements of the biology degree are the same as the requirements of the pharmacy degree until the last two years.

In my fifth year, I worked for five weeks in a hospital pharmacy. For a comparison, I then worked five weeks in a retail pharmacy setting. After that, the program required ten weeks in a clinical

Pharmacist

N A B I L E L K A R E H

rotation at a hospital. This means that I rotated with doctors and interns. Finally, I was sent on rounds for one week with a nutritionist. I did my rounds alone following that, as a pharmacist intern on an assigned floor of the hospital.

Have there been any changes in the requirements of a pharmacy degree since you graduated?

In the future, a pharmacy doctorate or Pharm.D. could become a job requirement. This means a sixth year of school, which emphasizes clinical and product-related issues and more time in a variety of practice settings. The course work emphasizes disease states and therapeutics. Hospital pharmacy jobs today prefer Pharm.D. graduates. In fact, some schools now only offer Pharm.D. programs.

How does your background in biology help you in your career?

It gives me personal satisfaction and a deeper understanding of disease biology. For example, we study cancer in pharmacy, but we stress the drugs more than the disease state. With a biology degree you have some knowledge of oncogenes (malfunctioning genes thought to cause cancer). You understand what causes cancer, how you can prevent it, and how the drugs work. Biology gives more of the human body background—from heredity to environment.

How did you get your retail pharmacy position?

I took my pharmacy board exam in Florida. Various pharmacies had employment booths outside the test center. I interviewed on the spot and was hired soon afterwards. There are many openings for pharmacists today.

What is the difference between retail pharmacy and hospital pharmacy?

In retail, counseling is reduced. Instead of counseling with every prescription, you ask the patient if they have questions. If I'm not dealing with many prescriptions, I can

counsel each patient. But if I did that regularly, I would have a line-up of patients.

At hospital sites, on the other hand, counseling is frequent, as is interaction with the doctors. Pharmacists are more involved because they witness patient care inside the hospital. They walk with the doctors during clinical rotations and discuss drug effectiveness. Hospital pharmacists do not have to handle 400 people and their prescriptions daily. That makes a big difference.

What are your daily activities?

I dispense pills with the aid of technicians who enter prescriptions from the doctor in the computer. I verify each prescription to make sure the medication is correct, checking to see if there are any allergies or drug interactions. The computer will flag these. If anything is flagged, I go through the patient's profile, then double-check the medication. I either call the doctor or I tell the patient to observe themselves for a few days to see how they feel. I try to counsel the patients whenever I can. I enjoy counseling.

How do you keep up with the changes in the field?

Florida state law requires that pharmacists take fifteen hours per year of continuing education. Other states may have different requirements. You can fulfill this by attending some of the many seminars offered by the pharmaceutical companies, whether it's about antidepressants, hormones, or cancer medications. As a refresher, a talk is given about the drugs that have been available for a long time. Then they present the new drugs.

Where do you see yourself five years from now?

Pharmacy supervisor and intern recruiter for the company. I hope to manage operations, supervise 20 to 30 pharmacies, making sure that they follow company policies, as well as state and federal laws. Every career step counts. I could also work in research for drug companies or for the FDA. Another option is to get onto hospital committees that advise pharmaceutical houses on formulary drugs, which are the drugs the hospital carries and dispenses. The formulary is a regularly revised list of drugs. It is the current clinical judgment of the hospital staff that these drugs are the best in their class. For that reason, it is a shorter list than what a retail pharmacy carries.

CHAPTER 6

Energy and Metabolism

All living things require energy because life processes involve work. It may seem obvious that cells need energy to grow and reproduce, but even nongrowing cells need energy simply to maintain themselves. The sun is the ultimate source of almost all the energy that powers life. Plants and other photosynthetic organisms capture a tiny portion of the sun's energy and, in the process of photosynthesis, convert it to chemical energy in organic molecules. The chemical energy captured by photosynthesis and stored in seeds and leaves is transferred to animals, such as this black-tailed prairie dog, when they eat. Plants, animals, or other organisms need the energy stored in these organic molecules, and they commonly use the process of cellular respiration to break them apart and convert their energy to more immediately usable forms.

Because energy cannot be created or destroyed, cells have no way to produce new energy. Energy is captured from the environment, temporarily stored, and then used to perform biological work. However, not all of the captured energy can be used for work; at every step some inevitably becomes converted to heat and is dispersed back into the environment.

Cells obtain energy in many forms, but seldom can that energy be used directly to power cellular processes. For this reason cells have mechanisms that convert energy from one form to another. Because most of the components of these energy conversion systems evolved very early in the history of life, many aspects of energy metabolism tend to be very similar in a wide range of organisms.

This chapter focuses on some of the basic principles that govern how cells capture, transfer, store, and use energy. We discuss the functions of ATP and other molecules used in energy conversions, including those that transfer electrons in redox reactions. We also pay particular attention to the essential role of enzymes in cellular energy dynamics. In Chapter 7 we will explore some of the main metabolic pathways used in cellular respiration, and in Chapter 8 we will discuss the energy transformations of photosynthesis. The flow of energy in ecosystems is discussed in Chapter 53.

(Barbara Gerlach/Visuals Unlimited)

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Define energy, emphasizing how it is related to work and to heat.
2. Use examples to contrast potential energy and kinetic energy.
3. State the first and second laws of thermodynamics and discuss the implications of these laws as they relate to organisms.
4. Discuss how changes in free energy in a reaction are related to changes in entropy and enthalpy.
5. Compare the energy dynamics of a reaction at equilibrium with the dynamics of a reaction not at equilibrium.
6. Distinguish between exergonic and endergonic reactions and give examples of how they may be coupled.
7. Explain how the chemical structure of ATP allows it to transfer a phosphate group. Discuss the central role of ATP in the overall energy metabolism of the cell.
8. Relate the transfer of electrons (or hydrogen atoms) to the transfer of energy.
9. Explain how an enzyme lowers the required energy of activation for a reaction.
10. Describe some of the ways enzymes are regulated.

BIOLOGICAL WORK REQUIRES ENERGY

Energy, one of the most important concepts in biology, can be understood in the context of **matter**, which is anything that has mass and takes up space. **Energy** can be defined as the capacity to do **work**, which is any change in the state or motion of matter.

Biologists generally express energy in units of work (**kilojoules, kJ**) or units of heat energy (**kilocalories, kcal**). One kilocalorie equals 4.184 kilojoules. Because heat energy cannot do cellular work, the kilojoule is the unit preferred by most biologists today (see *Making the Connection: Energy, Work, and Heat*). However, we will use both units because references to the kilocalorie are common in the scientific literature.

Many of the activities performed by an organism are mechanical. At this very moment you are expending considerable energy to carry out such activities as breathing and circulating your blood. In these processes, the state or position of matter is changed in some way. However, these forms of mechanical work are the consequence of cellular activities. For example, the cells of the heart muscle use a great deal of energy to contract, thereby pumping the blood through your body. As we will see, however, not all of the work of cells is mechanical. A great deal of it is chemical. For example, heart muscle cells expend energy to synthesize the proteins required for contraction. Energy can be converted to many different forms, including not only mechanical and chemical energy, but also heat energy, electrical energy, and radiant energy.

MAKING THE CONNECTION

ENERGY, WORK, AND HEAT

Why can we express energy both in units of work (kilojoules) and in units of heat energy (kilocalories)? We can because of a conceptual breakthrough that came about in the 1800s, after the invention of the steam engine. Scientists studying the connections among the heat energy that powered the engine, the mechanical work that the engine was able to perform, and the heat that was transferred to the environment were able to demonstrate that all these forms of energy are interconvertable.

Today we know that not only mechanical work but all forms of energy can be converted to heat. In fact, the study of energy and its transformations has been named thermodynamics, that is, heat dynamics. (Recall from Chapter 2 that *heat* refers to the total amount of kinetic energy in a sample of a substance, whereas *temperature* refers to the average kinetic energy of the particles.) **Heat energy** is energy that can flow from an object with a higher temperature (known as the heat source) to an object with a lower temperature (the heat sink).

Cells cannot work as heat engines because they are isothermal; they are too small to have regions that differ in temperature. Therefore, heat cannot be used to do biological work. Nevertheless, the fact that all forms of energy can be converted to heat is useful to scientists because heat energy is particularly convenient to measure.

Nutritionists use the kilocalorie to express the potential energy of foods and usually refer to it as a Calorie (with a capital C; see Chapter 45). For example, the energy content of 10 grams, about 2 teaspoons, of table sugar (sucrose) is about 36 Calories (36 kcal or 151 kJ), whereas the energy content of 20 potato chips is about 150 Calories (150 kcal or 628 kJ). A person weighing 58 kilograms (130 pounds) uses about 1 kcal (4.184 kJ) per minute to maintain the body while sleeping and up to 10 kcal (41.84 kJ) per minute when engaged in strenuous activity.

Organisms carry out conversions between potential energy and kinetic energy

When an archer draws a bow, **kinetic energy**, which is energy of motion, is used and work is done (Fig. 6–1). The resulting tension in the bow and string represents stored energy, or **potential energy**. Potential energy is the capacity to do work owing to position or state. When the string is released, this potential energy is converted to kinetic energy in the motion of the bow, which propels the arrow.

Most of the actions of an organism involve a complex series of energy transformations that occur as kinetic energy is converted to potential energy or as potential energy is converted to kinetic energy. For example, potential energy derived from chemical energy of food molecules is converted to kinetic energy in the muscles of the archer.

TWO LAWS OF THERMODYNAMICS GOVERN ENERGY TRANSFORMATIONS

All the activities of our universe, from the life and death of cells to the life and death of stars, are governed by **thermodynamics**, which is the study of energy and its transformations. When considering thermodynamics, scientists use the term *system* to refer to an object that is being studied, whether it is a cell, an organism, or planet Earth. The rest of the universe other than the system being studied is known as the *surroundings*. A **closed system** is one that does not exchange energy or matter with its surroundings, whereas an **open system** is one that can exchange matter and energy with its surroundings (Fig. 6–2). There are two laws about energy that apply to all things in the universe. These are known as the first and second laws of thermodynamics.

The total energy in the universe does not change

According to the **first law of thermodynamics**, energy cannot be created or destroyed, although it can be transferred or changed from one form to another. As far as we know, the energy present in the universe at its formation, approximately 15 to 20 billion years ago, equals the amount of energy present in the universe today.¹ This is all the energy that can ever be present in the universe. Similarly, the energy of any system and its surroundings is constant. A system may absorb energy from its surroundings, or it may give up some energy into its surroundings, but the total energy content of that system and its surroundings is always the same.

¹Technically, mass is a form of energy, and so we should say that the total mass-energy of the universe is a constant. Energy can be produced from mass (recall Einstein's famous equation $E = mc^2$). This is the basis behind the energy generated by the sun and stars. More than 4 billion kilograms of matter per second are converted to energy in our sun.

Figure 6–1 Potential versus kinetic energy. The potential chemical energy released by cellular respiration is converted to kinetic energy in the muscles, which do the work of drawing the bow. The potential energy stored in the drawn bow is transformed into kinetic energy as the bowstring pushes the arrow toward its target.

As specified by the first law of thermodynamics, then, organisms cannot create the energy that they require to live. Instead, they must capture energy from the environment to use for biological work, a process involving the transformation of energy from one form to another. In photosynthesis, for example, plants absorb the radiant energy of the sun and convert it into the chemical energy contained in the bonds of carbohydrate molecules. Some of that chemical energy may later be transformed by the plant to do various types of cellular work or by some animal that eats the plant and might convert it to the mechanical energy of muscle contraction or some other needed form.

The entropy of the universe is increasing

As each energy transformation occurs, some of the energy is converted to heat energy that is then given off into the cooler surroundings. This energy can never again be used by any organism for biological work; it is lost from the biological point of view. However, it is not really gone from a thermodynamic

Figure 6-2 Closed and open systems. (a) Matter and energy are not exchanged between a closed system and its surroundings. (b) Matter and energy are exchanged between an open system and its surroundings. (Adapted from Tobin and Morel)

point of view because it still exists in the surroundings. For example, the use of food to enable us to walk or run does not destroy the chemical energy that was once present in the food molecules. After we have performed the task of walking or running, the energy still exists in the surroundings as heat.

The **second law of thermodynamics** can be stated most simply as follows: when energy is converted from one form to another, some usable energy, that is, energy available to do work, is degraded into a less usable form, heat, that disperses into the surroundings. As a result, the amount of usable energy available to do work in the universe decreases over time.

It is important to understand that the second law of thermodynamics is consistent with the first law; that is, the total amount of energy in the universe is *not* decreasing with time. However, the energy available to do work is being degraded to less-usable energy with time.

Less-usable energy is more diffuse, or disorganized. **Entropy (S)** is a measure of this disorder or randomness; organized, usable energy has a low entropy, whereas disorganized energy such as heat has a high entropy (Fig. 6-3). The total entropy of the universe is continuously increasing in all natural processes. It may be that at some time, billions of years from now, all energy will exist as heat uniformly distributed throughout the universe. If that happens, the universe will cease to operate because no work will be possible. Everything will be at the same temperature, so there will be no way to convert the thermal energy of the universe into usable mechanical energy.

Another way to explain the second law of thermodynamics, then, is that entropy, or disorder, in a closed system tends to increase spontaneously over time. (The word *spontaneously* in this context means that entropy occurs naturally rather than being caused by some external influence.)

(a)

(b)

Figure 6-3 Entropy. (a) Entropy as demonstrated by frogs. The frogs are placed on one side of a box with partitions to represent a highly ordered system. As the frogs hop into the other side and back again so that they are randomly distributed throughout both sides of the box, they represent a system of greater entropy. (b) Similarly, the beaker on the left, in which all marbles of the same color are located together, represents a highly organized system with low entropy. The beaker on the right, in which the marbles are randomly arranged, regardless of color, represents a more disorganized system with greater entropy. (a, Adapted from Tobin and Morel; b, Dennis Drenner)

As a result of the second law of thermodynamics, no process requiring an energy conversion is ever 100% efficient, because much of the energy is dispersed as heat, resulting in an increase in entropy. For example, an automobile engine, which converts the chemical energy of gasoline to mechanical energy, is between 20% and 30% efficient. That is, only 20% to 30% of the original energy stored in the chemical bonds of

Figure 6–4 LM of club moss stem cross section. The highly organized cellular structure of this *Lycopodium clavatum* stem is developed and maintained only by the constant input of energy from the sun. Thus, the high degree of organization of living things does not refute the second law of thermodynamics. (John D. Cunningham/Visuals Unlimited)

the gasoline molecules is actually transformed into mechanical energy; the other 70% to 80% is dissipated as waste heat. Energy utilization in our cells is about 40% efficient, with the remaining energy given to the surroundings as heat.

Organisms have a high degree of organization, and at first glance they appear to refute the second law of thermodynamics (Fig. 6–4). As organisms grow and develop, they maintain a high level of order and do not appear to become more disorganized. However, organisms are able to maintain their degree of order over time only with the constant input of energy from their surroundings. That is why plants must photosynthesize and animals must eat. Although the order of organisms might tend to increase temporarily, the total entropy of the universe (organisms plus surroundings) will increase over time.

METABOLIC REACTIONS INVOLVE ENERGY TRANSFORMATIONS

The chemical reactions that enable an organism to carry on its activities—to grow, move, maintain and repair itself, reproduce, and respond to stimuli—together make up its **metabolism**. Metabolism was defined in Chapter 1 as the sum of all the chemical activities that take place in an organism. An organism's metabolism consists of many intersecting series of chemical reactions, or pathways, which are of two main types. **Anabolism** refers to the various pathways in which complex molecules are synthesized from simpler substances, such as the linking of amino acids to form proteins. **Catabolism** includes

the pathways in which larger molecules are broken down into smaller ones, such as the degradation of starch to form monosaccharides.

As we will see, these changes not only involve alterations in the arrangement of atoms, but also various energy transformations. Catabolism and anabolism are complementary processes; catabolic pathways involve an overall release of energy, some of which is used to power the anabolic pathways, which have an overall energy requirement. In the following sections we will discuss how to predict whether a particular chemical reaction requires energy or releases it.

Enthalpy is the total potential energy of a system

In the course of any chemical reaction, including the metabolic reactions of a cell, chemical bonds break, and new and different bonds may form. Every specific type of chemical bond has a certain amount of **bond energy**, defined as the energy required to break that bond. The total bond energy is essentially equivalent to the total potential energy of the system, a quantity known as **enthalpy** (H). Because energy can be conveniently measured as heat, enthalpy is often referred to as the heat content of the system.

Free energy is energy that is available to do cellular work

Entropy and enthalpy are related by a third dimension of energy, termed **free energy** (G), which is the amount of energy available to do work under the conditions of a biochemical reaction. Free energy, the only kind of energy that can do cellular work, is the aspect of thermodynamics of greatest interest to a biologist.

Entropy (S) and free energy (G) are related inversely; as entropy increases, the amount of free energy decreases. The two are related by the following equation:

$$G = H - TS$$

in which G is the free energy, H is the enthalpy of the system, T is the absolute temperature expressed in degrees Kelvin, and S is entropy. If we assume that entropy is zero, the free energy is simply equal to the total potential energy (enthalpy); an increase in entropy reduces the amount of free energy.

What is the significance of the temperature (T)? Remember that as the temperature increases, there is an increase in random molecular motion that contributes to disorder and multiplies the effect of the entropy term.

Chemical reactions involve changes in free energy

Biologists need ways to analyze the role of energy in the many reactions that comprise metabolism. Although the total free energy of a system (G) cannot be effectively measured, the equation $G = H - TS$ can be extended to predict whether any

particular chemical reaction will release energy or require an input of energy. This is because *changes* in free energy can be measured. We use the Greek letter delta (Δ) to denote any change that occurs in the system between its initial state before the reaction and its final state after the reaction. To express what happens with respect to energy in a chemical reaction, the equation becomes:

$$\Delta G = \Delta H - T\Delta S$$

Notice that the temperature does not change; it is held constant during the reaction. Thus the change in free energy (ΔG) during the reaction is equal to the change in enthalpy (ΔH) minus the product of the absolute temperature (T) multiplied by the change in entropy (ΔS). ΔG and ΔH are expressed in kilojoules or kilocalories per mole; ΔS is expressed in kilojoules per degree or in kilocalories per degree.

Free energy decreases during an exergonic reaction

In accordance with the second law of thermodynamics, no chemical reaction is 100% efficient. No reaction can take place without a decrease in enthalpy, an increase in entropy, or both (see *Making the Connection: Energy and Diffusion*). For this reason, the total free energy of the system in its final state is

always less than the total free energy of the system in its initial state. When calculated in this way, ΔG is a negative number. Such a reaction, with a $-\Delta G$, is referred to as an **exergonic reaction** (Fig. 6–5*a*).

An exergonic reaction releases energy and is said to be a spontaneous or a “downhill” reaction. The term *spontaneous* may give the false impression that such reactions are always instantaneous. In fact, spontaneous reactions do not necessarily occur readily; some are extremely slow. This is because energy, known as activation energy, is required to initiate every reaction, even a spontaneous one. Activation energy will be discussed later in the chapter.

Free energy increases during an endergonic reaction

An **endergonic reaction** is a reaction in which there is a gain of free energy (Fig. 6–5*b*). Because the free energy of the products is greater than the free energy of the reactants, ΔG has a positive value. Such a reaction cannot take place in isolation. Instead, it must occur in such a way that energy can be supplied from the surroundings. Of course, many energy-requiring reactions take place in cells, and, as we will see, metabolic mechanisms have evolved that supply the energy needed to “drive” these nonspontaneous cellular reactions in a particular direction.

MAKING THE CONNECTION

ENERGY AND DIFFUSION

What is the source of energy for diffusion? In Chapter 5 we saw that randomly moving particles can diffuse down their own **concentration gradient** (see figure). That is, although the movements of the individual particles are random, net movement of the group of particles seems to be directional. What provides the energy for this seemingly directed process? A concentration gradient, with a region of higher concentration and another region of lower concentration, is an orderly state. A cell must expend energy to produce a concentration gradient. Because work must be done to produce this order, the concentration gradient is a form of potential energy. As

the particles move about randomly, disorder increases. Although there is no change in enthalpy, entropy increases. The process is spontaneous because there is an overall decrease in free energy ($-\Delta G$); diffusion is paid for by an increase in entropy.

In cellular respiration and photosynthesis, the potential energy stored in a concentration gradient of hydrogen ions (H^+) can be transformed into chemical energy in ATP as the hydrogen ions pass through a membrane down the concentration gradient. This important concept, known as **chemiosmosis**, will be discussed further in Chapters 7 and 8.

Energy, entropy, and diffusion. The tendency of entropy to increase can be used to produce work, in this case, diffusion. (*Left*) A concentration gradient is a form of potential energy. (*Right*) When molecules are evenly distributed, they have a high entropy.

Figure 6-5 Exergonic and endergonic reactions. (a) In an exergonic reaction there is a net loss of free energy. The products have less free energy than was present in the reactants, and the reaction proceeds spontaneously. (b) In an endergonic reaction there is a net gain in free energy. The products have more free energy than was present in the reactants. An endergonic reaction occurs only if energy lost from some other system is fed into the reaction. (Adapted from Tobin and Morel)

Free energy changes depend on the concentrations of reactants and products

According to the second law of thermodynamics, any process that increases entropy (S) can do work. Differences in concentration of a substance, for example, between two different parts of a cell, represent a more orderly state than when the substance is diffused homogeneously throughout the cell. We have seen that free energy changes in any chemical reaction depend mainly on the difference in bond energies (enthalpy, H) between reactants and products. Free energy also depends on *concentrations* of both reactants and products. The change in molecules from a more concentrated to a less concentrated state increases entropy because it is movement from a more orderly to a less orderly state.

In most biochemical reactions there is little intrinsic free energy difference between reactants and products. Such reactions are reversible, a fact that is indicated by drawing double arrows (\rightleftharpoons) between the reactants and the products.

At the beginning of a reaction, only the reactant molecules (A) may be present. As the reaction proceeds, the concentration of the reactant molecules decreases, and the concentration of the product molecules (B) increases. As the concentration of the product molecules increases, they may have enough free energy to initiate the reverse reaction. The reaction thus proceeds in both directions simultaneously; if undisturbed it could eventually reach a state of **dynamic equilibrium**, in which the rate of the reverse reaction is equal to the rate of the forward reaction. At equilibrium there is no net change in the system; every forward reaction is balanced by a reverse reaction.

Knowledge that a system is at equilibrium tells us nothing about the relative concentrations of reactants and products at equilibrium. If the reactants have much greater intrinsic free energy than the products, the reaction goes almost to completion; that is, it reaches equilibrium at a point at which most of the reactants have been converted to products. Reactions in which the reactants have much less intrinsic free energy than

the products reach equilibrium at a point where very few of the reactant molecules have been converted to products.

If we increase the initial concentration of A, then the equilibrium will “shift to the right,” and more A will be converted to B; a similar effect can be obtained if B is removed from the reaction mixture. The opposite effect occurs if the concentration of B is increased, or if A is removed; here the equilibrium “shifts to the left.” The actual free energy change that occurs during a reaction is defined mathematically to include these effects, which are a consequence of the relative initial concentrations of reactants and products.

Cells manipulate the relative concentrations of reactants and products of almost every reaction. Cellular reactions are virtually never at equilibrium. By displacing their reactions far from equilibrium, cells are able to supply energy to endergonic reactions and direct their metabolism in accordance with their needs.

Cells drive endergonic reactions by coupling them to exergonic reactions

Many metabolic reactions such as protein synthesis are anabolic and endergonic. Because an endergonic reaction cannot take place without an input of energy, endergonic reactions are coupled to exergonic reactions. In **coupled reactions**, the thermodynamically favorable exergonic reaction provides the energy required to drive the thermodynamically unfavorable endergonic reaction. The endergonic reaction can proceed only if it absorbs free energy released by the exergonic reaction to which it is coupled.

Consider the free energy change, ΔG , in the following reaction:

Because ΔG has a positive value, we know that the product of this reaction has more free energy than the reactant. This is an endergonic reaction. It is not spontaneous and does not take place without an energy source.

By contrast, consider the following reaction:

The negative value of ΔG tells us that the free energy of the reactant is greater than the free energy of the product. This exergonic reaction can proceed spontaneously.

We can sum up Reactions 1 and 2 as follows:

Because thermodynamics considers the overall changes in these two reactions, which show a net negative value of ΔG , the two reactions taken together are exergonic.

The fact that we can write reactions this way is a useful bookkeeping device, but it does not mean that an exergonic reaction can mysteriously transfer energy to an endergonic “by-stander” reaction. However, these reactions can be coupled if their pathways are altered such that they are linked by a common intermediate. Reactions 1 and 2 might be coupled by an intermediate (I) in the following way:

Note that Reactions 3 and 4 are sequential. Thus the reaction pathways have changed, but overall the reactants and products are the same, and the free energy change is the same.

Generally, for each endergonic reaction occurring in a living cell, there is a coupled exergonic reaction to drive it. Often, the exergonic reaction involves the breakdown of adenosine triphosphate (ATP). We now examine specific examples of the role of ATP in energy coupling.

ATP IS THE ENERGY CURRENCY OF THE CELL

In all living cells, energy is temporarily packaged within a remarkable chemical compound called **adenosine triphosphate (ATP)**, which holds readily available energy for very short periods of time. We may think of ATP as the energy currency of the cell. When you work to earn money, you might say that your energy is symbolically stored in the money you earn. The energy the cell requires for immediate use is temporarily stored in ATP, which is like cash. When you earn extra money, you might deposit some in the bank; similarly, a cell might deposit energy in the chemical bonds of lipids, starch, or glycogen. Moreover, just as you dare not make less money than you spend, so too the cell must avoid energy bankruptcy, which would mean its death. Finally, just as you (alas) do not keep what you make very long, so too the cell continuously spends its ATP, which must be replaced immediately.

ATP is a nucleotide consisting of three main parts: adenine, a nitrogen-containing organic base; ribose, a five-carbon sugar; and three phosphate groups, identifiable as phosphorus atoms surrounded by oxygen atoms (Fig. 6–6*a*). Notice that the phosphate groups are bonded to the end of the molecule in a series, rather like three cars behind a locomotive, and, like the cars of a train, they can be attached and detached.

ATP donates energy through the transfer of a phosphate group

When the terminal phosphate is removed from ATP, the remaining molecule is **adenosine diphosphate (ADP)** (Fig. 6–6*b*). If the phosphate group is not transferred to another molecule, it is released as inorganic phosphate (P_i). This is an exergonic reaction. ATP is sometimes called a “high-energy” compound because the hydrolysis reaction that releases a phosphate has a relatively large $-\Delta G$.²

Reaction 5 can be coupled to endergonic reactions in cells. Consider the following endergonic reaction in which the disaccharide sucrose is formed from two monosaccharides, glucose and fructose.

With a free energy change of $-32 \text{ kJ/mole } (-7.6 \text{ kcal/mole})$, the hydrolysis of ATP in Reaction 5 can drive Reaction 6, but only if the reactions can be coupled through a common intermediate. The following series of reactions is a simplified version of an alternative pathway used by some bacteria.

Reaction 7 is a **phosphorylation reaction**, one in which a phosphate group is transferred to some other compound. Glucose is phosphorylated to form glucose phosphate (glucose-P), the intermediate that links the two reactions. Glucose-P, which corresponds to “I” in Reactions 3 and 4, reacts exergonically with fructose to form sucrose. For energy coupling to work in this way, Reactions 7 and 8 must occur in sequence. It is convenient to summarize the reactions in the following way:

When encountering an equation written in this way, remember that it is actually a summary of a series of reactions and that transitory intermediate products are sometimes not shown.

²Calculations of the free energy of ATP hydrolysis vary somewhat, but range between about -28 and $-37 \text{ kJ/mole } (-6.8 \text{ to } -8.7 \text{ kcal/mole})$.

(a) Adenosine triphosphate (ATP)

ATP links exergonic and endergonic reactions

We have just discussed how the transfer of a phosphate group from ATP to some other compound can be coupled to endergonic reactions in the cell. Conversely, adding a phosphate group to AMP (forming ADP) or to ADP (forming ATP) requires coupling to exergonic reactions in the cell.

Thus ATP occupies an intermediate position in the metabolism of the cell and is an important link between exergonic reactions, which are generally components of catabolic pathways, and endergonic reactions, which are generally part of anabolic pathways (Fig. 6–7).

The cell maintains a very high ratio of ATP to ADP

The cell maintains the ratio of ATP to ADP far from the equilibrium point. ATP is constantly formed from ADP and inorganic phosphate as nutrients are oxidized in cellular respiration or as the radiant energy of sunlight is trapped in photosynthesis (see Chapters 7 and 8). At any point in time,

Figure 6–7 ATP links exergonic and endergonic reactions. Because ATP is responsible for coupling many exergonic and endergonic reactions, it is an important link between catabolism and anabolism in cells.

a typical cell contains more than ten ATP molecules for every ADP molecule. The fact that the cell maintains the ATP concentration at such a high level (relative to the concentration of ADP) makes its hydrolysis reaction even more strongly exergonic and more able to drive the endergonic reactions to which it is coupled.

Although the cell maintains a high ratio of ATP to ADP, large quantities of ATP cannot be stored in the cell. The concentration of ATP is always very low, less than 1 millimole per liter. In fact, studies suggest that a bacterial cell has no more than a one-second supply of ATP. Thus, ATP molecules are used almost as quickly as they are produced. A human at rest uses about 45 kilograms (99 pounds) of ATP each day, but the amount present in the body at any given moment is less than 1 gram (0.035 ounce). Every second in every cell, an estimated 10 million molecules of ATP are made from ADP and phosphate, and an equal number of ATPs transfer their phosphate groups along with their energy to whatever chemical reactions may require them.

CELLS TRANSFER ENERGY BY REDOX REACTIONS

We have seen that cells can transfer energy through the transfer of a phosphate group from ATP. Energy can also be transferred through the transfer of electrons. As discussed in Chapter 2, **oxidation** is the chemical process in which a substance loses electrons, whereas **reduction** is the complementary process in which a substance gains electrons. Because electrons released during an oxidation reaction cannot exist in the free state in living cells, every oxidation reaction must be accompanied by a reduction reaction, in which the electrons are accepted by another atom, ion, or molecule. Oxidation and reduction reactions are often called **redox reactions** because they occur simultaneously. The substance that becomes oxidized gives up energy as it releases electrons, and the substance that becomes reduced receives energy as it gains electrons.

Redox reactions often occur in a series as electrons are transferred from one molecule to another. These electron transfers, which are equivalent to energy transfers, are an essential part of cellular respiration, photosynthesis, and many other chemical reactions. Redox reactions, for example, release the energy stored in food molecules so that ATP can be synthesized using that energy.

Most electron carriers carry hydrogen atoms

Generally it is not easy to remove one or more electrons from a covalent compound; it is much easier to remove a whole atom. For this reason, redox reactions in cells usually involve the transfer of a hydrogen atom rather than just an electron. A hydrogen atom contains an electron and a proton that does not participate in the oxidation/reduction.

When an electron, either singly or as part of a hydrogen atom, is removed from an organic compound, it takes with it

Figure 6–8 NAD⁺. The acceptor molecule NAD⁺ is composed of two nucleotides joined together. The oxidized form, NAD⁺, becomes reduced (NADH) by the transfer of two electrons and one proton from another organic compound, which becomes oxidized in the process.

some of the energy stored in the chemical bond of which it was a part. That electron, along with its energy, is transferred to an acceptor molecule. An electron progressively loses free energy as it is transferred from one acceptor to another.

One of the most frequently encountered acceptor molecules is **nicotinamide adenine dinucleotide (NAD⁺)**. When NAD⁺ becomes reduced, it temporarily stores large amounts of free energy. Here is a generalized equation showing the transfer of hydrogen from a compound we call X to NAD⁺:

Note that the NAD⁺ becomes reduced when it combines with hydrogen. NAD⁺ is an ion with a net charge of +1. When two electrons and one proton are added, the charge is neutralized and the reduced form of the compound, **NADH**, is produced (Fig. 6–8).³ Some of the energy stored in the bonds holding the hydrogen atoms to molecule X has been transferred by this redox reaction and is temporarily held by NADH. When NADH transfers the electrons to some other molecule, some of their energy is transferred. This energy is usually then transferred through a complex series of reactions that result in the formation of ATP (see Chapter 7).

Nicotine adenine dinucleotide phosphate (NADP⁺) is a hydrogen acceptor that is chemically similar to NAD⁺ but

³Although the correct way to write the reduced form of NAD⁺ is NADH + H⁺, for simplicity we will present the reduced form as NADH in this and succeeding chapters.

with an extra phosphate group. Unlike NADH, the reduced form of NADP^+ (abbreviated **NADPH**) is not involved in ATP synthesis. Instead, the electrons of NADPH are used more directly to provide energy for certain reactions, including certain essential reactions of photosynthesis (see Chapter 8).

Other important hydrogen acceptors or electron acceptors include **flavin adenine dinucleotide (FAD)** and the **cytochromes**. FAD is a nucleotide that accepts hydrogen atoms and their electrons; its reduced form is **FADH_2** . The cytochromes are proteins that contain iron; the iron component accepts electrons from hydrogen atoms and then transfers these electrons to some other compound. Like NAD^+ and NADP^+ , FAD and the cytochromes are electron transfer agents. Each can exist in a reduced state in which it has more free energy or in an oxidized state in which it has less. Each is an essential component of many redox reaction sequences in cells.

ENZYMES ARE CHEMICAL REGULATORS

The principles of thermodynamics help us predict whether a reaction can occur, but they tell us nothing about the speed of the reaction. The breakdown of glucose, for example, is an exergonic reaction, yet a glucose solution keeps virtually indefinitely in a bottle if kept free of bacteria and molds and not subjected to high temperature or strong acids or bases. Cells cannot wait for centuries for glucose to break down, nor can they use extreme conditions to cleave glucose molecules. Cells regulate the rates of chemical reactions with **enzymes**, which are protein **catalysts** that affect the speed of a chemical reaction without being consumed by the reaction.⁴

Cells require a steady release of energy, and they must be able to regulate that release to meet metabolic energy requirements. Metabolism generally proceeds by a series of steps so that a molecule may go through as many as 20 or 30 chemical transformations before it reaches some final state. Even then, the seemingly completed molecule may enter yet another chemical pathway and become totally transformed or consumed to produce energy. The changing needs of the cell require a system of flexible metabolic control. The key directors of this control system are enzymes.

The catalytic ability of some enzymes is truly remarkable. For example, hydrogen peroxide (H_2O_2) breaks down extremely slowly if the reaction is uncatalyzed, but a single molecule of the enzyme catalase brings about the decomposition of 5 million molecules of hydrogen peroxide per minute at 0°C ! Catalase protects cells because hydrogen peroxide is a poisonous substance produced as a byproduct of some cellular reactions. The bombardier beetle uses the enzyme catalase as a defense mechanism (Fig. 6–9).

Figure 6–9 Catalase. When threatened, a bombardier beetle uses the enzyme catalase to decompose hydrogen peroxide. The oxygen gas formed in the decomposition ejects water and other chemicals with explosive force. Because the reaction releases a great deal of heat, the water comes out as steam. (The beetle is immobilized by a wire attached to its back by a drop of adhesive. His leg was just prodded with the dissecting needle on the left to trigger the ejection.)

(Thomas Eisner and Daniel Aneshansley/Cornell University)

All reactions have a required energy of activation

All reactions have an energy barrier known as the **energy of activation (E_A)** or **activation energy**. The energy barrier is the energy required to break the existing bonds and begin the reaction. In a population of molecules of any kind, some have a relatively high energy content, while others have a lower energy content. Only molecules with a relatively high energy content are likely to react to form the product (Fig. 6–10*a*).

Even a strongly exergonic reaction, one that releases a substantial quantity of energy as it proceeds, may be prevented from proceeding by the activation energy required to begin the reaction. For example, molecular hydrogen and molecular oxygen can react explosively to form water:

This reaction is spontaneous (exergonic), yet hydrogen and oxygen can be safely mixed as long as all sparks are kept away. This is because the required energy of activation for this particular reaction is relatively high. A tiny spark provides the activation energy that allows a few molecules to react. Their reaction liberates so much heat that the rest react, producing an explosion. Such an explosion occurred on the Hindenburg, an airship that used hydrogen gas, which is lighter than air, for buoyancy (Fig. 6–11). At the end of a transatlantic voyage in 1937, it exploded on landing, probably because a small spark supplied the activation energy for the reaction of hydrogen with oxygen from the air.

⁴In recent years scientists have learned that protein enzymes are not the only cellular catalysts; some types of RNA molecules have catalytic activity as well (see Chapter 12).

(a) Uncatalyzed reaction, high activation energy

(b) Catalyzed reaction, low activation energy

Figure 6–10 Kinetic energy in molecules and activation energy, as demonstrated by frogs.

(a) If a reaction is uncatalyzed, only a small fraction of reactant molecules (frogs) have sufficient energy to overcome the barrier of activation energy and undergo a chemical reaction to form product molecules (jump into the adjacent compartment). (b) An enzyme lowers the activation energy barrier and increases the fraction of molecules (frogs) that can react (jump). (Adapted from Tobin and Morel)

An enzyme lowers a reaction's activation energy

As do all catalysts, enzymes affect the rate of a reaction by lowering the energy needed to initiate the reaction. An enzyme greatly reduces the activation energy necessary to initiate a chemical reaction (Figs. 6–10b and 6–12). If molecules need less energy to react because the activation barrier is lowered, a larger fraction of the reactant molecules reacts at any one time.

As a result, the reaction proceeds more quickly.

Although an enzyme lowers the activation energy for a reaction, it has no effect on the overall free energy change. That is, an enzyme can only promote a chemical reaction that could proceed without it. No catalyst can cause a reaction to proceed in a thermodynamically unfavorable direction or can influence the final concentrations of reactants and products if the reaction goes to equilibrium. Enzymes simply speed up reaction rates.

Figure 6–11 The Hindenburg explosion. This disaster resulted when a spark triggered an explosive, exergonic reaction between hydrogen in the airship and oxygen in the atmosphere. (Archive Photos)

Figure 6–12 Activation energy and enzymes. An enzyme speeds up a reaction by lowering its activation energy (E_A). In the presence of an enzyme, it takes less activation energy for reacting molecules to complete a reaction.

Figure 6-13 Active site and induced fit. (a) Computer graphic model of the enzyme hexokinase (blue) and its substrate, glucose (red), before forming an ES complex. The active site of the enzyme is the furrow where glucose will bind. (b) The binding of glucose to the active site of hexokinase changes the shape of the enzyme, a phenomenon known as induced fit. Hexokinase, which is involved in cellular respiration, catalyzes the transfer of a phosphate group from ATP to glucose. (Courtesy of Thomas A. Steitz)

An enzyme works by forming an enzyme-substrate complex

An uncatalyzed reaction depends on random collisions among reactants. Because of its ordered structure, an enzyme is able to reduce this reliance on random events and thereby control the reaction. The enzyme is thought to accomplish this by forming an unstable intermediate complex with the **substrate**, the substance on which it acts. When the **enzyme-substrate complex**, or **ES complex**, breaks up, the product is released; the original enzyme molecule is regenerated and is free to form a new ES complex.

The enzyme itself is not permanently altered or consumed by the reaction and can be reused.

As shown in Figure 6-13a, every enzyme contains one or more **active sites**, regions to which the substrate binds, forming the ES complex. The active sites of some enzymes are grooves or cavities in the enzyme molecule, formed by amino acid side chains. The active sites of most enzymes are located close to the surface. During the course of a reaction, substrate molecules occupying these sites are brought close together and react with one another.

The shape of the enzyme does not seem to be exactly complementary to that of the substrate. When the substrate binds to the enzyme molecule, it causes a change, known as **induced fit**, in the shape of the enzyme molecule. Usually the shape of the substrate also changes slightly, in a way that may distort its chemical bonds (Fig. 6-13b). The proximity and orientation of the reactants, together with strains in their chemical bonds, facilitate the breakage of old bonds and the formation of new ones. Thus the substrate is changed into product, which moves away from the enzyme. The enzyme is then free to catalyze the reaction of more substrate molecules to form more product molecules.

Most enzyme names end in *-ase*

Enzymes are usually named by the addition of the suffix *-ase* to the name of the substrate. The enzyme sucrase, for example, splits sucrose into glucose and fructose. A few enzymes retain traditional names that do not end in *-ase*; some of these end in *-zyme*. For example, lysozyme (from the Greek *lysis*, “to dissolve”) is an enzyme found in tears and saliva; this enzyme breaks down bacterial cell walls. Other examples of enzymes with traditional names include pepsin and trypsin, which break internal peptide bonds in proteins.

Enzymes are specific

Virtually every chemical reaction that takes place in an organism is catalyzed by an enzyme. Because there is a close relationship between the shape of the active site and the shape of the substrate, the majority of enzymes are highly specific. Most are capable of catalyzing only a few closely related chemical reactions or, in many cases, only one particular reaction. For example, the enzyme urease, which decomposes urea to ammonia and carbon dioxide, attacks no other substrate. The enzyme sucrase splits only sucrose; it does not act on other disaccharides such as maltose or lactose.

A few enzymes are specific only to the extent that they require the substrate to have a certain kind of chemical bond. For example, lipase secreted by the pancreas splits the ester linkages connecting the glycerol and fatty acids of a wide variety of fats.

Enzymes that catalyze similar reactions are classified into groups, although each particular enzyme in the group may catalyze only one specific reaction. Some of the important classes of enzymes and their roles are listed in Table 6-1. Each class is divided into many subclasses. For example, sucrase, mentioned above, is referred to as a glycosidase because it cleaves a glycosidic linkage. Glycosidases are a subclass of the hydrolases.

TABLE 6–1 Some Important Classes of Enzymes

Enzyme Class	Function
Oxidoreductases	Catalyze oxidation-reduction reactions
Transferases	Catalyze the transfer of a functional group from a donor molecule to an acceptor molecule
Hydrolases	Catalyze hydrolysis reactions
Isomerases	Catalyze conversion of a molecule from one isomeric form to another
Ligases	Catalyze certain reactions in which two molecules are joined
Lyases	Catalyze certain reactions in which double bonds are formed or broken.

Many enzymes require cofactors

Some enzymes, for example, pepsin, which is secreted by the stomach, consist only of protein. Others have two components: a protein referred to as the **apoenzyme** and an additional chemical component called a **cofactor**. Neither the apoenzyme nor the cofactor alone has catalytic activity; only when the two are combined does the enzyme function. A cofactor may be inorganic, or it may be an organic molecule.

Some enzymes require a specific metal ion as a cofactor. Two very common inorganic cofactors are magnesium ions and calcium ions. Most of the trace elements, such as iron, copper, zinc, and manganese, all of which are required in very small amounts, function as cofactors.

An organic, nonpolypeptide compound that binds to the apoenzyme and serves as a cofactor is called a **coenzyme**. Most coenzymes are carrier molecules that transfer electrons or part of a substrate from one molecule to another. Some examples of coenzymes have already been introduced in this chapter. NADH, NADPH, and FADH₂ are coenzymes; they transfer electrons. ATP functions as a coenzyme; it is responsible for transferring phosphate groups. Yet another coenzyme, **coenzyme A**, is involved in the transfer of groups derived from organic acids. Most vitamins, which are organic compounds that an organism requires in small amounts but cannot synthesize itself, are coenzymes or components of coenzymes (see Table 45–4).

Enzymes are most effective at optimal conditions

Enzymes generally work best under certain narrowly defined conditions, such as appropriate temperature, pH, and ion con-

centration. Any departure from optimal conditions adversely affects enzyme activity.

Each enzyme has an optimal temperature

Most enzymes have an optimal temperature at which the rate of reaction is fastest. For human enzymes, the temperature optima are near body temperature (35° to 40°C). Enzymatic reactions occur slowly or not at all at low temperatures. As the temperature increases, molecular motion increases, resulting in more molecular collisions. The rates of most enzyme-controlled reactions therefore increase as the temperature increases, within limits (Fig. 6–14*a*). High temperatures rapidly denature most enzymes; the molecular conformation of the protein

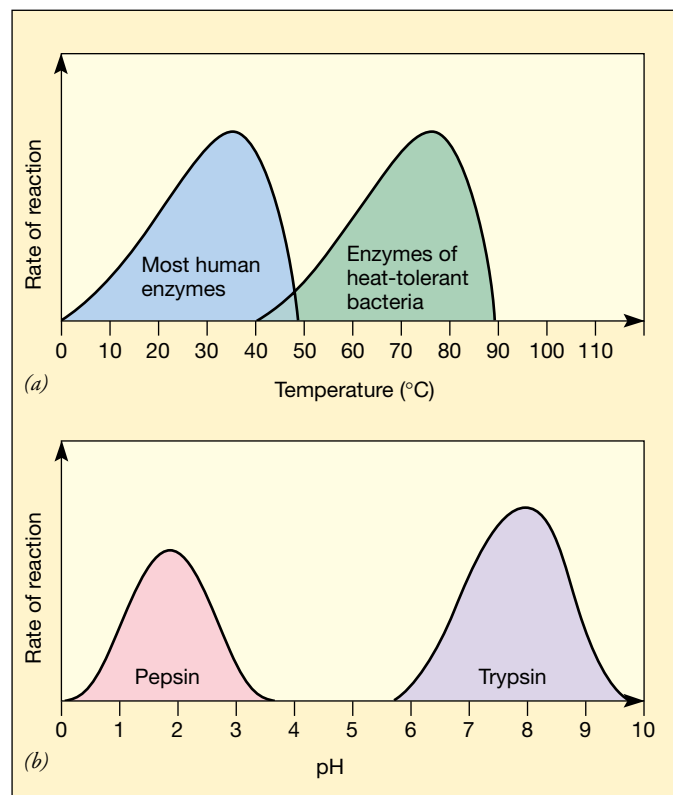

Figure 6–14 Effect of temperature and pH on enzyme activity. Substrate and enzyme concentrations are held constant in the reactions illustrated. (a) Generalized curves for the effect of temperature on enzyme activity. As temperature increases, enzyme activity increases until it reaches an optimal temperature. Enzyme activity abruptly falls after it exceeds the optimal temperature because the enzyme, being a protein, denatures. (b) Enzyme activity is very sensitive to pH. Pepsin is a protein-digesting enzyme in the very acidic stomach juice. Trypsin, secreted by the pancreas into the slightly alkaline small intestine, digests polypeptides.

becomes altered as the hydrogen bonds responsible for its secondary, tertiary, and quaternary structures are broken. Because this inactivation is usually not reversible, activity is not regained when the enzyme is cooled.

Most organisms are killed by even a short exposure to high temperature; their enzymes are denatured, and they are unable to continue metabolism. A few remarkable exceptions to this rule exist: certain species of bacteria can survive in the waters of hot springs, such as those in Yellowstone Park, where the temperature is almost 100°C; these organisms are responsible for the brilliant colors in the terraces of the hot springs. Still other bacteria live at temperatures much above that of boiling water, near deep-sea vents, where the extreme pressure keeps water in its liquid state (see Chapter 23 and *Focus On: Life Without the Sun* in Chapter 52).

Each enzyme has an optimal pH

Most enzymes are active only over a narrow pH range and have an optimal pH at which the rate of reaction is fastest. The optimal pH for most human enzymes is between 6 and 8. Pepsin, a protein-digesting enzyme secreted by cells lining the stomach, is remarkable in that it works only in a very acid medium, optimally at pH 2 (Fig. 6–14*b*). In contrast, trypsin, the protein-splitting enzyme secreted by the pancreas, functions best under slightly basic conditions.

The activity of an enzyme may be markedly changed by any alteration in pH, which in turn alters charges on the enzyme. Changes in charge affect the ionic bonds that contribute to tertiary and quaternary structure, thus changing the protein's conformation and activity. Many enzymes become inactive, and usually irreversibly denatured, when the medium is made very acidic or very basic.

Enzymes are organized into teams in metabolic pathways

Enzymes play an essential role in energy coupling because they usually work in sequence, with the product of one enzyme-controlled reaction serving as the substrate for the next. We can picture the inside of a cell as a factory with many different assembly (and disassembly) lines operating simultaneously. An assembly line is composed of a number of enzymes. Each enzyme carries out one step, such as changing molecule A into molecule B. Then molecule B is passed along to the next enzyme, which converts it into molecule C, and so on. Such a series of reactions is referred to as a **metabolic pathway**.

Each of these reactions is theoretically reversible, and the fact that it is catalyzed by an enzyme does not change that fact. An enzyme does not itself determine the direction of the reaction it catalyzes. However, the overall reaction sequence is portrayed as proceeding from left to right. You will recall that if there is little intrinsic free energy difference between the re-

actants and products for a particular reaction, its direction will be determined mainly by the relative concentrations of reactants and products.

In biological pathways, both intermediate and final products are often removed and converted to other chemical compounds. Such removal drives the sequence of reactions in a particular direction. Let us assume that Reactant A is being constantly supplied and that its concentration remains constant. Enzyme 1 converts Reactant A to Product B. The concentration of B is always lower than the concentration of A because B is removed as it is converted to C in the reaction catalyzed by Enzyme 2. If C is removed as quickly as it is formed (perhaps by leaving the cell), the entire pathway is “pulled” toward C.

The cell regulates enzymatic activity

Enzymes regulate the chemistry of the cell, but what controls the enzymes? One mechanism depends simply on controlling the amount of enzyme produced. The synthesis of each type of enzyme is directed by a specific gene. The gene, in turn, may be switched on by a signal from a hormone or by some other type of cellular product. When the gene is switched on, the enzyme is synthesized. The amount of enzyme present then influences the rate of the reaction.

If the pH and temperature are kept constant, the rate of the reaction can be affected by the substrate concentration or by the enzyme concentration. If an excess of substrate is present, the enzyme concentration is the rate-limiting factor. The initial rate of the reaction is then directly proportional to the concentration of enzyme present (Fig. 6–15*a*).

Figure 6–15 Effect of enzyme concentration and substrate concentration on the rate of a reaction. (a) In this example, the rate of reaction is measured at different enzyme concentrations, and an excess of substrate is present at all times. The rate of the reaction is therefore directly proportional to the enzyme concentration. (b) In this example, the rate of reaction is measured at different substrate concentrations, and enzyme concentration is constant. If the substrate concentration is relatively low, then the reaction rate is directly proportional to substrate concentration. However, higher substrate concentrations do not increase the reaction rate because the enzyme molecules become saturated with substrate.

If the enzyme concentration is kept constant, the initial rate of an enzymatic reaction is proportional to the concentration of substrate present. Substrate concentration is the rate-limiting factor at lower concentrations; the rate of the reaction is therefore directly proportional to the substrate concentration. However, at higher substrate concentrations the enzyme molecules become saturated with substrate, and increasing the substrate concentration does not increase the reaction rate (Fig. 6–15*b*).

The product of one enzymatic reaction may control the activity of another enzyme, especially in a complex sequence of enzymatic reactions. For example, in the following metabolic pathway,

each step is catalyzed by a different enzyme, and the final product E may inhibit the activity of Enzyme 1. When the concentration of E is low, the sequence of reactions proceeds rapidly. However, an increasing concentration of E serves as a signal for Enzyme 1 to slow down and eventually to stop functioning. Inhibition of Enzyme 1 stops the entire reaction sequence. This type of enzyme regulation, in which the formation of a product inhibits an earlier reaction in the sequence, is called **feedback inhibition** (Fig. 6–16).

Another important method of enzymatic control depends on the activation of enzyme molecules. In their inactive form the active sites of the enzyme are inappropriately shaped, so that the substrates do not fit. Among the factors that influence the shape of the enzyme are pH, the concentration of certain ions, and the addition of phosphate groups to certain amino acids in the enzyme.

Some enzymes possess a receptor site, called an **allosteric site**, on some region of the enzyme molecule other than the active site. (The word *allosteric* means “another space.”) Substances that affect enzyme activity by binding to allosteric sites are called **allosteric regulators**. Some allosteric regulators are inhibitors that keep the enzyme in its inactive shape. Other allosteric regulators are activators that result in an enzyme with a functional active site.

The enzyme cyclic AMP-dependent protein kinase is an

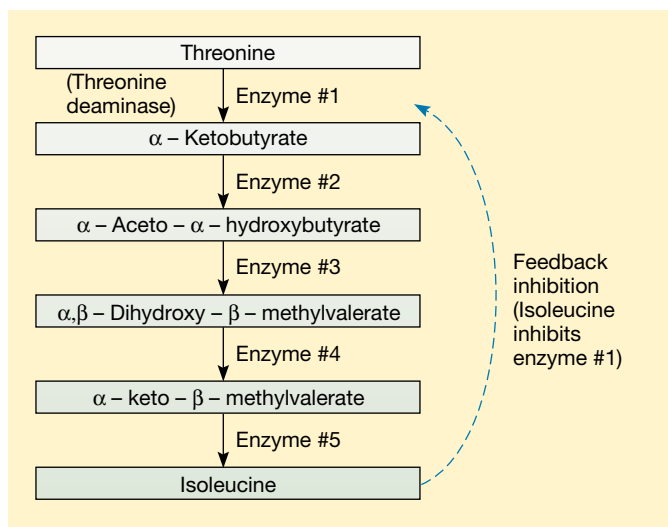

Figure 6–16 Feedback inhibition. Bacteria synthesize the amino acid isoleucine from the amino acid threonine. The isoleucine synthetic pathway involves five steps, each catalyzed by a different enzyme. When enough isoleucine accumulates in the cell, the isoleucine inhibits the enzyme that catalyzes the first step in this pathway.

allosteric enzyme with a regulator that is a protein that binds reversibly to the allosteric site and inactivates the enzyme. Protein kinase is in this inactive form most of the time (Fig. 6–17). When protein kinase activity is needed, the compound cyclic AMP (cAMP; see Fig. 3–25) contacts the enzyme-inhibitor complex and removes the inhibitory protein, thereby activating the protein kinase. Activation of protein kinases by cAMP is an important aspect of the mechanism of action of certain hormones (see Chapter 47).

Enzymes can be inhibited by certain chemical agents

Most enzymes may be inhibited or even destroyed by certain chemical agents. Enzyme inhibition may be reversible or irreversible. **Reversible inhibition** occurs when an inhibitor forms

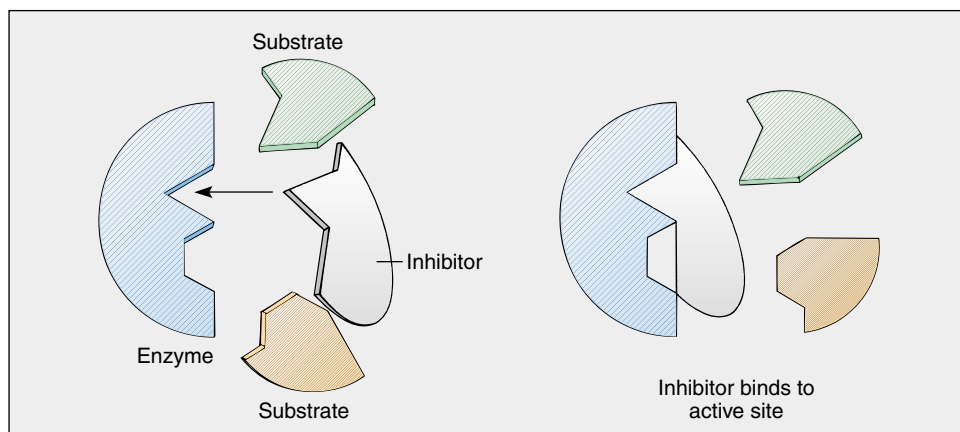

Figure 6–17 Allosteric enzyme. (a) The enzyme protein kinase is inhibited by a regulatory protein that binds reversibly to its allosteric site. When the enzyme is in this inactive form, the shape of the active site is modified so that the substrate cannot combine with it. (b) Cyclic AMP removes the allosteric inhibitor and activates the enzyme. The substrate can then combine with the active site (c).

(a) Competitive inhibition

(b) Noncompetitive inhibition

Figure 6–18 Competitive and non-competitive inhibition. (a) In competitive inhibition, the inhibitor competes with the normal substrate for the active site of the enzyme. A competitive inhibitor occupies the active site only temporarily. (b) In noncompetitive inhibition, the inhibitor binds with the enzyme at a site other than the active site, altering the shape of the enzyme and thereby inactivating it. Noncompetitive inhibition may be reversible.

weak chemical bonds with the enzyme. Reversible inhibition can be competitive or noncompetitive.

In **competitive inhibition**, the inhibitor competes with the normal substrate for binding to the active site of the enzyme (Fig. 6–18a). Usually a competitive inhibitor is structurally similar to the normal substrate and so fits into the active site and combines with the enzyme. However, it is not similar enough to substitute fully for the normal substrate in the chemical reaction, and the enzyme cannot attack it to form product molecules. A competitive inhibitor occupies the active site only temporarily and does not permanently damage the enzyme. In competitive inhibition, an active site is occupied by the inhibitor part of the time and by the normal substrate part of the time. If the concentration of the substrate is increased relative to the concentration of the inhibitor, the active site will usually be occupied by the substrate. Competitive inhibition is demonstrated experimentally by the fact that it can be reversed by increasing the substrate concentration.

In **noncompetitive inhibition**, the inhibitor binds with the enzyme at a site other than the active site (Fig. 6–18b). Such an inhibitor inactivates the enzyme by altering its shape so that the active site cannot bind with the substrate. Many important noncompetitive inhibitors are metabolic substances that regulate enzyme activity by combining reversibly with the enzyme. Noncompetitive inhibition has some features in common with allosteric inhibition discussed previously.

In **irreversible inhibition**, an inhibitor permanently inactivates or destroys an enzyme when it combines with one of its functional groups. Many poisons are irreversible enzyme inhibitors. For example, heavy metals such as mercury and lead bind irreversibly to and denature many proteins, including enzymes. Certain nerve gases poison the enzyme acetylcholinesterase, which is important to the function of nerves and muscles. Cytochrome oxidase, one of the enzymes that transports electrons in cellular respiration, is especially sensitive to cyanide. Death results from cyanide poisoning because cytochrome oxidase is irreversibly inhibited and can no longer transfer electrons from substrate to oxygen. A number of insecticides and drugs are irreversible enzyme inhibitors. Irreversible inhibition may also occur if a protein is denatured by heat or organic solvents.

Some drugs are enzyme inhibitors

Many bacterial infections are treated with drugs that directly or indirectly inhibit bacterial enzyme activity. For example, sulfa drugs have a chemical structure similar to that of the nutrient para-aminobenzoic acid (PABA) (Fig. 6–19). When PABA is available, microorganisms can synthesize the vitamin folic acid, which is necessary for growth. Humans do not synthesize folic acid from PABA, and that is why sulfa drugs selectively affect bacteria.

Figure 6–19 Para-aminobenzoic acid and sulfonamides. Sulfa drugs owe their antibiotic properties to their similarity in structure to para-aminobenzoic acid, a precursor in the synthesis of folic acid. Sulfa drugs block the synthesis of folic acid, an important vitamin necessary for growth. Animals, including humans, obtain folic acid in their diets, but many bacteria synthesize it.

When a sulfa drug is present, competitive inhibition occurs within the bacterium: the drug competes with PABA for the active site of the bacterial enzyme. When bacteria use the sulfa drug instead of PABA, they synthesize a compound that cannot be used to make folic acid. Therefore, the bacterial cells are unable to grow.

Penicillin and related antibiotics irreversibly inhibit a bacterial enzyme called transpeptidase. This enzyme is responsible for establishing some of the chemical linkages in the bacterial cell wall. Susceptible bacteria cannot produce properly constructed cell walls and are prevented from multiplying effectively. Human cells do not have cell walls and do not employ this enzyme. Thus, except for individuals allergic to it, penicillin is harmless to humans. Unfortunately, during the years since it was introduced, resistance to penicillin has evolved in many bacterial strains. The resistant bacteria fight back with an enzyme of their own, penicillinase, which breaks down the penicillin and renders it ineffective. Because bacteria evolve at such a rapid rate, drug resistance is a growing problem in medical practice (see *Making the Connection: Tuberculosis, Bacterial Resistance to Antibiotics, and Evolution* in Chapter 17). Although new antibacterial drugs are constantly under development, certain serious infections, such as tuberculosis, are becoming increasingly difficult to treat.

SUMMARY WITH KEY TERMS

- I. **Energy** can be defined as the capacity to do work (expressed in **kilojoules, kJ**).
 - A. All life depends on a continuous input of energy. Most producers capture energy during photosynthesis and incorporate some of it into the chemical bonds of organic compounds. Some of this chemical energy then becomes available to consumers and decomposers.
 - B. All forms of energy are interconvertible.
 1. **Potential energy** is stored energy; **kinetic energy** is energy of motion.
 2. Energy can be conveniently measured as **heat energy**; the unit of heat energy is the **kilocalorie (kcal)**, which is equal to 4.184 kilojoules. Heat energy cannot do cellular work.
- II. The **first law of thermodynamics** states that energy cannot be created or destroyed but can be transferred and changed in form. The **second law of thermodynamics** states that disorder (**entropy**) in the universe is continuously increasing.
 - A. The first law explains why organisms cannot produce energy but must continuously capture it from the surroundings.
 - B. The second law explains why no process requiring energy is ever 100% efficient. In every energy transaction, some energy is dissipated as heat, which contributes to entropy.
- III. When a chemical reaction is in a state of **dynamic equilibrium**, the rate of change in one direction is exactly the same as the rate of change in the opposite direction; the system can do no work because the **free energy** difference between the reactants and products is zero.
 - A. As entropy (S) increases, the amount of free energy (G) decreases, as shown in the equation $G = H - TS$, in which G is the free energy, H is the **enthalpy** (total potential energy of the system), T is the absolute temperature (expressed in degrees Kelvin), and S is entropy.
 - B. The equation $\Delta G = \Delta H - T\Delta S$ indicates that the change in free energy (ΔG) during a chemical reaction is equal to the change in enthalpy (ΔH) minus the product of the absolute temperature (T) multiplied by the change in entropy (ΔS).
- IV. A **spontaneous reaction** releases free energy and can perform work.
 - A. Free energy decreases in an **exergonic reaction**. Exergonic reactions are spontaneous.
 - B. Free energy increases in an **endergonic reaction**. The input of free energy required to drive an endergonic reaction may be supplied by **coupling** it to an exergonic reaction.
- V. **Adenosine triphosphate (ATP)** is the immediate energy currency of the cell; it generally transfers energy through the transfer of its terminal phosphate group to acceptor molecules.
 - A. ATP is formed by the **phosphorylation** of ADP, an endergonic process that requires an input of energy.
 - B. ATP is the common cellular link between exergonic and endergonic reactions and between **catabolism** and **anabolism**.
- VI. Energy can be transferred in **oxidation-reduction (redox) reactions**.
 - A. A substance that becomes oxidized gives up one or more electrons (and energy) to a substance that becomes reduced. Electrons are typically transferred as part of hydrogen atoms.
 - B. **NAD⁺** and **NADP⁺** accept electrons as part of hydrogen atoms and become reduced to form NADH and NADPH, respectively. These electrons (along with some of their energy) can be transferred to other acceptors.
- VII. An **enzyme** is a biological **catalyst**; it greatly increases the speed of a chemical reaction without being consumed.
 - A. An enzyme lowers the **activation energy** necessary to get a reaction going.
 - B. An **active site** of an enzyme is a three-dimensional region where **substrates** come into close contact and thereby react more readily. A substrate binds to an active site, causing an **induced fit** in which the shape of the enzyme changes slightly.
 - C. Some enzymes consist of an **apoenzyme** and a **cofactor**.
 1. Most inorganic cofactors are metal ions.
 2. A **coenzyme** is an organic cofactor; many coenzymes transfer electrons or part of a substrate from one molecule to another.
 - D. Enzymes work best at specific temperature and pH conditions.

- E. A cell can regulate enzymatic activity by controlling the amount of enzyme produced and by regulating metabolic conditions that influence the shape of the enzyme.
- Some enzymes have **allosteric sites**, noncatalytic sites to which a substance can bind, changing the enzyme's activity.
 - Allosteric enzymes are subject to **feedback inhibition**, in which the formation of an end product inhibits an earlier reaction in the sequence.
- F. Most enzymes can be inhibited by certain chemical substances. Inhibition may be reversible or irreversible.

- Reversible inhibition** occurs when an inhibitor forms weak chemical bonds with the enzyme. Reversible inhibition may be **competitive**, in which the inhibitor competes with the substrate for the active site, or **noncompetitive**, in which the inhibitor binds with the enzyme at a site other than the active site.
- Irreversible inhibition** occurs when an inhibitor combines with an enzyme and permanently inactivates it.

POST-TEST

- According to the first law of thermodynamics (a) energy may be changed from one form to another but is neither created nor destroyed (b) much of the work an organism does is mechanical work (c) the disorder of the universe is increasing (d) free energy is available to do cellular work (e) a cell is in a state of dynamic equilibrium
- According to the second law of thermodynamics (a) energy may be changed from one form to another but is neither created nor destroyed (b) much of the work an organism does is mechanical work (c) the disorder of the universe is increasing (d) free energy is available to do cellular work (e) a cell is in a state of dynamic equilibrium
- In thermodynamics, _____ is a measure of the amount of disorder in the system. (a) bond energy (b) catabolism (c) entropy (d) enthalpy (e) work
- The _____ of a system is that part of the total energy available to do cellular work. (a) activation energy (b) bond energy (c) kinetic energy (d) free energy (e) heat energy
- A reaction that requires a net input of free energy is described as (a) exergonic (b) endergonic (c) spontaneous (d) both a and c (e) both b and c
- A reaction that releases energy is described as (a) exergonic (b) endergonic (c) spontaneous (d) both a and c (e) both b and c
- A spontaneous reaction is one in which the change in free energy (ΔG) has a _____ value. (a) positive (b) negative (c) positive or negative (d) none of these (ΔG has no value)
- To drive a reaction that requires an input of energy (a) an enzyme-sub-

strate complex must form (b) the concentration of ATP must be decreased (c) the activation energy must be increased (d) some reaction that yields energy must be coupled to it (e) some reaction that requires energy must be coupled to it

- The energy required to initiate a reaction is called (a) activation energy (b) bond energy (c) kinetic energy (d) free energy (e) heat energy
- A biological catalyst that affects the rate of a chemical reaction without being consumed by the reaction is a(n) (a) product (b) cofactor (c) coenzyme (d) substrate (e) enzyme
- The region of an enzyme molecule that combines with the substrate is the (a) allosteric site (b) reactant (c) active site (d) coenzyme (e) product
- This inhibitor binds to the active site of an enzyme. (a) noncompetitive inhibitor (b) competitive inhibitor (c) irreversible inhibitor (d) allosteric regulator
- Which of the following reactions could be coupled to an endergonic reaction with $\Delta G = +3.56$ kJ/mole? (a) $A \rightarrow B$, $\Delta G = +6.08$ kJ/mole (b) $C \rightarrow D$, $\Delta G = +3.56$ kJ/mole (c) $E \rightarrow F$, $\Delta G = -1.22$ kJ/mole (d) $G \rightarrow H$, $\Delta G = -5.91$ kJ/mole
- In the following reaction series, which enzyme is most likely to have an allosteric site to which the end product E binds?

(a) enzyme 1 (b) enzyme 2 (c) enzyme 3 (d) enzyme 4

REVIEW QUESTIONS

- Why can we express energy either in kilojoules or in kilocalories? Which is more convenient to measure? Which has more meaning in biology?
- You exert tension on a spring and then release it. Explain how these actions relate to work, potential energy, and kinetic energy.
- Life is sometimes described as a constant struggle against the second law of thermodynamics. How do organisms succeed in this struggle without violating the second law?
- Consider the free energy change in a reaction in which enthalpy decreases and entropy increases. Is ΔG zero, or does it have a positive value or a negative value? Is the reaction exergonic or endergonic?
- Why do coupled reactions typically have common intermediates? Give a generalized example involving ATP. Why is ATP able to serve as an important link between exergonic and endergonic reactions?
- What is activation energy? What effect does an enzyme have on activation energy?
- Give the function of each of the following (a) active site of an enzyme (b) coenzyme (c) allosteric site
- Describe three factors that influence how an enzyme functions.
- Label the diagram. Use Figure 6–12 to check your answers.

YOU MAKE THE CONNECTION

1. Reaction 1 and Reaction 2 happen to have the same free energy change: $\Delta G = -41.8 \text{ kJ/mole}$ (-10 kcal/mole). Reaction 1 is at equilibrium, but Reaction 2 is far from equilibrium. Is either reaction capable of performing work? If so, which one?
2. You are doing an experiment in which you are measuring the rate at which succinic acid is converted to fumaric acid by the enzyme succinic dehydrogenase. You decide to add a little malonic acid to make things interesting. You observe that the reaction rate slows markedly and conclude that malonic acid must be acting as an inhibitor. Design an experiment that will help you decide if malonic acid is acting as a competitive inhibitor or a noncompetitive inhibitor.
3. Based on what you have learned in this chapter, explain why an extremely high fever (above 105°F or 40°C) is often lethal.

How Cells Make ATP: Energy-Releasing Pathways

Cells are tiny factories that process materials on the molecular level, through thousands of metabolic reactions. Cells exist in a dynamic state and are continuously building up and breaking down the many different cellular constituents. As you learned in Chapter 6, metabolism has two complementary components: **catabolism**, which is the splitting of molecules into smaller components, and **anabolism**, the synthesis of complex molecules from simpler building blocks. Anabolic reactions in cells produce proteins, nucleic acids, lipids, polysaccharides, and other complex molecules that help to maintain the cell or the organism of which it is a part. Most anabolic reactions are endergonic and require ATP or some other energy source to drive them.

Every organism must extract energy from the organic food molecules that it either manufactures by photosynthesis or captures from the environment. The gerenuks in the photograph, for example, eat the leaves of thorny shrubs and trees to obtain energy. In gerenuks and other complex animals, food is first broken down by the digestive system. During digestion, proteins are split into their component amino acids, carbohydrates are digested to simple sugars, and fats are split into glycerol and fatty acids. These nutrients are then absorbed into the blood and transported to all the cells. Each cell converts the energy in the chemical bonds of nutrients to ATP energy in a process known as **cellular respiration**. (The term *cellular respiration* is used to distinguish these cellular processes from *organismic respiration*, the exchange of oxygen and carbon dioxide with the environment by animals that have special modifications, such as lungs or gills, for gas exchange.)

Cellular respiration may be either aerobic or anaerobic. **Aerobic** respiration requires molecular oxygen (O_2), whereas **anaerobic** pathways, which include anaerobic respiration and fermentation, do not require oxygen. Most cells use aerobic respiration, which is by far the most common pathway and the main subject of this chapter. All three pathways— aerobic respiration, anaerobic respiration, and fermentation—are exergonic and release free energy.

(Renee Lynn/Photo Researchers, Inc.)

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Write a summary reaction for aerobic respiration, showing which reactant becomes oxidized and which becomes reduced.
2. List and give a brief overview of the four stages of aerobic respiration, indicate where each stage takes place in a eukaryotic cell, and add up the energy captured (as ATP, NADH, and FADH₂) in each stage.
3. Draw a diagram illustrating chemiosmosis and explain (1) how a gradient of protons is established across the inner mitochondrial membrane and (2) the process by which the proton gradient drives ATP synthesis.
4. Summarize how the products of protein and lipid catabolism enter the same metabolic pathway that oxidizes glucose.
5. Compare and contrast aerobic and anaerobic pathways used by cells to extract free energy from nutrients; include the mechanism of ATP formation, the final electron acceptor, and the end products.
6. Summarize the basic similarities of alcohol and lactate fermentation.

AEROBIC RESPIRATION IS A REDOX PROCESS

Most eukaryotes and prokaryotes use a form of cellular respiration requiring oxygen and hence carry out **aerobic respiration**. During aerobic respiration, nutrients are catabolized to carbon dioxide and water. Most cells of plants, animals, protists, fungi, and bacteria use aerobic respiration to obtain energy from glucose. The overall reaction pathway for the aerobic respiration of glucose is summarized as follows:

Note that water is shown on both sides of the equation; this is because it is a reactant in some reactions and a product in others.

For purposes of discussion, the equation for aerobic respiration can be simplified to indicate that there is a net yield of water:

If we analyze this summary reaction, it appears that carbon dioxide is produced by the removal of hydrogen atoms from glucose. Conversely, water appears to be formed as the hydrogen atoms are accepted by oxygen. Because the transfer of hydrogen atoms is equivalent to the transfer of electrons, this is a redox process in which glucose is oxidized and oxygen is reduced (see Chapter 6).

The products of the reaction would be the same if the glucose were simply placed in a test tube and burned in the presence of oxygen. However, if cells were to burn glucose, its energy would be released all at once as heat, which would not only be unavailable to the cell but would actually destroy it. For this reason, cells do not transfer hydrogen atoms directly from glucose to oxygen. Aerobic respiration is a redox process in which electrons associated with the hydrogen atoms in glucose are transferred to oxygen in a series of about 30 steps (Fig. 7–1). During this process, the free energy of the electrons is used for ATP synthesis.

AEROBIC RESPIRATION HAS FOUR STAGES

The chemical reactions of the aerobic respiration of glucose can be grouped into four stages (Fig. 7–2 and Table 7–1). In eukaryotes, the first stage (glycolysis) takes place in the cytosol, and the rest take place inside the mitochondria. Most bacteria also carry out these processes, but because these cells lack mitochondria, the reactions of aerobic respiration occur in the cytosol and in association with the plasma membrane.

1. **Glycolysis.** A six-carbon glucose molecule is converted to two, three-carbon molecules of pyruvate,¹ and ATP and NADH are formed.²
2. **Formation of acetyl coenzyme A.** Each pyruvate enters a mitochondrion and is oxidized to a two-carbon group (acetate) that combines with coenzyme A, forming acetyl coenzyme A. NADH is produced and carbon dioxide is released as a waste product.
3. **The citric acid cycle.** The acetate group of acetyl coenzyme A combines with a four-carbon molecule (oxaloacetate) to form a six-carbon molecule (citrate). In the course of the cycle, citrate is recycled to oxaloacetate and carbon dioxide is released as a waste product. Energy is captured as ATP and the reduced, high-energy compounds NADH and FADH₂.
4. **The electron transport chain and chemiosmosis.** The electrons removed from glucose during the preceding stages are transferred from NADH and FADH₂ to a chain of electron acceptor compounds. As the electrons are passed from one electron acceptor to another, some of their energy is used to pump hydrogen ions (protons) across the inner mitochondrial membrane, forming a proton gradient. In a process known as chemiosmosis, to be described later, the energy of this proton gradient is used to produce ATP.

¹Pyruvate and many other compounds in cellular respiration exist as anions at the pH found in the cell. They sometimes associate with H⁺ to form acids. For example, pyruvate forms pyruvic acid. In some textbooks these compounds are presented in the acid form.

²Although the correct way to write the reduced form of NAD⁺ is NADH + H⁺, for simplicity we will present the reduced form as NADH throughout the chapter.

Figure 7-1 Changes in free energy. The release of energy from a glucose molecule is analogous to the liberation of energy by a falling object. The total energy released is the same whether it occurs all at once or in a series of steps.

Most reactions involved in aerobic respiration are one of three types: dehydrogenations, decarboxylations, and those that we will informally categorize as preparation reactions. **Dehydrogenations** are reactions in which two hydrogen atoms (actually, two electrons plus two protons) are removed from the substrate and transferred to NAD^+ or FAD. **Decarboxylations** are reactions in which part of a carboxyl group ($-\text{COOH}$) is removed from the substrate as a molecule of CO_2 . The carbon dioxide we exhale with each breath is derived from decarboxylations that occur in our cells. The rest of the reactions are preparation reactions in which molecules undergo rearrangements and other changes so that they can subsequently undergo further dehydrogenations or decarboxylations. As we examine the individual reactions of aerobic respiration, we will encounter many examples of these three basic types.

In following the reactions of aerobic respiration, it helps to do some bookkeeping as you go along. Because glucose is the starting material, it is useful to express changes on a per

glucose basis. We will be paying particular attention to changes in the number of carbon atoms per molecule and to steps where some type of energy transfer takes place.

In glycolysis, glucose yields two pyruvates

Glycolysis (from Greek words meaning “sugar-splitting”) does not require oxygen and can proceed under aerobic or anaerobic conditions. Figure 7-3 shows a simple summary of glycolysis, in which a glucose molecule comprising six carbons is converted to two molecules of pyruvate, a three-carbon molecule. Some of the energy in the glucose is captured; there is a net yield of two ATP molecules and two NADH molecules. The reactions of glycolysis take place in the cytosol, where the necessary reactants, such as ADP, NAD^+ , and inorganic phosphates, float freely and are used as needed.

The glycolysis pathway consists of a series of reactions, each of which is catalyzed by a specific enzyme (Fig. 7-4).

(Text continues on p. 160)

Figure 7-2 The four stages of aerobic respiration. The first stage, glycolysis, occurs in the cytosol. Pyruvate, the product of glycolysis, enters a mitochondrion, where cellular respiration continues with the formation of acetyl coenzyme A, the citric acid cycle, and electron transport/chemiosmosis. Most ATP is synthesized by chemiosmosis.

TABLE 7–1 Summary of Aerobic Respiration

Phase	Summary	Some Starting Materials	Some End Products
1. Glycolysis (in cytosol)	Series of reactions in which glucose is degraded to pyruvate; net profit of 2 ATPs; hydrogen atoms are transferred to carriers; can proceed anaerobically	Glucose, ATP, NAD^+ ADP, P_i	Pyruvate, ATP, NADH
2. Formation of acetyl CoA (in mitochondria)	Pyruvate is degraded and combined with coenzyme A to form acetyl CoA; hydrogen atoms are transferred to carriers; CO_2 is released	Pyruvate, coenzyme A, NAD^+	Acetyl CoA, CO_2 , NADH
3. Citric acid cycle (in mitochondria)	Series of reactions in which the acetyl portion of acetyl CoA is degraded to CO_2 ; hydrogen atoms are transferred to carriers; ATP is synthesized	Acetyl CoA, H_2O , NAD^+ , FAD, ADP, P_i	CO_2 , NADH, FADH_2 , ATP
4. Electron transport and chemiosmosis (in mitochondria)	Chain of several electron transport molecules; electrons are passed along chain; energy released is used to form a proton gradient; ATP is synthesized as protons diffuse down the gradient; oxygen is final electron acceptor	NADH, FADH_2 , oxygen, ADP, P_i	ATP, H_2O , NAD^+ , FAD

Figure 7–3 Overview of glycolysis. The energy investment phase of glycolysis (*left column*) leads to the splitting of sugar; ATP and NADH are produced during the energy capture phase (*right column*). During glycolysis, each glucose molecule is converted to two pyruvates, with a net yield of two ATP molecules and two NADH molecules.

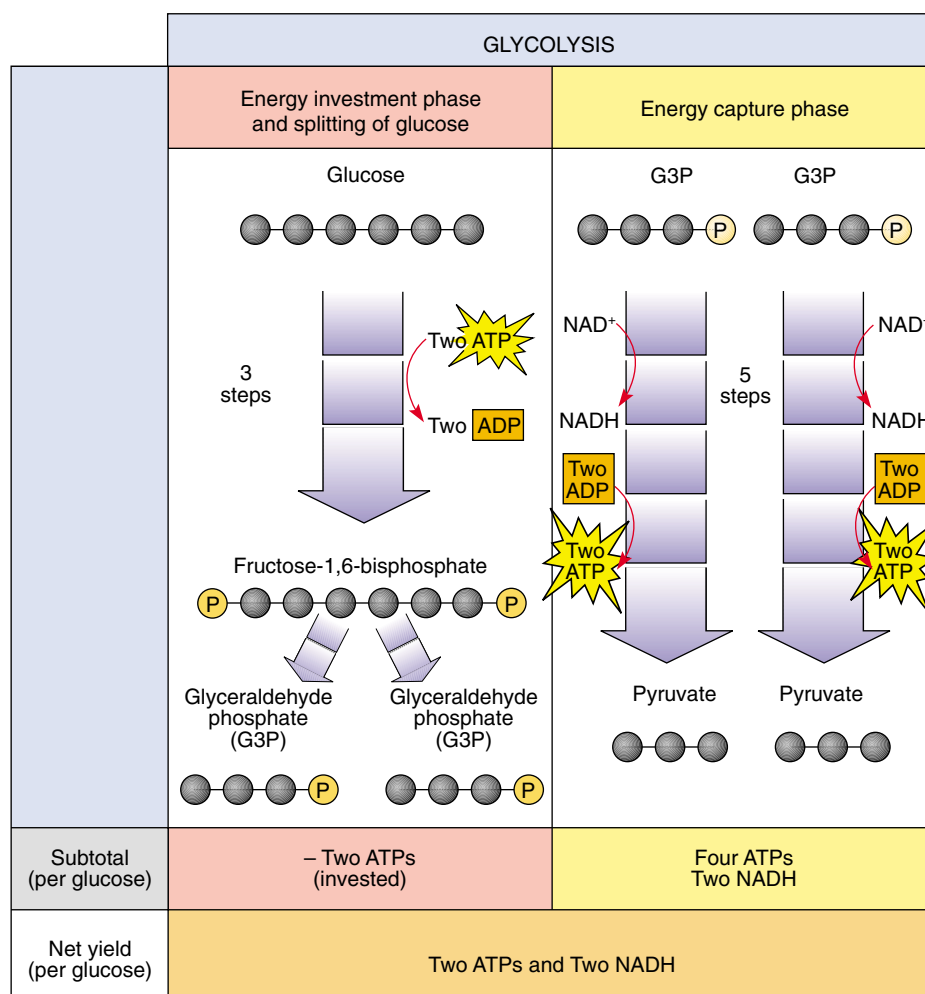

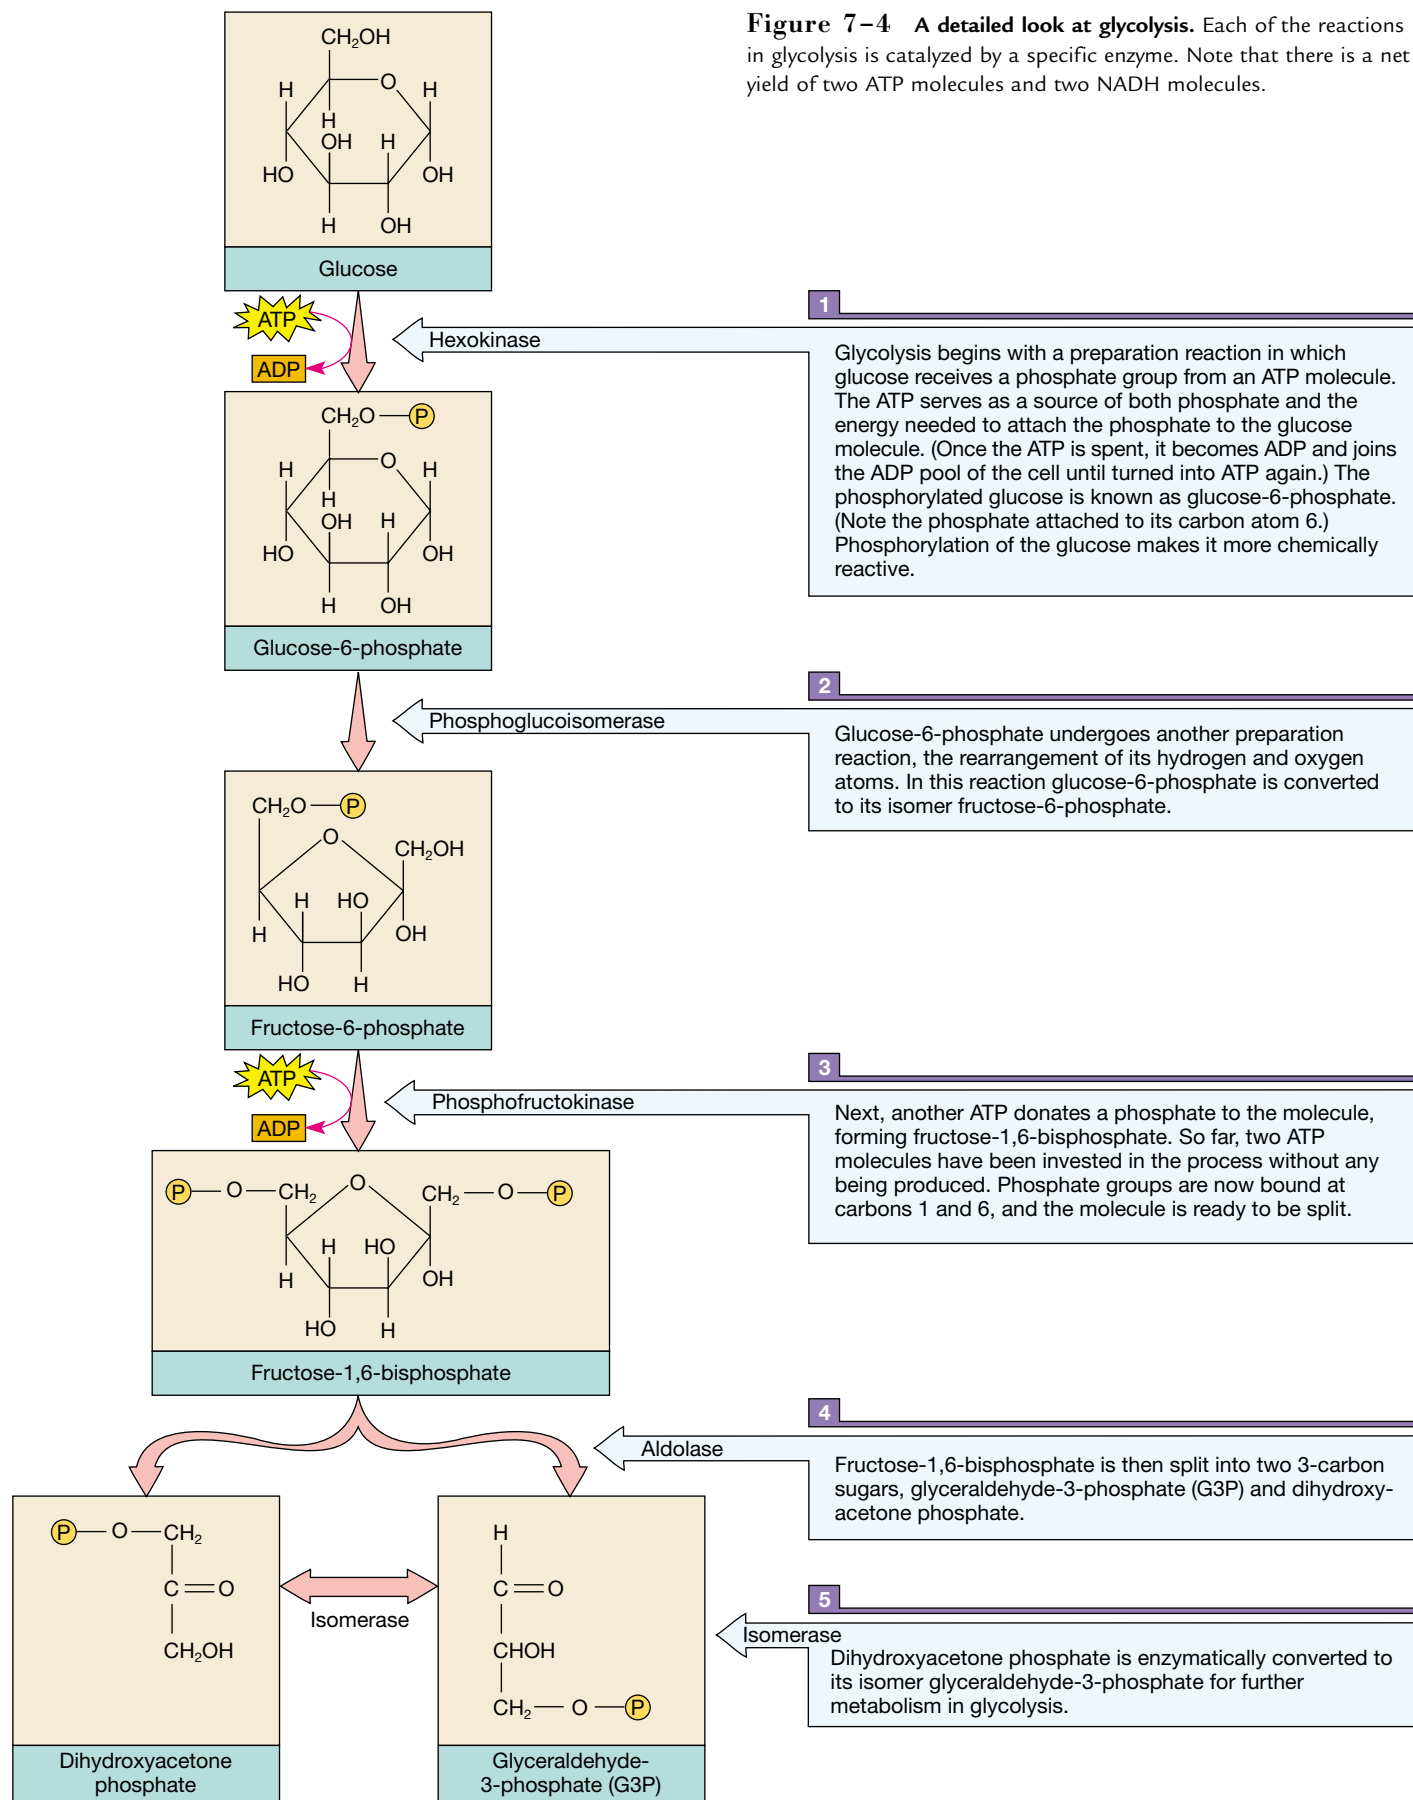

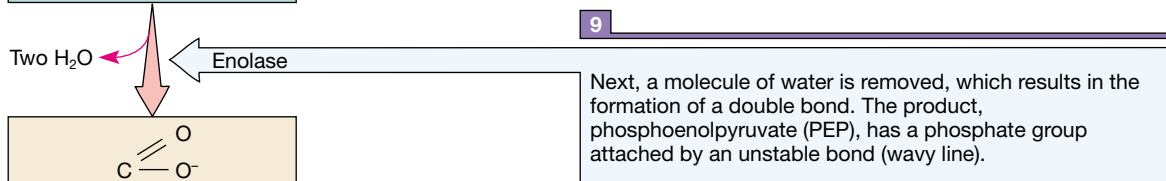

Figure 7-4 A detailed look at glycolysis. Each of the reactions in glycolysis is catalyzed by a specific enzyme. Note that there is a net yield of two ATP molecules and two NADH molecules.

Two glyceraldehyde-3-phosphate (G3P) from bottom of previous page

Glycolysis is divided into two major phases: the first includes endergonic reactions that require ATP, while the second includes exergonic reactions that yield ATP and NADH.

The first phase of glycolysis requires an initial investment of ATP

The first phase of glycolysis is sometimes referred to as the “energy investment” phase. Glucose is a relatively stable molecule and is not easily broken down. In two separate **phosphorylation reactions**, a phosphate group is transferred from ATP to the sugar. The resulting phosphorylated sugar (fructose-1,6-bisphosphate) is less stable and is broken enzymatically into two molecules of a three-carbon compound: glyceraldehyde-3-phosphate (G3P). We may summarize this portion of glycolysis as follows:

The second phase of glycolysis yields NADH and ATP

Each G3P is converted to pyruvate. In the first step of this process each G3P is oxidized by the removal of two electrons (as part of two hydrogen atoms). These immediately combine with the hydrogen carrier molecule, NAD^+ :

Because there are two G3P molecules for every glucose, two NADH are formed. The energy of the electrons carried by

NADH can be used to form ATP later. The process by which this is accomplished is discussed in conjunction with the electron transport chain.

In two of the reactions leading to the formation of pyruvate, ATP is formed when a phosphate group is transferred to ADP from a phosphorylated intermediate. This process is called **substrate-level phosphorylation**. Note that in the first phase of glycolysis two molecules of ATP are consumed, but in the second phase four molecules of ATP are produced. Thus, glycolysis yields a net energy profit of *two* ATPs per glucose.

We may summarize the second phase of glycolysis as follows:

Pyruvate is converted to acetyl CoA

In eukaryotes, the pyruvate molecules formed in glycolysis enter the mitochondria, where they are converted to **acetyl coenzyme A (acetyl CoA)**. These reactions occur in the cytosol of aerobic prokaryotes. In this series of reactions, pyruvate undergoes a process known as oxidative decarboxylation. First, a carboxyl group is removed as carbon dioxide, which diffuses out of the cell (Fig. 7–5). Then the remaining two-carbon fragment is oxidized, and the electrons removed during the oxidation are accepted by NAD^+ . Finally, the oxidized two-carbon fragment, an acetyl group, becomes attached to **coenzyme A**, yielding acetyl CoA.

Recall from Chapter 6 that coenzyme A transfers groups derived from organic acids. In this case, coenzyme A transfers an acetyl group, which is related to acetic acid. Coenzyme A is manufactured in the cell from one of the B vitamins, pantothenic acid. The attachment of an acetyl group to coenzyme

Figure 7–5 Formation of acetyl coenzyme A. Pyruvate, a three-carbon molecule that is the end product of glycolysis, enters the mitochondrion and undergoes oxidative decarboxylation. First, the carboxyl group is split off as carbon dioxide. Then the remaining two-carbon fragment is oxidized, and its electrons are transferred to NAD^+ . Finally, the oxidized two-carbon group, an acetyl group, is attached to coenzyme A. Coenzyme A has a sulfur atom that forms a very unstable bond, shown as a wavy line, with the acetyl group.

A is catalyzed by a multienzyme complex that contains several copies of each of three different enzymes. The overall reaction for the formation of acetyl coenzyme A is the following:

Note that the original glucose molecule has now been partially oxidized, yielding two acetyl groups and two CO_2 molecules. The electrons removed have reduced NAD^+ to NADH. At this point in aerobic respiration, four NADH molecules have been formed as a result of the catabolism of a single glucose molecule: two during glycolysis and two during the formation of acetyl CoA from pyruvate.

The citric acid cycle oxidizes acetyl CoA

The **citric acid cycle** is also known as the **tricarboxylic acid (TCA) cycle** and as the **Krebs cycle** after Hans Krebs, who assembled the accumulated contributions of many scientists

and worked out the details of the cycle in the 1930s. A simple summary of the citric acid cycle, which takes place in the mitochondria, is given in Figure 7–6. The eight steps of the citric acid cycle are shown in Figure 7–7. Each reaction is catalyzed by a specific enzyme.

The first reaction of the cycle occurs when acetyl CoA transfers its two-carbon acetyl group to the four-carbon acceptor compound **oxaloacetate**, forming **citrate**, a six-carbon compound:

The citrate then goes through a series of chemical transformations, losing first one and then a second carboxyl group as CO_2 . Most of the energy made available by the oxidative steps of the cycle is transferred as energy-rich electrons to NAD^+ , forming NADH. For each acetyl group that enters the citric acid cycle, three molecules of NADH are produced. Electrons

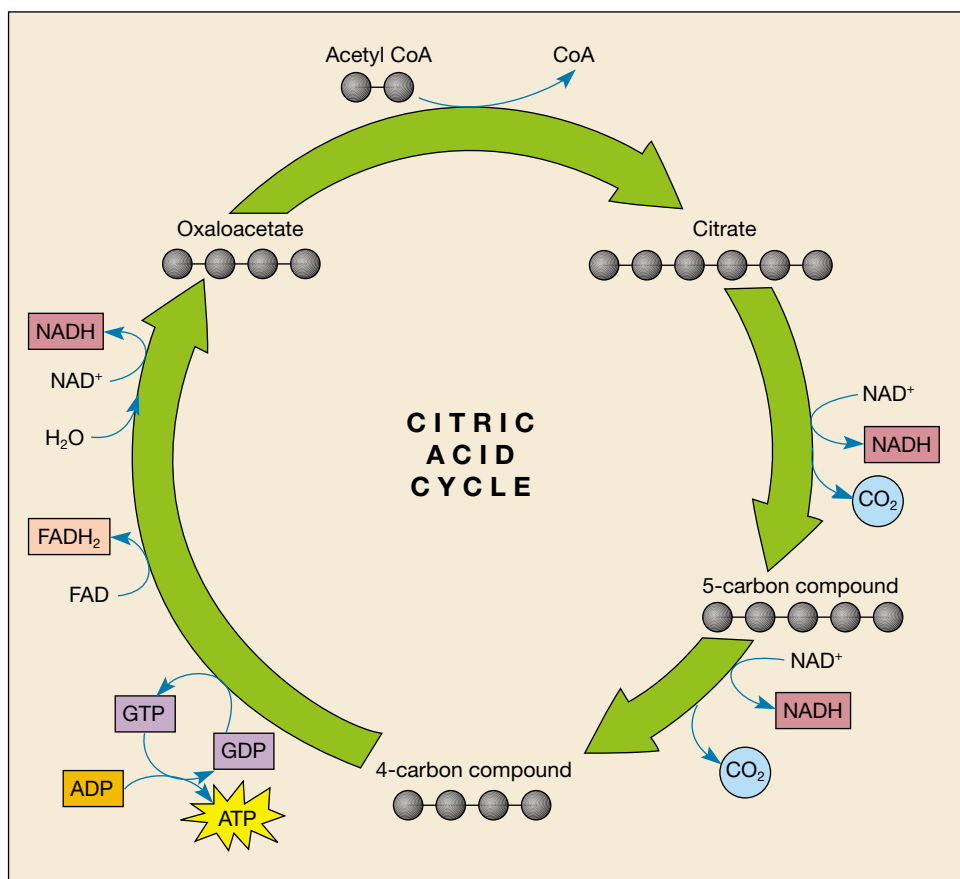

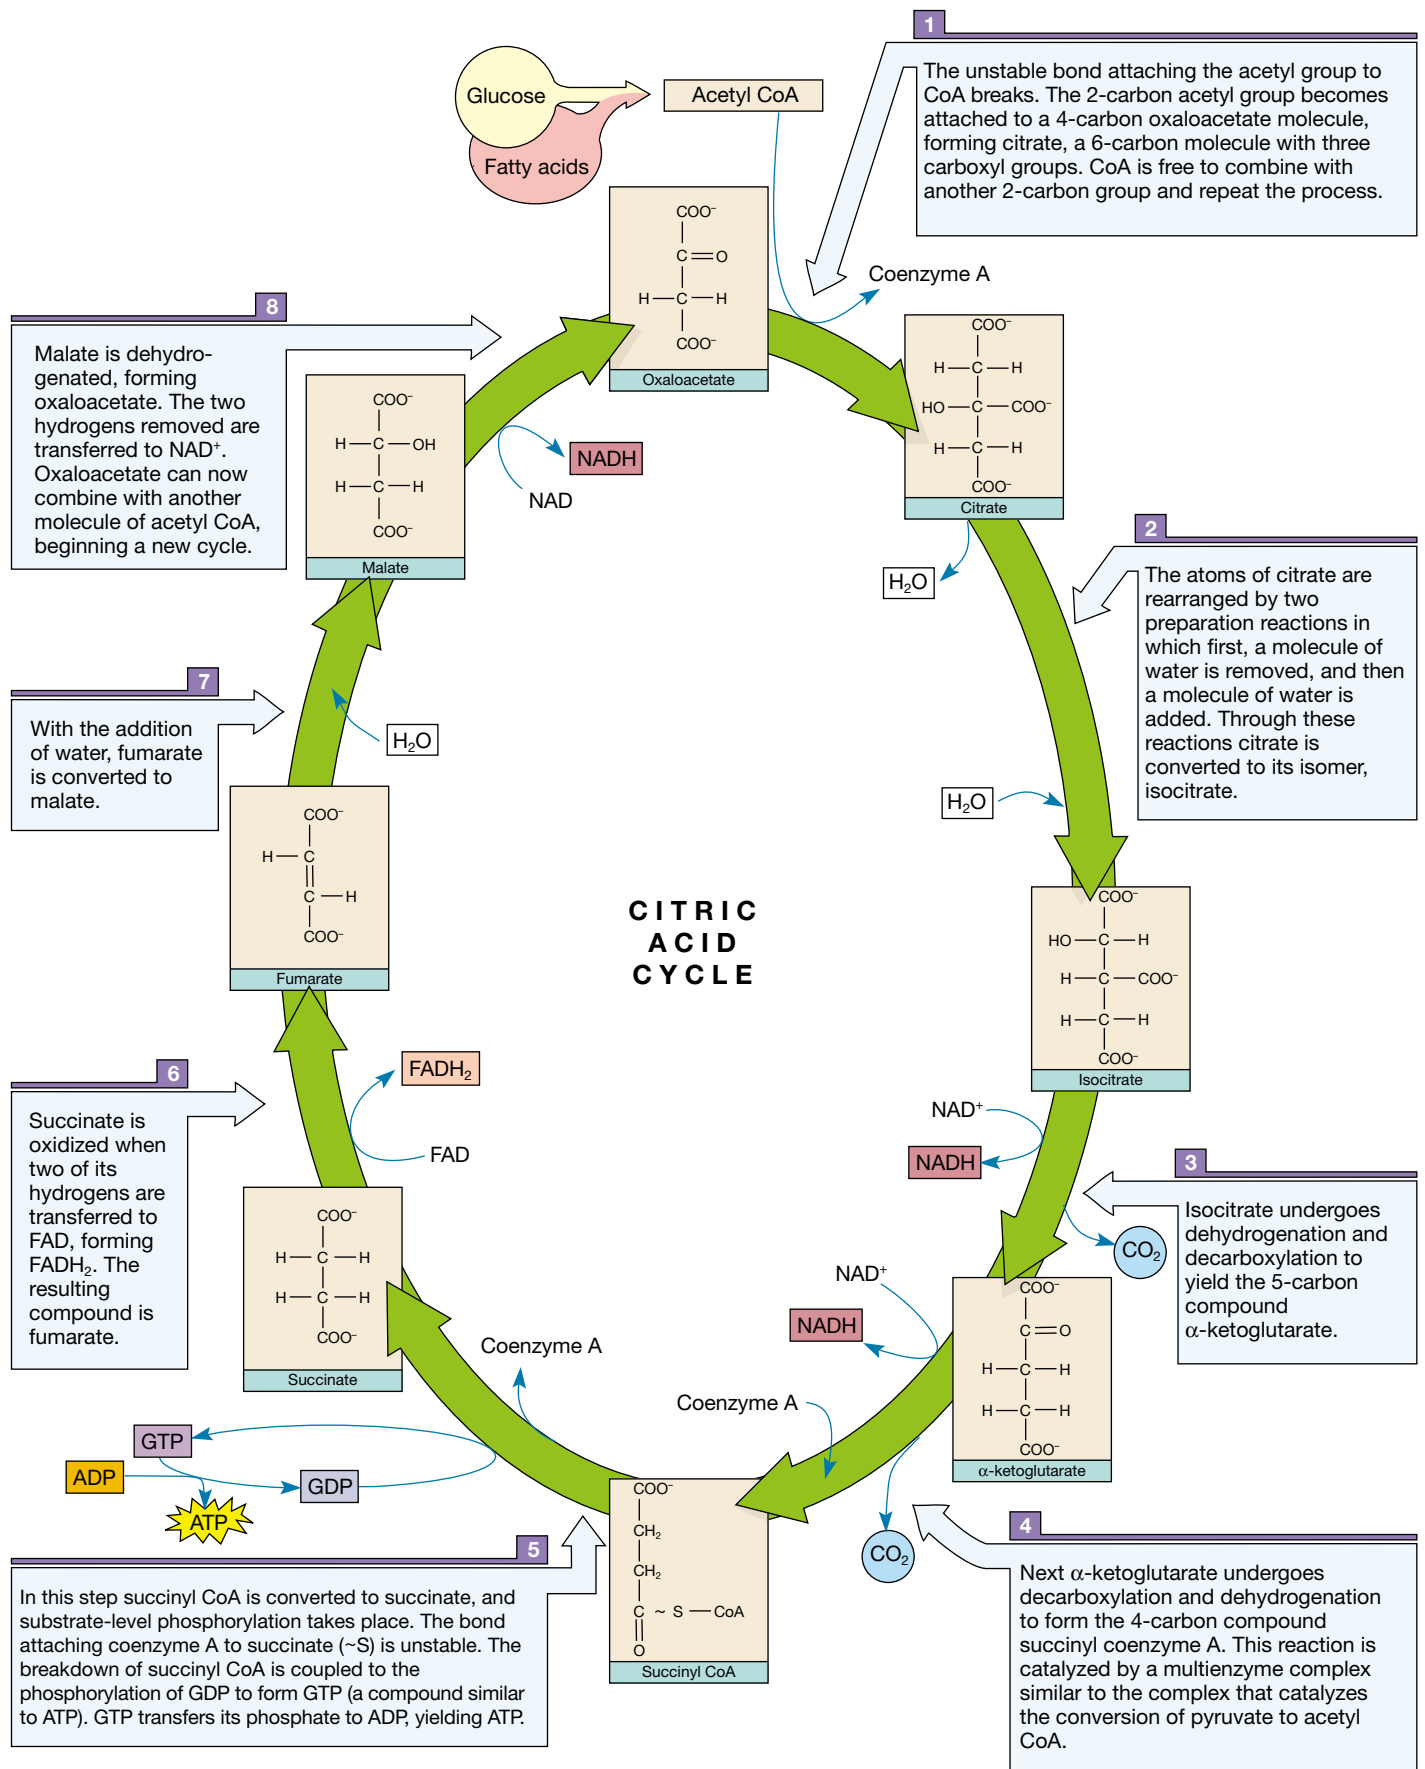

Figure 7–6 Overview of the citric acid cycle. Two acetyl groups enter the citric acid cycle for every glucose. Each two-carbon acetyl group combines with the four-carbon compound oxaloacetate to form the six-carbon compound citrate. Two CO_2 molecules are removed to regenerate oxaloacetate, and in the process, energy is captured as one ATP, three NADH, and one FADH_2 per acetyl group (or two ATPs, six NADH, and two FADH_2 per glucose).

◀ **Figure 7-7 A detailed look at the citric acid cycle.** During the citric acid cycle, the entry of a two-carbon acetyl group is balanced by the release of two molecules of CO_2 . Electrons are transferred to NAD^+ or FAD , yielding NADH and FADH_2 , respectively, and ATP is formed by substrate-level phosphorylation.

are also transferred to the electron acceptor FAD , forming FADH_2 .

In the course of the citric acid cycle, two molecules of CO_2 and the equivalent of eight hydrogen atoms (eight protons and eight electrons) are removed, forming three NADH and one FADH_2 . You may wonder why more hydrogen is generated by these reactions than entered the cycle with the acetyl CoA molecule. These hydrogen atoms come from water molecules that are added during the reactions of the cycle. The CO_2 produced accounts for the two carbon atoms of the acetyl group that entered the citric acid cycle. At the end of each cycle, the four-carbon oxaloacetate has been regenerated, and the cycle can continue.

Because two acetyl CoA molecules are produced from each glucose molecule, two cycles are required per glucose. After two turns of the cycle, the original glucose has lost all of its carbons and may be regarded as having been completely consumed. To summarize, the citric acid cycle yields 4 CO_2 , 6 NADH , 2 FADH_2 , and 2 ATP per glucose molecule.

At the end of the citric acid cycle, glucose has been completely catabolized. Only four molecules of ATP have been formed by substrate-level phosphorylation: two during glycolysis and two during the citric acid cycle. At this time, most of the energy of the glucose is in the form of high-energy electrons in NADH and FADH_2 . Their energy will be used to synthesize additional ATP through the electron transport chain and chemiosmosis.

The electron transport chain is coupled to ATP synthesis

Let us consider the fate of all the electrons removed from a molecule of glucose during glycolysis, acetyl CoA formation, and the citric acid cycle. Recall that these electrons were transferred as part of hydrogen atoms to the acceptors NAD^+ and FAD , forming NADH and FADH_2 . These reduced compounds now enter the **electron transport chain**, where the high-energy electrons of their hydrogen atoms are shuttled from one acceptor to another. As the electrons are passed along in a series of exergonic redox reactions, some of their energy is used to drive the synthesis of ATP, which is an endergonic process. Because ATP synthesis (by phosphorylation of ADP) is coupled to the redox reactions in the electron transport chain, the entire process is known as **oxidative phosphorylation**.

The electron transport chain transfers electrons from NADH and FADH_2 to oxygen

The electron transport chain is a series of electron carriers embedded in the inner membrane of the mitochondrion of eukaryotes and in the plasma membrane of aerobic prokaryotes. Like NADH and FADH_2 , each carrier can exist in an oxidized form or a reduced form. Electrons pass down the electron transport chain in a series of redox reactions: each acceptor molecule is alternately reduced as it accepts electrons and oxidized as it gives up electrons. The electrons entering the electron transport chain have a relatively high energy content. They lose some of their energy at each step as they pass along the chain of electron carriers.

The electron transport chain consists of four complexes, or groups, of acceptors (Fig. 7-8). Each complex is a multi-protein aggregate. Members of the electron transport chain include flavin mononucleotide (FMN), ubiquinone (CoQ), and a group of closely related proteins called **cytochromes**. The last cytochrome in the chain, cytochrome a_3 , passes two electrons to oxygen. The electrons simultaneously unite with protons from the surrounding medium to form hydrogen, and the chemical reaction between hydrogen and oxygen produces water.

Because oxygen is the final electron acceptor in the electron transport chain, organisms that respire aerobically require oxygen. What happens when cells that are strict aerobes are deprived of oxygen? When no oxygen is available to accept them, the last cytochrome in the chain is stuck with its electrons. When that occurs, each acceptor molecule in the chain remains stuck with electrons (i.e., is reduced), and the entire chain is blocked all the way back to NADH . Because oxidative phosphorylation is coupled to electron transport, no further ATPs are produced by way of the electron transport chain. Most cells of complex organisms cannot live long without oxygen because the amount of ATP they produce in its absence is insufficient to sustain life processes.

Lack of oxygen is not the only factor that interferes with the electron transport chain. Some poisons, including cyanide, inhibit the normal activity of the cytochromes. Cyanide binds tightly to the iron in cytochrome a_3 , making it unable to transport electrons on to oxygen. This blocks the further passage of electrons through the chain, halting ATP production.

Although the flow of electrons in electron transport is usually tightly coupled to the production of ATP, some organisms are able to uncouple the two processes to produce heat (see *Making the Connection: Electron Transport and Heat*).

The chemiosmotic model explains the coupling of ATP synthesis to electron transport

For decades scientists were aware that oxidative phosphorylation occurs in mitochondria, and many experiments had shown that the transfer of two electrons from each NADH to oxygen (via the electron transport chain) usually results in the production of up to three ATP molecules. However, for a long

Figure 7–8 Overview of the electron transport chain. Electrons fall to successively lower energy levels as they are passed along the four complexes of the electron transport chain, which are located in the mitochondrial inner membrane. (The orange arrows indicate the pathway of electrons.) The carriers within each complex are alternately reduced and oxidized as they accept and donate electrons. The terminal acceptor is oxygen; one of the two atoms of an oxygen molecule (written $\frac{1}{2} \text{O}_2$) accepts two electrons, which are added to two protons from the surrounding medium to produce water.

MAKING THE CONNECTION

ELECTRON TRANSPORT AND HEAT

What is the source of our body heat? Essentially, it is a byproduct of various exergonic reactions, especially those involving the electron transport chains in our mitochondria. Some organisms are able to produce unusually large amounts of heat by uncoupling electron transport from ATP production. As a consequence, most of the energy of glucose is converted to heat rather than to ATP energy.

Even some plants, which are not generally considered “warm” organisms, have this capability. Skunk cabbage (*Symplocarpus foetidus*), for example, lives in North American swamps and wet woodlands and generally flowers during February and March when the ground is still covered with snow (see figure). Its uncoupled mitochondria generate large amounts of heat, enabling the plant to melt the snow and presumably attract pollinators. The flower temperature of skunk cabbage is 15° to 22°C (59° to 72°F) when the air surrounding it is –15° to 10°C (5° to 50°F). Skunk cabbage flowers maintain this temperature for two weeks or more. Other plants, such as splitleaf philodendron (*Philodendron selloum*) and sacred lotus (*Nelumbo nucifera*), also generate heat when they bloom and maintain their temperatures within precise limits.

Some plants generate as much or more heat per gram of tissue than animals in flight, which have long been considered the greatest heat producers in the living world. The European plant lords-and-ladies (*Arum maculatum*), for example, produces 0.4 joules (0.1

cal) of heat per second per gram of tissue, whereas a hummingbird in flight produces 0.24 joules (0.06 cal) per second per gram of tissue.

Skunk cabbage (*Symplocarpus foetidus*). This plant not only produces a significant amount of heat when it flowers, but regulates its temperature within a specific range. (Earth Scenes © 1999 Leonard Lee Rue III)

Figure 7–9 Accumulation of protons (H^+) within the intermembrane space. As electrons move down the electron transport chain, the electron transport complexes move protons (H^+) from the matrix to the intermembrane space, creating a proton gradient. The higher concentration of H^+ in the intermembrane space lowers the pH.

time, the connection between ATP synthesis and electron transport remained a mystery. Then, in 1961 Peter Mitchell proposed the **chemiosmotic model**, based on his experiments with bacteria. His model was so radical that it was not accepted immediately, but by 1978 so much supporting evidence had accumulated in support of the chemiosmotic model that Peter Mitchell was awarded a Nobel Prize.

Because the respiratory electron transport chain is located in the plasma membrane of an aerobic bacterial cell, the bacterial plasma membrane can be considered comparable to the inner mitochondrial membrane. Mitchell was able to show that if bacterial cells were placed in an acidic environment (that is, an environment with a high hydrogen ion, or proton, concentration), the cells would synthesize ATP even if no electron transport were taking place. On the basis of these and other experiments, Mitchell proposed that electron transport and ATP synthesis are coupled by means of a proton gradient across the inner mitochondrial membrane in eukaryotes (or across the plasma membrane in bacteria).

The proton gradient is established by the electron transport chain; some of the energy released as electrons pass down the electron transport chain is used to pump protons (H^+) across a membrane. In eukaryotes the protons are pumped across the inner mitochondrial membrane into the intermembrane space, that is, the space between the inner and outer mitochondrial membranes (Fig. 7–9). Hence the inner mitochondrial membrane separates a space with a higher concentration of protons (the intermembrane space) from a space with a lower concentration of protons (the mitochondrial matrix).

Protons are pumped across the inner mitochondrial membrane by three of the four electron transport complexes (Fig. 7–10). The result is a proton gradient across the inner mitochondrial membrane. This gradient is a form of potential energy, like water behind a dam; it can be harnessed to provide the energy for ATP synthesis.

Diffusion of protons through the inner mitochondrial membrane is limited to specific channels formed by the en-

zyme complex **ATP synthase**, a transmembrane protein. Portions of these complexes project from the inner surface of the membrane (the surface that faces the matrix) and are visible by electron microscopy. Diffusion of the protons down their gradient, through the ATP synthase complex, is exergonic because the entropy of the system increases. This exergonic process provides the energy for ATP production, although the exact mechanism by which ATP synthase catalyzes the phosphorylation of ADP is still incompletely understood.

Chemiosmosis is a fundamental mechanism of energy coupling in cells; it allows exergonic redox processes to drive the endergonic reaction in which ATP is produced by phosphorylating ADP. In photosynthesis (see Chapter 8), ATP is produced by a comparable process.

AEROBIC RESPIRATION OF ONE GLUCOSE YIELDS A MAXIMUM OF 36 TO 38 ATPs

Let us now review where biologically useful energy is captured in aerobic respiration and calculate the total energy yield from the complete oxidation of glucose. Table 7–2 summarizes the arithmetic involved.

1. In glycolysis, glucose is activated by the addition of phosphates from 2 ATP molecules and converted ultimately to 2 pyruvates + 2 NADH + 4 ATPs, yielding a net profit of 2 ATPs.
2. The 2 pyruvates are metabolized to 2 acetyl CoA + 2 CO₂ + 2 NADH.
3. In the citric acid cycle the 2 acetyl CoA molecules are metabolized to 4 CO₂ + 6 NADH + 2 FADH₂ + 2 ATPs.

Because the oxidation of NADH in the electron transport chain yields up to 3 ATPs per molecule, the 10 NADH molecules can yield up to 30 ATPs. The 2 NADH molecules from glycolysis, however, yield either 2 or 3 ATPs each. This is because certain types of eukaryotic cells must expend energy to shuttle the NADH produced by glycol-

Figure 7-10 A detailed look at electron transport and chemiosmosis. The electron transport chain in the inner mitochondrial membrane includes three proton pumps that are located in three of the four electron transport complexes. The energy released during electron transport is used to transport protons (H^+) from the mitochondrial matrix to the intermembrane space, where a high concentration of protons accumulates. The protons are prevented from diffusing back into the matrix except through special channels in ATP synthase in the inner membrane. The flow of the protons through ATP synthase generates ATP.

ysis across the mitochondrial membrane (see *Focus On: Shuttles across the Mitochondrial Membrane*). Prokaryotic cells lack mitochondria; hence they have no need to shuttle NADH molecules. For this reason, bacteria are able to generate three ATPs for every NADH, even those produced during glycolysis.

Thus, the maximum number of ATPs formed using the energy from NADH is 28 to 30. The oxidation of FADH_2 yields 2 ATPs per molecule, so the 2 FADH_2 molecules produced in the citric acid cycle yield 4 ATPs.

4. Summing all the ATPs (2 from glycolysis, 2 from the citric acid cycle, and 32 to 34 from electron transport and

TABLE 7-2 Energy Yield from the Complete Oxidation of Glucose by Aerobic Respiration

1. Net ATP profit from glycolysis	2 ATP (substrate-level phosphorylation)
Also from glycolysis:	2 NADH ----> 4-6 ATP (oxidative phosphorylation)
2. 2 pyruvate to 2 acetyl CoA	2 NADH ----> 6 ATP (oxidative phosphorylation)
3. 2 acetyl CoA through citric acid cycle and electron transport system	2 ATP (substrate-level phosphorylation) 6 NADH ----> 18 ATP (oxidative phosphorylation) 2 FADH ₂ ----> 4 ATP (oxidative phosphorylation)
Total ATP Profit	36-38 ATP

chemiosmosis), we see that the complete aerobic metabolism of 1 molecule of glucose yields a maximum of 36 to 38 ATPs. Note that most of the ATPs are generated by oxidative phosphorylation, which involves the electron transport chain and chemiosmosis. Only 4 ATPs are formed by substrate-level phosphorylation in glycolysis and the citric acid cycle.

We can analyze the efficiency of the overall process of aerobic respiration by comparing the free energy captured as ATP to the total free energy in a glucose molecule. You will recall from Chapter 6 that, although heat energy cannot power cellular reactions, it is convenient to measure energy as heat. This can be done through the use of a calorimeter, an instrument that measures the heat of a reaction. A sample is placed in a compartment surrounded by a chamber of water. As the sample burns (becomes oxidized), the temperature of the water rises, providing a measure of the heat released during the reaction.

When one mole of glucose is burned in a calorimeter, some 686 kcal (2879.2 kJ) are released as heat. The free energy tem-

porarily held in the phosphate bonds of ATP is about 7.6 kcal (31.8 kJ) per mole; when 36 to 38 ATPs are generated during the aerobic respiration of glucose, the free energy trapped in ATP amounts to 7.6 kcal per mole \times 36, or about 274 kcal (1146.4 kJ) per mole. Thus, the efficiency of aerobic respiration is 274/686, or about 40%. (By comparison, a steam power plant has an efficiency of 35% to 36% in converting its fuel energy into electricity.) The remainder of the energy in the glucose is released as heat.

NUTRIENTS OTHER THAN GLUCOSE ALSO PROVIDE ENERGY

Many organisms depend on nutrients other than glucose as a source of energy. Humans and many other animals usually obtain more of their energy by oxidizing fatty acids than by oxidizing glucose. Amino acids derived from protein digestion are also used as fuel molecules. Such nutrients are transformed

FOCUS ON

SHUTTLES ACROSS THE MITOCHONDRIAL MEMBRANE

The inner mitochondrial membrane is not permeable to NADH, which is a large molecule. Therefore the NADH molecules produced in the cytosol during glycolysis cannot diffuse into the mitochondria to transfer their electrons to the electron transport chain. Unlike ATP and ADP, NADH does not have a carrier protein to transport it across the membrane. Instead, several systems have evolved to transfer just the *electrons* of NADH, not the NADH molecules themselves, into the mitochondria.

In liver, kidney, and heart cells, a special shuttle system transfers the electrons from NADH through the inner mitochondrial membrane to an NAD⁺ molecule in the matrix. These electrons are transferred to the electron transport chain in the inner mitochondrial membrane, and up to three molecules of ATP are produced per pair of electrons.

In skeletal muscle, brain, and some other types of cells, another type of shuttle operates. Because this shuttle requires more

energy than the shuttle in liver, kidney, and heart cells, the electrons are at a lower energy level when they enter the electron transport chain. They are accepted by coenzyme Q rather than by NAD⁺ and so generate a maximum of 2 ATP molecules per pair of electrons. This is why the number of ATPs produced by aerobic respiration of 1 molecule of glucose in skeletal muscle cells is 36 rather than 38.

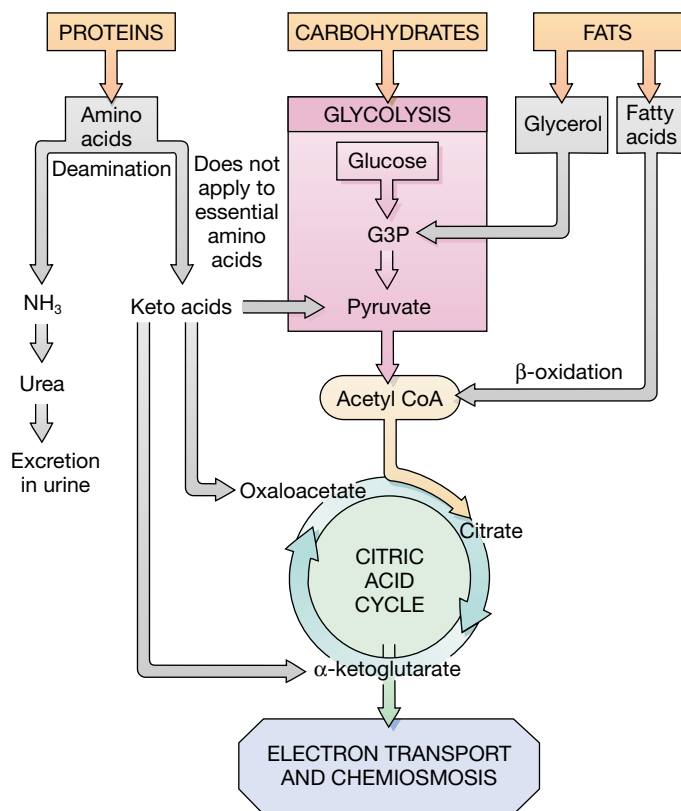

Figure 7–11 Energy from carbohydrates, proteins, and fats. Products of the catabolism of carbohydrates, proteins, and fats enter glycolysis or the citric acid cycle at various points. This diagram is greatly simplified and illustrates only a few of the principal catabolic pathways.

into one of the metabolic intermediates that are fed into glycolysis or the citric acid cycle (Fig. 7–11).

Amino acids are metabolized by reactions in which the amino group is first removed, a process called **deamination**. In mammals and some other animals, the amino group is converted to urea and excreted, but the carbon chain is metabolized and eventually is used as a reactant in one of the steps of the citric acid cycle. The amino acid alanine, for example, undergoes deamination to become pyruvate, the amino acid glutamate is converted to α -ketoglutarate, and the amino acid aspartate yields oxaloacetate. Ultimately, the carbon chains of all the amino acids are metabolized in this way.

Each gram of lipid in the diet contains 9 kcal (38 kJ), more than twice as much energy as one gram of glucose or amino acids, which have about 4 kcal (17 kJ) per gram. Lipids are rich in energy because they are highly reduced; that is, they have many hydrogen atoms and few oxygen atoms. When completely oxidized in aerobic respiration, a molecule of a six-carbon fatty acid generates up to 44 ATPs (compared with 36 to 38 ATPs for a molecule of glucose, which also has six carbons).

Both the glycerol and fatty acid components of a neutral fat (see Chapter 3) are used as fuel; phosphate is added to glycerol, converting it to G3P or another compound that enters glycolysis. Fatty acids are oxidized and split enzymatically into

two-carbon acetyl groups that are bound to coenzyme A; that is, fatty acids are converted to acetyl CoA. This process, which occurs in the mitochondrial matrix, is called **β -oxidation**. Acetyl CoA molecules formed by β -oxidation enter the citric acid cycle.

CELLS REGULATE AEROBIC RESPIRATION

Aerobic respiration requires a steady input of fuel molecules and oxygen. Under normal conditions these materials are adequately provided and do not affect the rate of respiration. Instead, the rate of aerobic respiration is regulated by how much ADP and phosphate are available. In a resting muscle cell, for example, ATP synthesis continues until most of the ADP has been converted to ATP. At this point oxidative phosphorylation slows considerably. Because electron flow is tightly coupled to oxidative phosphorylation, the flow of electrons also slows, which in turn slows down the citric acid cycle.

When ATP transfers energy to power an energy-requiring process like muscle contraction, many molecules of ATP are hydrolyzed. The ADP molecules produced can then accept phosphate to become ATP once again; aerobic respiration speeds up until most of the ADP has again been converted to ATP.

The control of most metabolic pathways is exerted on a particular enzyme that catalyzes a reaction early in the pathway (see Fig. 6–16 and discussion of feedback inhibition in Chapter 6). The regulated enzyme is usually inhibited by the presence of the end product of the pathway. One of the important control points in aerobic respiration in mammals is phosphofructokinase, an enzyme that catalyzes an early reaction of glycolysis (Fig. 7–12). The active site of phosphofructokinase binds ATP and fructose-6-phosphate. However, the enzyme is inhibited by the presence of very high levels of ATP and activated by the presence of ADP and AMP (adenosine monophosphate, a molecule formed when two phosphates are removed from ATP). Therefore, this enzyme is inactivated when ATP levels are high and activated when they are low.³ Phosphofructokinase possesses different allosteric sites for both enzyme inhibitors (in this case, ATP) and enzyme activators (in this case, ADP and AMP).

When respiration produces more ATP than the cell currently needs, some of the excess ATP binds to the allosteric inhibitor site of phosphofructokinase, changing its conformation so that it is no longer active. Thus, glycolysis and aerobic respiration slow down and less ATP is produced. As excess ATP is used by the cell, ADP and AMP are produced. Now the allosteric inhibitor site of phosphofructokinase is no longer occupied by ATP. Instead, the allosteric activator sites are filled with ADP and AMP. Thus the enzyme becomes activated and binds ATP to its active site; respiration proceeds, generating more ATP.

³Other materials, including citrate, also affect the activity of phosphofructokinase.

Figure 7–12 Regulation of aerobic respiration. When enough ATP accumulates in the cell, the ATP inhibits phosphofructokinase, an enzyme that catalyzes an early step in glycolysis. This feedback inhibition controls the rate of aerobic respiration, matching it to the cell's demands for energy.

an inorganic substance such as nitrate (NO_3^-) or sulfate (SO_4^{2-}) replaces molecular oxygen as the terminal electron acceptor. The end products of this type of anaerobic respiration are carbon dioxide, one or more reduced inorganic substances, and ATP. One representative type of anaerobic respiration, summarized below, is part of the biogeochemical cycle known as the nitrogen cycle (see Chapter 53).

Certain other bacteria, as well as some fungi, regularly use **fermentation**, an anaerobic pathway that does not involve an electron transport chain. During fermentation only two ATPs are formed per glucose (by phosphorylation at the substrate level during glycolysis). One might expect that a cell that obtains energy from glycolysis would produce pyruvate, the end product of glycolysis. However, this cannot happen because every cell has a limited supply of NAD^+ . If virtually all NAD^+ becomes reduced to NADH during glycolysis, then glycolysis stops, and no more ATP can be produced. In fermentation, NADH molecules transfer their hydrogen atoms to organic molecules, thus regenerating the NAD^+ needed to keep glycolysis going. The resulting, relatively reduced, organic molecules (commonly alcohol or lactate) tend to be toxic to the cells and are essentially waste products. Table 7–3 summarizes features of aerobic respiration, anaerobic respiration, and fermentation.

ANAEROBIC RESPIRATION AND FERMENTATION DO NOT REQUIRE OXYGEN

Anaerobic respiration, which does not use oxygen as the final electron acceptor, is performed by some types of bacteria that live in such anaerobic environments as waterlogged soil, stagnant ponds, or animal intestines. As in aerobic respiration, electrons are transferred in anaerobic respiration from glucose to NADH; they then pass down an electron transport chain that is coupled to ATP synthesis by chemiosmosis. However,

TABLE 7–3 A Comparison of Aerobic Respiration, Anaerobic Respiration, and Fermentation

	Aerobic Respiration	Anaerobic Respiration	Fermentation
Immediate Fate of Electrons in NADH	Transferred to an electron transport chain	Transferred to an electron transport chain	Transferred to an organic molecule
Terminal Electron Acceptor of Electron Transport Chain	O_2	Inorganic substances such as NO_3^- or SO_4^{2-}	(No electron transport chain)
Reduced Product(s) Formed	Water	Relatively reduced inorganic substances	Relatively reduced organic compounds (commonly alcohol or lactate)
Mechanism of ATP Synthesis	Chemiosmosis; also substrate-level phosphorylation	Chemiosmosis; also substrate-level phosphorylation	Substrate-level phosphorylation only (during glycolysis)

(a)

(b)

Figure 7–13 Fermentation. (a) LM of live brewer's yeast (*Saccharomyces cerevisiae*). Yeast cells possess mitochondria and carry on aerobic respiration when O_2 is present. In the absence of O_2 , yeasts carry on alcohol fermentation. (b) Glycolysis is the first part of fermentation pathways. In alcohol fermentation, CO_2 is split off, and the two-carbon compound ethyl alcohol is the end product. In lactate fermentation, the final product is the three-carbon compound lactate. In both alcohol and lactate fermentation, there is a net gain of only two ATPs per molecule of glucose. (Dwight R. Kuhn)

Alcohol fermentation and lactate fermentation are inefficient

Yeasts are **facultative anaerobes**. These eukaryotic, unicellular fungi have mitochondria and carry out aerobic respiration when oxygen is available but switch to **alcohol fermentation** when deprived of oxygen (Fig. 7–13a). They have enzymes that decarboxylate pyruvate, releasing carbon dioxide and forming a two-carbon compound called acetaldehyde. NADH produced during glycolysis transfers hydrogen atoms to acetaldehyde, reducing it to form **ethyl alcohol** (Fig. 7–13b). Alcohol fermentation is the basis for the production of beer, wine, and other alcoholic beverages. Yeast cells are also used in baking to produce the carbon dioxide that causes dough to rise; the alcohol evaporates during baking.

Certain fungi and bacteria perform **lactate (lactic acid) fermentation**. In this alternative pathway, NADH produced during glycolysis transfers hydrogen atoms to pyruvate, reducing it to form **lactate** (see Fig. 7–13b). The ability of some bacteria to produce lactate is exploited by humans, who use them to make yogurt and to ferment cabbage for sauerkraut.

Lactate is also produced during strenuous activity in the muscle cells of humans and other complex animals. If the amount of oxygen delivered to muscle cells is insufficient to support aerobic respiration, the cells shift briefly to lactate fermentation. The shift is only temporary, however, and oxygen is required for sustained work. As lactate accumulates in mus-

cle cells, it contributes to fatigue and muscle cramps.⁴ About 80% of the lactate is eventually exported to the liver, where it is used to regenerate more glucose for the muscle cells. The remaining 20% of the lactate is metabolized in muscle cells in the presence of oxygen. This explains why you continue to breathe heavily after you have stopped exercising; the additional oxygen is needed to oxidize lactate, thereby restoring the muscle cells to their normal state.

Although humans can only use lactate fermentation to produce ATP for a few minutes, a few animals can live without oxygen for much longer periods. The red-eared slider can remain underwater for as long as two weeks (Fig. 7–14). It relies on lactate fermentation for ATP production.

Both alcohol fermentation and lactate fermentation are very inefficient because the fuel is only partially oxidized. Alcohol, the end product of fermentation by yeast cells, can be burned and can even be used as automobile fuel; obviously, it contains a great deal of energy that the yeast cells are unable to extract using anaerobic methods. Lactate, a three-carbon compound, contains even more energy than the two-carbon alcohol. In contrast, all available energy is removed during aerobic respiration because the fuel molecules become completely

⁴Why exercise causes fatigue and muscle cramps is incompletely understood at this time, but these conditions may be related to lactate buildup, insufficient oxygen, and/or the depletion of fuel molecules.

Figure 7–14 Long-term use of lactate fermentation for ATP production. The red-eared slider (*Trachemys scripta*) can stay submerged for as long as two weeks. (Cleveland P. Hickman, Jr./Visuals Unlimited)

oxidized to CO_2 . A net profit of only 2 ATPs is produced by the fermentation of one molecule of glucose, compared with up to 36 to 38 ATPs when oxygen is available.

The inefficiency of fermentation necessitates a large supply of fuel. For example, skeletal muscle cells, which often metabolize anaerobically for short periods, store large quantities of glucose in the form of glycogen. To perform the same amount of work, a cell engaged in fermentation must consume up to 20 times more glucose or other carbohydrate per second than a cell using aerobic respiration.

S U M M A R Y W I T H K E Y T E R M S

- I. Metabolism, the total of all the chemical reactions that occur in cells, has two complementary components.
 - A. **Catabolism** releases energy by breaking down molecules into simpler molecules. Catabolic pathways include aerobic respiration, anaerobic respiration, and fermentation.
 - B. **Anabolism** is the synthesis of complex molecules from simpler building blocks. Protein synthesis is an example of anabolism.
- II. During **aerobic respiration**, a fuel molecule such as glucose is oxidized to form carbon dioxide and water.
 - A. Aerobic respiration is a redox process in which electrons are transferred from glucose (which becomes **oxidized**) to oxygen (which becomes **reduced**).
 - B. Up to 36 to 38 **ATPs** are produced per molecule of glucose.
- III. The chemical reactions of aerobic respiration occur in four stages: glycolysis, formation of acetyl CoA, the citric acid cycle, and the electron transport chain/chemiosmosis.
 - A. During **glycolysis**, which occurs in the cytosol, a molecule of glucose is degraded to two molecules of **pyruvate**.
 1. Two ATP molecules (net) are produced by **substrate-level phosphorylation** during glycolysis.
 2. Four hydrogen atoms are removed from the fuel molecule and used to produce two **NADH**.
 - B. The two pyruvate molecules each lose a molecule of carbon dioxide, and the remaining **acetyl groups** each combine with **coenzyme A**, producing two molecules of **acetyl CoA**. One NADH is produced as each pyruvate is converted to acetyl CoA.
 - C. Each acetyl CoA enters the **citric acid cycle** by combining with a four-carbon compound, oxaloacetate, to form **citrate**, a six-carbon compound. Two acetyl CoA molecules enter the cycle for every glucose molecule.
 1. For every two carbons that enter the cycle as part of an acetyl CoA molecule, two leave as carbon dioxide.
 - D. For every acetyl CoA, hydrogen atoms are transferred to three **NAD⁺** and one **FAD**; only one ATP is produced by substrate-level phosphorylation.
- D. Hydrogen atoms (or their electrons) removed from fuel molecules are transferred from one electron acceptor to another down an **electron transport chain** located in the mitochondrial inner membrane.
 1. Water is formed when oxygen combines with H^+ and with electrons from the electron transport chain.
 2. According to the **chemiosmotic model**, some of the energy of the electrons in the electron transport chain is used to establish a proton gradient across the inner mitochondrial membrane.
 3. The diffusion of protons through the membrane from the intermembrane space to the mitochondrial matrix (through channels formed by the enzyme **ATP synthase**) provides the energy needed to synthesize ATP.
- IV. Organic nutrients other than glucose are converted to appropriate compounds and fed into glycolysis or the citric acid cycle.
 - A. Amino acids are **deaminated** and their carbon skeletons are converted to metabolic intermediates of glycolysis and the citric acid cycle.
 - B. Both the glycerol and fatty acid components of lipids are oxidized as fuel. Fatty acids are converted to acetyl CoA molecules by the process of **β -oxidation**.
- V. In **anaerobic respiration**, electrons are transferred from fuel molecules to an electron transport chain; the final electron acceptor is an inorganic substance such as nitrate or sulfate, not molecular oxygen.
- VI. **Fermentation** is an anaerobic process that does not use an electron transport chain. There is a net gain of only two ATPs per glucose; these are produced during glycolysis. To maintain the supply of NAD^+ es-

essential for glycolysis, hydrogen atoms are transferred from NADH to an organic compound derived from the initial nutrient.

- A. Yeast cells carry out **alcohol fermentation**, in which **ethyl alcohol** and carbon dioxide are the final waste products.
- B. Certain fungi, bacteria, and animal cells carry out **lactate fermentation**, in which hydrogen atoms are added to pyruvate to form **lactate**, a waste product.

Summary Reactions for Aerobic Respiration

Summary reaction for the complete oxidation of glucose:

Summary reaction for glycolysis:

Summary reaction for the conversion of pyruvate to acetyl CoA:

Summary reaction for the citric acid cycle:

Summary reactions for the processing of the hydrogen atoms of NADH and FADH₂ in the electron transport chain:

Summary Reactions for Fermentation

Summary reaction for lactate fermentation:

Summary reactions for alcohol fermentation:

POST-TEST

- The process of splitting larger molecules into smaller ones is an aspect of metabolism called (a) anabolism (b) fermentation (c) catabolism (d) oxidative phosphorylation (e) chemiosmosis
- The synthetic aspect of metabolism is referred to as (a) anabolism (b) fermentation (c) catabolism (d) oxidative phosphorylation (e) chemiosmosis
- A chemical process during which a substance gains electrons is called (a) oxidation (b) oxidative phosphorylation (c) deamination (d) reduction (e) dehydrogenation
- The pathway through which glucose is degraded to pyruvate is referred to as (a) aerobic respiration (b) the citric acid cycle (c) the oxidation of pyruvate (d) alcohol fermentation (e) glycolysis
- The reactions of _____ take place within the cytosol of eukaryotic cells. (a) glycolysis (b) oxidation of pyruvate (c) the citric acid cycle (d) chemiosmosis (e) the electron transport chain
- Before pyruvate enters the citric acid cycle, it is decarboxylated, oxidized, and combined with coenzyme A, forming acetyl CoA, carbon dioxide, and one molecule of (a) NADH (b) FADH₂ (c) ATP (d) ADP (e) C₆H₁₂O₆
- In the first step of the citric acid cycle, acetyl CoA reacts with oxaloacetate to form (a) pyruvate (b) citrate (c) NADH (d) ATP (e) CO₂
- Dehydrogenase enzymes remove hydrogen atoms from fuel molecules and transfer them to acceptors such as (a) O₂ and H₂O (b) ATP and FAD (c) NAD⁺ and FAD (d) CO₂ and H₂O (e) CoA and pyruvate
- In the process of _____, electron transport and ATP synthesis are coupled by a proton gradient across the inner mitochondrial membrane. (a) chemiosmosis (b) deamination (c) anaerobic respiration (d) glycolysis (e) decarboxylation
- Which of the following molecules provides the greatest yield of ATP in a cell carrying out aerobic respiration? (a) glucose (b) pyruvate (c) acetyl CoA (d) NADH (e) oxaloacetate
- A net profit of only 2 ATPs can be produced anaerobically from the _____ of 1 molecule of glucose, compared with a maximum of 38 ATPs produced in _____. (a) fermentation; anaerobic respiration (b) aerobic respiration; fermentation (c) aerobic respiration; anaerobic respiration (d) dehydrogenation; decarboxylation (e) fermentation; aerobic respiration
- When deprived of oxygen, yeast cells obtain energy by fermentation, producing carbon dioxide, ATP, and (a) acetyl CoA (b) ethyl alcohol (c) lactate (d) pyruvate (e) citrate
- During strenuous muscle activity, the pyruvate in muscle cells may accept hydrogen from NADH to become _____. (a) acetyl CoA (b) ethyl alcohol (c) lactate (d) pyruvate (e) citrate

REVIEW QUESTIONS

- What is the specific role of oxygen in most cells? What happens when cells that can only respire aerobically are deprived of oxygen?
- Mitochondria are often referred to as the "power plants" of the cell. Justify this with a specific explanation.
- Refer to Figure 7–7, the diagram of the steps in the citric acid cycle. Look at each reaction and, without reading the description, determine if it is a dehydrogenation, decarboxylation, or preparation reaction.
- Sketch a mitochondrion and indicate the locations of the electron transport chain and the proton gradient that drives ATP production.
- Why is each of the following essential to chemiosmotic ATP synthesis? (a) electron transport chain (b) proton gradient (c) ATP synthase complex
- Explain the roles of the following in aerobic respiration: (a) NAD⁺ and FAD (b) oxygen
- Sum up how much energy (as ATP) is made available to the cell from a single glucose molecule by the operation of glycolysis, the formation of acetyl CoA, the citric acid cycle, and the electron transport chain.
- Trace the fate of hydrogen atoms removed from glucose during glycolysis when oxygen is present in muscle cells; compare this to the fate of hydrogen atoms removed from glucose when the amount of available oxygen is insufficient to support aerobic respiration.
- Compare the ATP yields of aerobic respiration and fermentation.
- Label the figure on p. 173. Use Figure 7–2 to check your answers.

YOU MAKE THE CONNECTION

1. The reactions of glycolysis are identical in *all* organisms—bacteria, protists, fungi, plants, and animals—that obtain energy from glucose catabolism. What does this universality suggest about the evolution of glycolysis?
2. How are the endergonic reactions of the first phase of glycolysis coupled to the hydrolysis of ATP, which is exergonic? How are the exergonic reactions of the second phase of glycolysis coupled to the endergonic synthesis of ATP and NADH?
3. What is the role of the mitochondrial inner membrane in the coupling of electron transport and ATP synthesis?
4. Based on what you have learned in this chapter, explain why a school child can run 17 miles per hour in a 100-meter dash, but a trained athlete can run only about 11.5 miles per hour in a 26-mile marathon.

CHAPTER 8

Photosynthesis: Capturing Energy

All living things are either producers or dependent on the activities of producers. Producers are **autotrophs** (from the Greek *auto*, “self,” and *trophos*, “nourishing”), organisms that can make organic molecules from inorganic raw materials. Most producers, including plants, algae, and certain bacteria, are **photoautotrophs**, producers uniquely capable of absorbing and converting light energy into stored chemical energy of organic molecules by the process of **photosynthesis**. These blue lupines (*Lupinus hirsutus*) and the trees behind them, for example, are photoautotrophs. Photoautotrophs use light energy to make ATP and other molecules that temporarily hold chemical energy but are unstable and cannot be stockpiled in the cell. Their energy drives the anabolic pathway by which a photosynthetic cell synthesizes stable organic molecules from the simple inorganic compounds, carbon dioxide and water. These organic compounds are used not only as starting materials to synthesize all the other organic compounds the photosynthetic organism needs (such as complex carbohydrates, amino acids, and lipids) but also for energy storage. They include relatively reduced compounds, such as glucose and other carbohydrates, that can be subsequently oxidized by aerobic respiration or by some other catabolic pathway (see Chapter 7).

Consumers and decomposers are **heterotrophs** (from the Greek *heter*, “other,” and *trophos*, “nourishing”), organisms that cannot make their own organic compounds and so must obtain them from other organisms. Consumers live by feeding on producers or on organisms that have eaten producers, whereas decomposers live by breaking down dead organic material. Photosynthesis sustains not only plants and most other producers but also indirectly supports almost all animals and other organisms in the biosphere. Each year photosynthetic organisms convert carbon dioxide into billions of tons of organic molecules. The chemical energy stored in these molecules fuels the metabolic reactions that sustain almost all life.

(Skip Moody/Dembinsky Photo Associates)

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Explain the relationship between a wavelength of light and its energy and describe the physical properties of light.
2. Describe what can happen to an electron in a biological molecule such as chlorophyll when a photon of light energy is absorbed.
3. Diagram the internal structure of a chloroplast and explain how its components interact and facilitate the process of photosynthesis.
4. Write a summary reaction for photosynthesis, showing the origin and fate of each substance involved.
5. Describe photosynthesis as a redox process.
6. Distinguish between the light-dependent reactions and carbon fixation reactions of photosynthesis.
7. Contrast cyclic and noncyclic photophosphorylation.
8. Explain how a proton (H^+) gradient is established across the thylakoid membrane and how this gradient functions in ATP synthesis.
9. Summarize the chemical reactions involved in the conversion of CO_2 to carbohydrate in the Calvin cycle and indicate the roles of ATP and NADPH in the process.
10. Discuss how the C_4 pathway increases the effectiveness of the Calvin cycle in certain types of plants.

LIGHT IS COMPOSED OF PARTICLES THAT TRAVEL AS WAVES

Because most life on our planet depends on light, either directly or indirectly, it is important to understand the nature of light and how it permits photosynthesis to occur. Light is a very small portion of a vast, continuous spectrum of radiation called the electromagnetic spectrum (Fig. 8–1). All radiations in this spectrum travel in waves. A **wavelength** is the distance from one wave peak to the next. At one end of the electro-

magnetic spectrum are gamma rays, which have very short wavelengths (measured in nanometers). At the other end of the spectrum are radio waves with wavelengths so long they can be measured in kilometers. The portion of the electromagnetic spectrum from 380 nanometers to 760 nanometers is called the visible spectrum because humans can see it. The visible spectrum includes all the colors of the rainbow; violet has the shortest wavelength, and red has the longest (Fig. 8–2).

Light behaves not only as waves do but also as particles. Light is composed of small particles, or packets, of energy called **photons**. The energy of a photon is inversely proportional to its wavelength; shorter wavelength light has more energy per photon than does longer wavelength light.

Why does photosynthesis depend on light detectable by the human eye (visible light) rather than on some other wavelength of radiation? We can only speculate on the answer. One reason may be that much of the radiation reaching our planet from the sun is within this portion of the electromagnetic spectrum; thus, organisms may have evolved the ability to use visible light because it was the most abundant form available. Perhaps more important, radiation within the visible light portion of the spectrum excites certain types of biological molecules, moving electrons into higher energy levels. Radiation with wavelengths longer than those of visible light does not possess

Figure 8–1 The electromagnetic spectrum. Visible light represents a small fraction of the electromagnetic spectrum and consists of a mixture of wavelengths ranging from approximately 380 nm to 760 nm. The energy from visible light is used in photosynthesis.

Figure 8–2 Radiation emitted from the sun. Electromagnetic radiation from the sun contains ultraviolet radiation and visible light of varying colors and wavelengths.

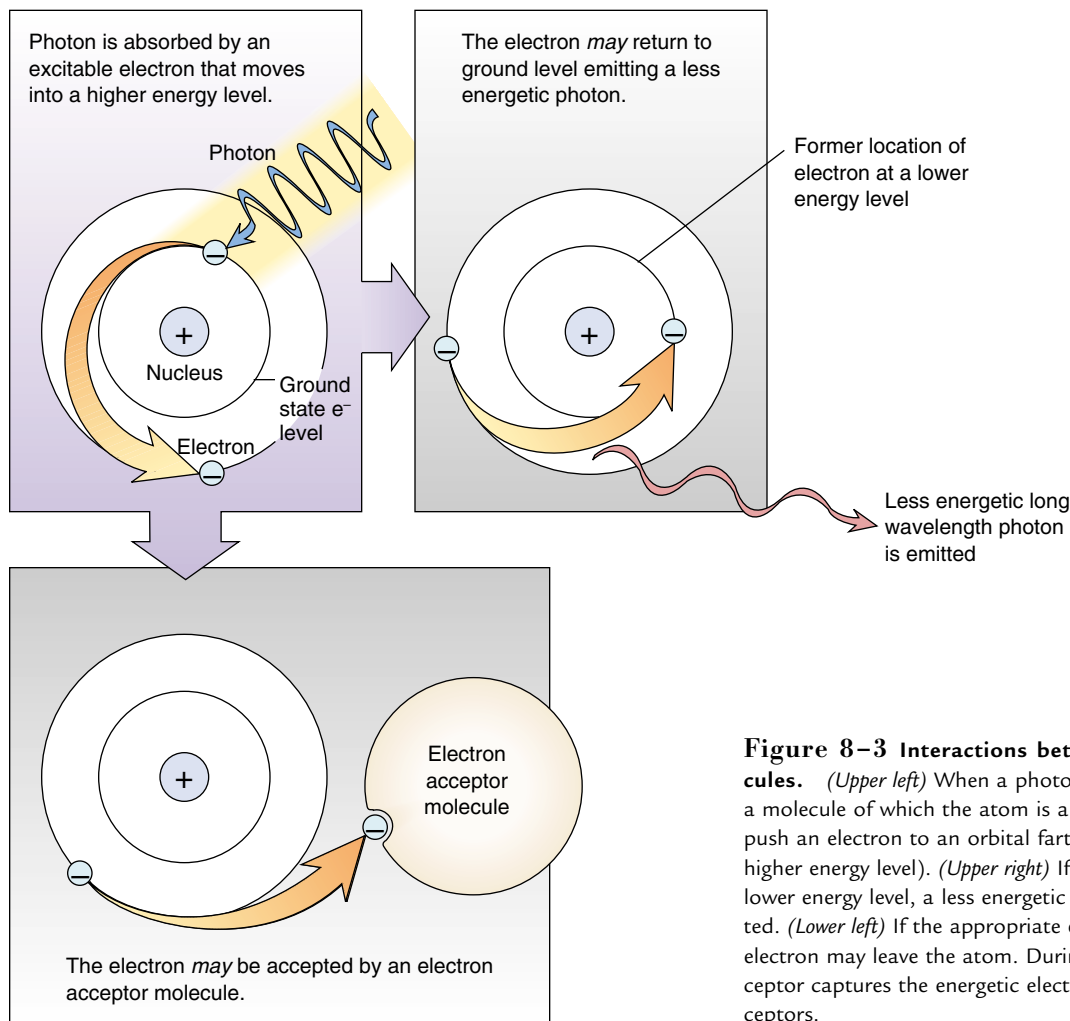

Figure 8–3 Interactions between light and atoms or molecules. (Upper left) When a photon of light energy strikes an atom, or a molecule of which the atom is a part, the energy of the photon may push an electron to an orbital farther from the nucleus (i.e., into a higher energy level). (Upper right) If the electron “falls” back to the next lower energy level, a less energetic (longer wavelength) photon is emitted. (Lower left) If the appropriate electron acceptors are available, the electron may leave the atom. During photosynthesis an electron acceptor captures the energetic electron and passes it to a chain of acceptors.

enough energy to excite these biological molecules. Radiation with wavelengths shorter than those of visible light is so energetic that it disrupts the bonds of many biological molecules.

When a molecule absorbs a photon of light energy, one of its electrons is energized. One of two things then happens, depending on the atom and its surroundings (Fig. 8–3). The electron may return to its ground state.¹ If this happens, its energy is dissipated as heat or as light of a longer wavelength than the wavelength of the absorbed light; this emission of light is called **fluorescence**. Alternatively, the energized electron may leave the atom and be accepted by an electron acceptor molecule; this is what occurs in photosynthesis.

Now that we have an understanding of some of the properties of light, we will consider the cellular location where light is used for photosynthesis.

¹The lowest energy state an atom possesses is called the ground state, but energy can be added to an electron so that it attains a higher energy level. When an electron is raised to a higher energy level than its ground state, the atom is said to be *excited*, or *energized*.

PHOTOSYNTHESIS IN EUKARYOTES TAKES PLACE IN CHLOROPLASTS

When a section of leaf tissue is examined under the microscope, we can see that the green pigment, **chlorophyll**, is not uniformly distributed in the cell but is confined to organelles called **chloroplasts** (Fig. 8–4). In plants, chloroplasts are located mainly in the cells of the **mesophyll**, a tissue inside the leaf. Each mesophyll cell has 20 to 100 chloroplasts.

The chloroplast, like the mitochondrion, is bounded by an outer and an inner membrane. The inner membrane encloses a fluid-filled region called the **stroma**, which contains most of the enzymes required to produce carbohydrate molecules. Suspended in the stroma is a third system of membranes that forms an interconnected set of flat, disclike sacs called **thylakoids**. The thylakoid membrane encloses a fluid-filled interior space, the **thylakoid interior space**. In some regions, thylakoid sacs are arranged in stacks called **grana** (sing., *granum*). Each granum looks something like a stack of coins, with each “coin” being a thylakoid disc. Some thylakoid mem-

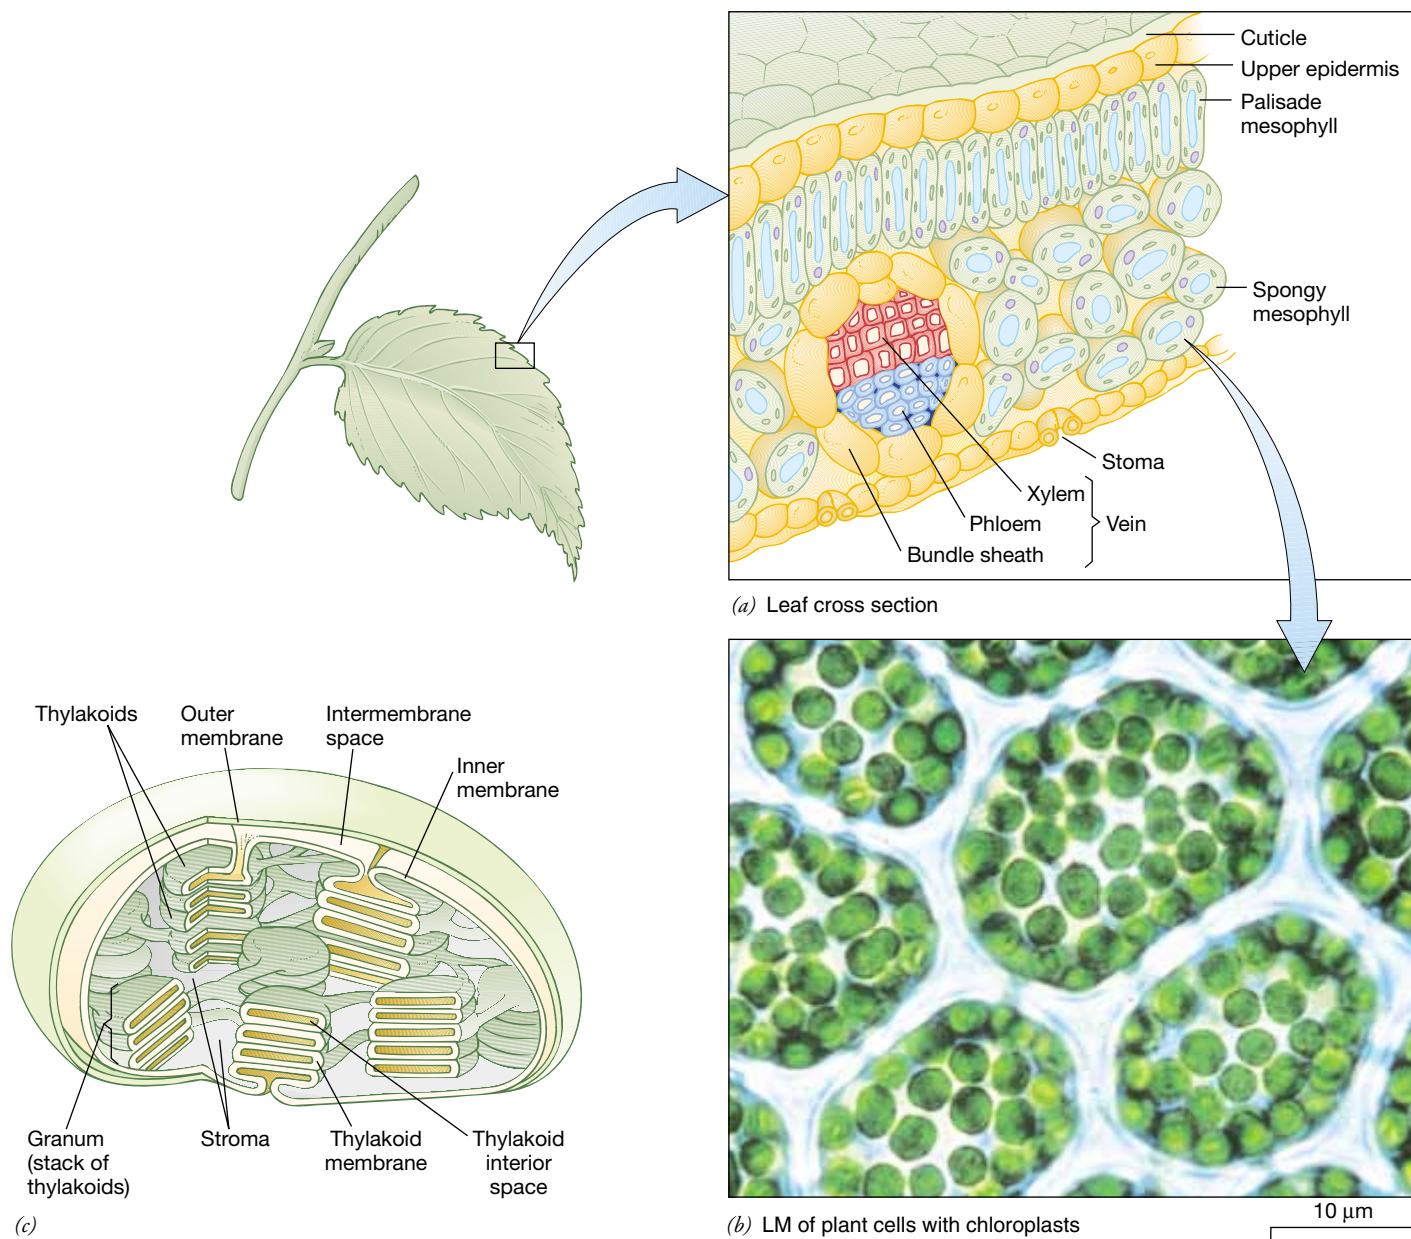

Figure 8-4 Where photosynthesis occurs in the plant.

(a) A leaf cross section reveals that the mesophyll is the photosynthetic tissue. CO_2 enters the leaf through tiny pores called stomata (sing., stoma), and H_2O is carried to the mesophyll in veins. (b) LM of plant cells with numerous chloroplasts. (c) Chloroplast structure. The pigments necessary for the light-capturing reactions of photosynthesis are part of thylakoid membranes, whereas the enzymes for the synthesis of carbohydrate molecules are in the stroma. It is not known if the inner chloroplast membrane is continuous with the thylakoid system (as shown) or not. (b, M.

Eichelberger/Visuals Unlimited)

branes extend from one granum to another. Chlorophyll and other photosynthetic pigments are part of the thylakoid membranes. These membranes, like the inner mitochondrial membrane (see Chapter 7), are involved in ATP synthesis. (Photosynthetic prokaryotes have no chloroplasts, but thylakoid membranes are often arranged around the periphery of the cell as infoldings of the plasma membrane.)

Chlorophyll is found in the thylakoid membrane

Thylakoid membranes contain several kinds of pigments, which are substances that absorb visible light. Different pigments absorb light of different wavelengths. Chlorophyll, the main pigment of photosynthesis, absorbs light primarily in the

Figure 8–5 Chlorophyll structure. Chlorophyll consists of a porphyrin ring and a hydrocarbon tail. The porphyrin ring, with a magnesium atom in its center, contains a system of alternating double and single bonds; these are commonly found in molecules that strongly absorb visible light. At the top right corner of the diagram, the methyl group (—CH_3) distinguishes chlorophyll *a* from chlorophyll *b*, which has a carbonyl group (—CHO) in this position.

blue and red regions of the visible spectrum. Green light is not appreciably absorbed by chlorophyll. Plants usually appear green because most of the green light that strikes them is scattered or reflected.

A chlorophyll molecule (Fig. 8–5) has two main parts: one captures energy and the other holds the molecule in place in the thylakoid membrane. Light energy is absorbed by a complex ring, called a *porphyrin ring*, made up of joined smaller rings composed of carbon and nitrogen atoms. The porphyrin ring of chlorophyll is strikingly similar to the heme portion of the red pigment hemoglobin in red blood cells. However, unlike heme, which contains an atom of iron in the center of the ring, chlorophyll contains an atom of magnesium in that position. The chlorophyll molecule is embedded in the thylakoid membrane by a long hydrophobic hydrocarbon tail. Because of their shape, many chlorophyll molecules can be grouped together like a stack of saucers. Each thylakoid membrane is filled

with precisely oriented chlorophyll molecules, an arrangement that permits transfer of energy from one molecule to another.

There are several kinds of chlorophyll. The most important is **chlorophyll *a***, the pigment that initiates the light-dependent reactions. **Chlorophyll *b*** is an accessory pigment that also participates in photosynthesis. It differs from chlorophyll *a* only in a functional group on the porphyrin ring: the methyl group (—CH_3) in chlorophyll *a* is replaced in chlorophyll *b* by a terminal carbonyl group (—CHO). This difference shifts the wavelengths of light absorbed and reflected by chlorophyll *b*, making it yellow-green, whereas chlorophyll *a* is bright green.

Chloroplasts also have other accessory photosynthetic pigments, such as **carotenoids**, which are yellow and orange (for a brief discussion of the carotenoid β -carotene, see *Making the Connection: Molecules That Absorb Light* in Chapter 3). Carotenoids absorb different wavelengths of light than chlorophyll does and so broaden the spectrum of light that provides energy for photosynthesis. Chlorophyll may be excited by light directly or indirectly by energy passed to it from accessory pigments that have become excited by light. When a carotenoid molecule is excited, its energy can be transferred to chlorophyll *a*.

CHLOROPHYLL IS THE MAIN PHOTOSYNTHETIC PIGMENT

As we have seen, the thylakoid membrane contains more than one kind of pigment. It is possible to determine which of these pigments is mainly responsible for photosynthesis by comparing the wavelengths of light absorbed by each pigment with the wavelengths of light that are most effective in promoting the reactions of photosynthesis. An instrument called a spectrophotometer is used to measure the relative abilities of different pigments to absorb different wavelengths of light. The **absorption spectrum** of a pigment is a plot of its absorption of light of different wavelengths. Figure 8–6*a* shows the absorption spectra for chlorophylls *a* and *b*.

The relative effectiveness of these different wavelengths of light in photosynthesis is given by an **action spectrum** of photosynthesis (Fig. 8–6*b*). The first action spectrum was obtained in one of the classic experiments in biology. In 1883 the German biologist T. W. Engelmann carried out an experiment that took advantage of the shape of the chloroplast in a species of *Spirogyra*, a green alga that occurs as long, filamentous strands in freshwater habitats, especially slow-moving or still waters (Fig. 8–7*a*). The individual cells of *Spirogyra* are exquisite, each containing a long, spiral-shaped, emerald-green chloroplast embedded in cytoplasm. Engelmann exposed these cells to a color spectrum produced by passing light through a prism. He reasoned that if chlorophyll were indeed responsible for photosynthesis, then it would take place most rapidly in the areas where the chloroplast was illuminated by the colors most readily absorbed by chlorophyll.

(a)

(b)

Figure 8–6 The absorption spectra for chlorophylls *a* and *b* and the action spectrum for photosynthesis. (a) Chlorophylls *a* and *b* absorb light mainly in the blue and red regions of visible light. (b) The action spectrum of photosynthesis shows how effective various wavelengths of light are in powering photosynthesis.

Yet how could photosynthesis be measured in those technologically unsophisticated days? Engelmann knew that photosynthesis produces oxygen and that certain motile bacteria are attracted to areas of high oxygen concentration (Fig. 8–7*b*). He determined the action spectrum of photosynthesis by observing that the bacteria swam toward the portions of

Spirogyra located in the red and blue regions of the spectrum. The fact that the bacteria did not move toward red and blue areas when *Spirogyra* was absent showed that bacteria are not merely attracted to any region where red or blue light is present. Because the action spectrum of photosynthesis closely matched the absorption spectrum of chlorophyll, Engelmann

(a)

(b)

Figure 8–7 The first action spectrum of photosynthesis. (a) LM of filaments of *Spirogyra* sp., the green alga that Engelmann used in his classic experiment. (b) Engelmann illuminated a filament of *Spirogyra* with light that had been passed through a prism. In this way, different parts of the filament were exposed to different wavelengths of light. He estimated the rate of photosynthesis indirectly, by observing the movement of aerobic bacteria toward the portions of the algal filament emitting the most oxygen. Watching through a microscope, Engelmann observed that the bacteria aggregated most densely along the cells in the blue and red portions of the spectrum. This indicated that blue and red light works most effectively for photosynthesis. (a, T.E. Adams/Visuals Unlimited)

MAKING THE CONNECTION

PHOTOSYNTHESIS AND AEROBIC RESPIRATION

In what ways are photosynthesis and aerobic respiration alike, and how do they differ? Both are redox processes that are intimately connected with the energy requirements of organisms. Although the series of steps by which photosynthesis and aerobic respiration occur are quite different, their overall equations are almost exactly opposite.

In photosynthesis:

In aerobic respiration:

The following table compares other aspects of these processes.

	Photosynthesis	Aerobic Respiration
Raw materials	CO_2 , H_2O	$\text{C}_6\text{H}_{12}\text{O}_6$, O_2
End products	$\text{C}_6\text{H}_{12}\text{O}_6$, O_2	CO_2 , H_2O
Which cells have these processes?	Cells that contain chlorophyll (certain cells of plants, algae, and some bacteria)	Every actively metabolizing cell has aerobic respiration or some other energy-releasing pathway.
Sites involved (in eukaryotic cells)	Chloroplasts	Cytosol (glycolysis); mitochondria
ATP production	By photophosphorylation (a chemiosmotic process)	By substrate-level phosphorylation and by oxidative phosphorylation (a chemiosmotic process)
Principal electron transfer compound	NADP^+ is reduced to form NADPH^*	NAD^+ is reduced to form NADH^*
Location of electron transport chain	Thylakoid membrane	Mitochondrial inner membrane (cristae)
Source of electrons for electron transport chain	In noncyclic phosphorylation: H_2O (undergoes photolysis to yield electrons, protons, and oxygen)	Immediate source: NADH , FADH_2 Ultimate source: glucose or other carbohydrate
Terminal electron acceptor for electron transport chain	In noncyclic phosphorylation: NADP^+ (becomes reduced to form NADPH)	O_2 (becomes reduced to form H_2O)
* NADPH and NADH are very similar hydrogen (i.e., electron) carriers, differing only in a single phosphate group. However, NADPH generally works with enzymes in anabolic pathways, such as photosynthesis. NADH is associated with catabolic pathways, such as cellular respiration.		

concluded that chlorophyll in the chloroplasts (and not another compound in another organelle) is responsible for photosynthesis. Numerous studies using sophisticated instruments have since confirmed Engelmann's conclusions.

The action spectrum of photosynthesis does not parallel the absorption spectrum of chlorophyll exactly (Fig. 8–6). This difference occurs because accessory pigments, such as carotenoids, transfer some of the energy of excitation produced by green light to chlorophyll molecules. The presence of these accessory photosynthetic pigments can be demonstrated by chemical analysis of almost any leaf, although it is obvious in temperate climates when leaves change color in the fall. Toward the end of the growing season, chlorophyll breaks down (and its magnesium is stored in the permanent tissues of the tree), leaving accessory pigments in the leaves.

PHOTOSYNTHESIS IS THE CONVERSION OF LIGHT ENERGY TO CHEMICAL BOND ENERGY

During photosynthesis, a cell uses light energy captured by chlorophyll to power the synthesis of carbohydrates. The overall reactions of photosynthesis can be summarized as follows:

The equation is typically written in the form given above, with H_2O on both sides, because water is a reactant in some reactions and a product in others. However, because there is no

Figure 8–8 A summary of photosynthesis. Photosynthesis consists of light-dependent reactions, which occur in association with the thylakoids, and carbon fixation reactions, which occur in the stroma.

net yield of H_2O , we can simplify the summary equation of photosynthesis for purposes of discussion:

When we analyze this process, it appears that hydrogen atoms are transferred from H_2O to CO_2 to form carbohydrate, and so we recognize it as an oxidation-reduction (redox) reaction. As you learned in Chapter 6, in a redox reaction one or more electrons, usually as part of one or more hydrogen atoms, are transferred from an electron donor (a reducing agent) to an electron acceptor (an oxidizing agent).

When the electrons are transferred, some of their energy is transferred as well. However, the summary equation of photosynthesis is somewhat misleading because no direct transfer of hydrogen atoms actually occurs. The summary equation describes what happens but not how it happens. The “how” is much more complex and involves many steps, many of which are redox reactions. (See *Making the Connection: Photosynthesis and Aerobic Respiration* on page 180 for a comparison of these two biologically important redox processes.)

The reactions of photosynthesis are divided into two parts: the light-dependent reactions (the *photo* part of photosynthe-

sis) and the carbon fixation reactions (the *synthesis* part of photosynthesis). Each set of reactions occurs in a different part of the chloroplast: the light-dependent reactions in association with the thylakoids, and the carbon fixation reactions in the stroma (Fig. 8–8).

ATP and NADPH are the products of the light-dependent reactions

Light energy is converted to chemical energy in the **light-dependent reactions**, which are associated with the thylakoids. The light-dependent reactions begin as chlorophyll captures light energy, which causes one of its electrons to move to a higher energy state. The energized electron is transferred to an acceptor molecule and is replaced by an electron from H_2O . When this happens, H_2O is split and molecular oxygen is released (Fig. 8–9). Some of the energy of the energized electrons is used to phosphorylate ADP, forming ATP. In addition, the coenzyme **nicotinamide adenine dinucleotide phosphate (NADP⁺)** is reduced, forming NADPH.² The products of the light-dependent reactions, ATP and NADPH, are both needed in the endergonic carbon fixation reactions.

Carbohydrates are produced during the carbon fixation reactions

The ATP and NADPH molecules produced during the light-dependent phase are suited for transferring chemical energy

²Although the correct way to write the reduced form of NADP^+ is $\text{NADPH} + \text{H}^+$, for simplicity's sake we present the reduced form as NADPH throughout the chapter.

Figure 8–9 Oxygen produced by photosynthesis. On sunny days the oxygen released by aquatic plants may sometimes be visible as bubbles in the water. This plant (*Elodea* sp.) is actively carrying on photosynthesis. (Bernd Wittich/Visuals Unlimited)

but not for long-term energy storage. For this reason, some of their energy is transferred to chemical bonds in carbohydrates, which can be produced in large quantities and stored for future use. Known as **carbon fixation** or **CO₂ fixation**, these reactions “fix” carbon atoms from CO₂ to existing skeletons of organic molecules. Because the carbon fixation reactions have no direct requirement for light, they are sometimes referred to as the light-independent reactions or the “dark” reactions. However, they certainly do not require darkness; in fact, many of the enzymes involved are much more active in

the light than in the dark. Furthermore, carbon fixation reactions depend on the products of the light-dependent reactions. Carbon fixation reactions take place in the stroma.

Now that we have presented an overview of photosynthesis, let’s examine the entire process more closely. (Table 8–1 provides a detailed summary of photosynthesis.)

THE LIGHT-DEPENDENT REACTIONS CONVERT LIGHT ENERGY TO CHEMICAL ENERGY

In the light-dependent reactions, the radiant energy from sunlight is used to make ATP and to reduce NADP⁺, forming NADPH. The light energy captured by chlorophyll is temporarily stored in these two compounds. The light-dependent reactions are summarized as follows:

Photosystems I and II include antenna complexes that trap light

The light-dependent reactions of photosynthesis begin when chlorophyll *a* and/or accessory pigments absorb light. According to the currently accepted model, chlorophyll molecules and accessory pigments are organized in the thylakoid membrane

TABLE 8–1 Summary of Photosynthesis			
Reaction Series	Summary of Process	Needed Materials	End Products
A. Light-dependent reactions (take place in thylakoid membranes)	Energy from sunlight used to split water, manufacture ATP, and reduce NADP ⁺		
	1. Photochemical reactions	Chlorophyll activated; reaction center gives up photoexcited electron to electron acceptor	Light energy; pigments (chlorophyll)
	2. Electron transport	Electrons are transported along chain of electron acceptors in thylakoid membranes; electrons reduce NADP ⁺ ; splitting of water provides some of H ⁺ that accumulates inside thylakoid space	Electrons
	3. Chemiosmosis	H ⁺ are permitted to move across the thylakoid membrane down their gradient; they cross the membrane through special channels in ATP synthase complex; energy released is used to produce ATP	NADPH, O ₂
B. Carbon fixation reactions (take place in stroma)	Carbon fixation: carbon dioxide is used to make carbohydrate	Proton gradient, ADP + P _i	ATP
		Ribulose biphosphate, CO ₂ , ATP, NADPH, necessary enzymes	Carbohydrates, ADP + P _i , NADP ⁺

Figure 8–10 An antenna complex. Chlorophyll molecules and accessory pigments are arranged in arrays that act as light-harvesting antennae. When a molecule in the antenna complex absorbs a photon, the energy of that photon is funneled into the reaction center. When this energy reaches a chlorophyll in the reaction center, an electron becomes energized and is accepted by a primary electron acceptor.

into units called **antenna complexes**. The pigments are arranged as highly ordered groups of 200 to 300 molecules associated with specific enzymes and other proteins. Each antenna complex traps light and transfers the energy to a **reaction center**, a complex of chlorophyll molecules and proteins that participates directly in photosynthesis (Fig. 8–10). Light energy is converted to chemical energy in the reaction centers by a series of electron transfer reactions.

Two types of photosynthetic units, designated Photosystem I and Photosystem II, are involved in photosynthesis. Their reaction centers are distinguishable because they are associated with proteins in a way that causes a slight shift in their absorption spectra. Ordinary chlorophyll *a* has a strong absorption peak at about 660 nanometers. In contrast, the chlorophyll *a* molecules that make up the reaction center associated with **Photosystem I** have an absorption peak at 700 nanometers and are referred to as **P700**. (The *P* in P700 stands for “pigment.”) The reaction center of **Photosystem II** (**P680**) is made up of chlorophyll *a* molecules with an absorption peak of about 680 nanometers.

When a pigment molecule absorbs light energy, that energy is passed from one pigment molecule to another until it reaches the reaction center. When the energy reaches a molecule of P700 or P680 at the reaction center, an electron is then raised to a higher energy level. This energized electron can be donated to an electron acceptor that becomes reduced in the process.

Noncyclic photophosphorylation produces ATP and NADPH

Both Photosystems I and II are used in **noncyclic photophosphorylation**, which is the more common light-dependent reaction. In noncyclic photophosphorylation, light ener-

gizes electrons, which pass down an **electron transport chain** from the ultimate electron source, H_2O , to the terminal electron acceptor, NADP^+ . The zigzag pathway of electrons shown in Figure 8–11 is sometimes called the **Z scheme**. For every two electrons that enter this pathway, there is an energy yield of as much as two ATP molecules and one NADPH molecule.

We begin our discussion of noncyclic photophosphorylation with the events associated with Photosystem I. A pigment molecule in an antenna complex associated with Photosystem I absorbs a photon of light. The absorbed energy is transferred to the reaction center, where it excites an electron in a molecule of P700. This energized electron is transferred to a primary electron acceptor, which transfers it to ferredoxin, a membrane-bound, iron-containing protein. Ferredoxin then transfers the electron to NADP^+ . The electron transport chain must furnish two electrons to reduce NADP^+ to NADPH. When NADP^+ accepts the two electrons, they unite with a proton (H^+); hence the reduced form of NADP^+ is NADPH, which is released into the stroma. P700 becomes positively charged when it gives up an electron to the primary electron acceptor; the missing electron is replaced by one donated by Photosystem II.

Like Photosystem I, Photosystem II is activated when a pigment molecule in an antenna complex absorbs a photon of light energy. The energy is transferred to the reaction center, where it causes an electron in a molecule of P680 to move to a higher energy level. This energized electron is accepted by a primary electron acceptor and then passes through a chain of acceptor molecules until it is donated to P700 in Photosystem I.

A molecule of P680 that has given up an energized electron to the primary electron acceptor is positively charged. This P680 molecule is an oxidizing agent so strong that it is capable of pulling electrons away from an oxygen atom that is part of a H_2O molecule. In a reaction catalyzed by a unique enzyme, the process of **photolysis** (literally “light-splitting”) breaks water into its components: two electrons, two protons, and oxygen. Each electron is donated to a P680 molecule, and the protons are released into the thylakoid interior space. Because oxygen does not exist in atomic form, the oxygen produced by splitting one H_2O molecule is written $\frac{1}{2} \text{O}_2$. Two H_2O molecules must be split to yield one molecule of oxygen (O_2), which is ultimately released into the atmosphere. The photolysis of H_2O is a remarkable reaction, but its name is somewhat misleading because it implies that H_2O is broken by light. Actually, light breaks H_2O indirectly, by oxidizing P680 molecules.

Noncyclic photophosphorylation is a continuous linear process

In the presence of light, there is a continuous, one-way flow of electrons from the ultimate electron source, H_2O , to the terminal electron acceptor, NADP^+ . Water undergoes enzymatically catalyzed photolysis to replace energized electrons donated to the electron transport chain by molecules of P680 in Photosystem II. These electrons travel down the electron trans-

Figure 8–11 Noncyclic photophosphorylation. In noncyclic photophosphorylation, also called the Z scheme, the formation of ATP is coupled to the one-way flow of energized electrons from H_2O to NADP^+ . Single electrons actually pass down the electron transport chain; two are shown in the figure because two are required to form one NADPH. Electrons are supplied to the system from the splitting of H_2O by Photosystem II, with the release of O_2 as a byproduct. When Photosystem II is activated by absorbing photons, electrons are passed along an electron transport chain and are eventually donated to Photosystem I. Electrons in Photosystem I are “re-energized” by the absorption of additional light energy and are passed to NADP^+ .

port chain that connects Photosystem II with Photosystem I and replace the energized electrons donated by P700 that ultimately reduce NADP^+ .

As electrons are transferred along the electron transport chain that connects Photosystem II with Photosystem I, they lose energy. Some of the energy released is used to pump protons across the thylakoid membrane, from the stroma to the thylakoid interior space, producing a proton gradient. The energy of this proton gradient is harnessed to produce ATP from ADP by chemiosmosis, which is discussed shortly. ATP and NADPH, the products of the light-dependent reactions, are released into the stroma, where both are required in the carbon fixation reactions.

Cyclic photophosphorylation produces ATP but no NADPH

Only Photosystem I is involved in **cyclic photophosphorylation**, the simplest light-dependent reaction. The pathway is cyclic because energized electrons that originate from P700 at the reaction center eventually return to P700. In the presence of light, there is a continuous flow of electrons through an electron transport chain within the thylakoid membrane. As they are passed from one acceptor to another, the electrons lose energy, some of which is used to pump protons across the thylakoid membrane. An enzyme (ATP synthase, discussed shortly) in the thylakoid membrane uses the energy of the pro-

TABLE 8–2 A Comparison of Noncyclic and Cyclic Photophosphorylation

	Noncyclic photophosphorylation	Cyclic photophosphorylation
Electron source	H_2O	None—electrons cycle through the system
Oxygen released?	Yes (from H_2O)	No
Terminal electron acceptor	NADP^+	None—electrons cycle through the system
Form in which energy is temporarily captured	ATP (by chemiosmosis); NADPH	ATP (by chemiosmosis)
Photosystem(s) required	PSI (P700) and PSII (P680)	PSI (P700) only

FOCUS ON

THE EVOLUTION OF PHOTOSYSTEMS I AND II

Photosynthesis is an extremely ancient biological process that has apparently changed a great deal since it first appeared more than 3 billion years ago. The use of light energy to manufacture organic molecules first evolved in ancient bacteria that were similar to the green sulfur bacteria existing today.

Initially there was only one photosystem, Photosystem I, which used a green pigment called *bacteriochlorophyll* to gather light energy. Photosystem I operated alone, generating ATP from light energy by cyclic photophosphorylation. However, cyclic photophosphorylation does not provide the reducing power of NADPH, which is needed to manufacture carbohydrate molecules from CO₂. (Recall that in cyclic photophosphorylation, the electrons from

chlorophyll are not passed to NADP⁺ but are instead returned to chlorophyll.) Ancient photosynthetic bacteria, like some of their modern counterparts, used electron donors such as hydrogen sulfide (H₂S) rather than H₂O to generate the reducing power needed to manufacture carbohydrates in photosynthesis:

This process is not very efficient, however; bacteriochlorophyll has enough oxidative potential to extract electrons from H₂S but not sufficient oxidative potential to extract electrons from H₂O.

Around 3.1 to 3.5 billion years ago, a new group of prokaryotes called **cyanobacteria** evolved (see Chapter 20). These ancient cyanobacteria were probably similar to modern cyanobacteria, which have light-requiring reactions that are similar to those of photosynthetic eukaryotes, including plants. They possess chlorophyll *a* instead of bacteriochlorophyll and can carry out noncyclic photophosphorylation because they have Photosystem II in addition to Photosystem I. Water provides the electrons required to generate NADPH, which in turn provides the reducing power required to manufacture carbohydrate molecules from CO₂.

ton gradient to manufacture ATP. NADPH is not produced, H₂O is not split, and oxygen is not generated. By itself, cyclic photophosphorylation could not serve as the basis of photosynthesis because, as we explain in the next section, NADPH is required to reduce CO₂ to carbohydrate.

The significance of cyclic photophosphorylation to photosynthesis in plants is not yet certain. Cyclic photophosphorylation may occur in plant cells when there is too little NADP⁺ to accept electrons from ferredoxin. Biologists generally agree that this process was used by ancient bacteria to produce ATP from light energy (see *Focus On: The Evolution of Photosystems I and II*). A reaction pathway analogous to cyclic photophosphorylation in plants is present in some modern photosynthetic bacteria. Noncyclic and cyclic photophosphorylation are compared in Table 8–2 on page 184.

ATP synthesis occurs by chemiosmosis

Each member of the electron transport chain, embedded in the thylakoid membrane, can exist in an oxidized (lower energy) form and a reduced (higher energy) form. The electron accepted from P680 by the primary electron acceptor is highly energized; it is passed from one carrier to the next in a series of exergonic redox reactions, losing some of its energy at each step. Some of the energy given up by the electron is not lost by the system, however; it is used to drive the synthesis of ATP (an endergonic reaction). Because the synthesis of ATP (that is, the phosphorylation of ADP) is coupled to the transport of electrons that have been energized by photons of light, the process is called **photophosphorylation**.

The chemiosmotic model explains the coupling of ATP synthesis and electron transport

As discussed earlier, the pigments and electron acceptors of the light-dependent reactions are embedded in the thylakoid membrane. Energy released from electrons traveling through the chain of acceptors is used to pump protons from the stroma, across the thylakoid membrane, and into the thylakoid interior space (Fig. 8–12). Thus, the pumping of protons results

Figure 8–12 Accumulation of protons (H⁺) within the thylakoid interior space. As electrons move down the electron transport chain, protons move from the stroma to the thylakoid interior space, creating a proton gradient. The greater concentration of H⁺ in the thylakoid interior space lowers the pH.

Figure 8–13 A detailed look at electron transport and chemiosmosis. The orange arrows indicate the pathway of electrons along the electron transport chain in the thylakoid membrane. The electron carriers within the membrane become alternately reduced and oxidized as they accept and donate electrons. The energy released during electron transport is used to transport H^+ from the stroma to the thylakoid interior space, where a high concentration of H^+ accumulates. The H^+ are prevented from diffusing back into the stroma except through special channels in ATP synthase in the thylakoid membrane. The flow of the H^+ through ATP synthase generates ATP.

in the formation of a proton gradient across the thylakoid membrane. Because protons are actually hydrogen ions (H^+), the accumulation of protons causes the pH of the thylakoid interior to fall to a pH of about 5 in the thylakoid interior space, as compared to a pH of about 8 in the stroma. This difference of about 3 pH units across the thylakoid membrane means there is an approximately 1000-fold difference in hydrogen ion concentration.

The proton gradient has a great deal of free energy be-

cause of its state of low entropy. How does the chloroplast convert that energy to a more useful form? According to the general principles of diffusion, the concentrated protons inside the thylakoid might be expected to diffuse out readily. However, they are prevented from doing so because the thylakoid membrane is impermeable to H^+ except through certain channels formed by an enzyme called **ATP synthase**. ATP synthase, a transmembrane protein, forms complexes so large they can be seen in electron micrographs; these project into the stroma. As

the protons diffuse through an ATP synthase complex, free energy decreases as a consequence of an increase in entropy. Each ATP synthase complex couples this exergonic process of diffusion down a concentration gradient to the endergonic process of phosphorylation of ADP to form ATP, which is released into the stroma (Fig. 8–13).

The mechanism by which the phosphorylation of ADP is coupled to diffusion down a proton gradient is called **chemiosmosis**. As the essential connection between the electron transport chain and the phosphorylation of ADP, chemiosmosis is a basic mechanism of energy coupling in cells. You may recall from Chapter 7 that chemiosmosis also occurs in cellular respiration.

THE CARBON FIXATION REACTIONS REQUIRE ATP AND NADPH

In carbon fixation, the energy of ATP and NADPH is used in the formation of organic molecules from CO₂. The carbon fixation reactions may be summarized as follows:

Most plants use the Calvin (C₃) cycle to fix carbon

Carbon fixation occurs in the stroma through a sequence of reactions known as the **Calvin cycle**. M. Calvin, A. Benson,

and others at the University of California were able to elucidate the details of this cycle; for his work, Calvin was awarded a Nobel Prize in 1961 (Fig. 8–14).

The Calvin cycle begins when a molecule of CO₂ reacts with a highly reactive phosphorylated five-carbon compound, **ribulose biphosphate (RuBP)**. This reaction is catalyzed by the enzyme **ribulose biphosphate carboxylase**, also known as **Rubisco**. The product of this reaction is an unstable, six-carbon intermediate, which immediately breaks down into two molecules of **phosphoglycerate (PGA)** with three carbons each. The carbon that was originally part of a CO₂ molecule is now part of a carbon skeleton; the carbon has been “fixed.” Because the product of the initial carbon fixation reaction is a three-carbon compound, the Calvin cycle is also known as the **C₃ pathway**. A total of six carbons must be fixed in this way to produce the equivalent of one molecule of glucose or some other hexose (six-carbon sugar), such as fructose. At the end of each cycle, the starting material, RuBP, is re-formed.

With the energy and reducing power from ATP and NADPH (both produced in the light-dependent reactions), the PGA molecules are converted to **glyceraldehyde-3-phosphate (G3P)**. As shown in Figure 8–15, for every six carbons that enter the cycle as CO₂, six carbons can leave the system as two molecules of G3P, to be used in carbohydrate synthesis. Each of these three carbon molecules of G3P is essentially half a hexose molecule. (In fact, you may recall that G3P is a key intermediate in the splitting of sugar in glycolysis; see Figs. 7–3 and 7–4.) The reaction of two molecules of G3P is exergonic and can lead to the formation of glucose or fructose. In some plants, glucose and fructose are then joined to produce sucrose (common table sugar). Sucrose can be harvested from

Figure 8–14 Experimental apparatus of Calvin and Benson. The classic experiments carried out by Calvin, Benson, and others in the 1950s elucidated the steps in carbon fixation of photosynthesis. Calvin and his colleagues grew algae in the green “lollipop.” CO₂ labeled with ¹⁴C was bubbled through the algae, and they were periodically killed by dumping the “lollipop” contents into a beaker of boiling alcohol. By identifying which compounds contained the ¹⁴C at different times, Calvin was able to determine the steps of carbon fixation in photosynthesis. (Courtesy of Melvin Calvin, University of California, Berkeley)

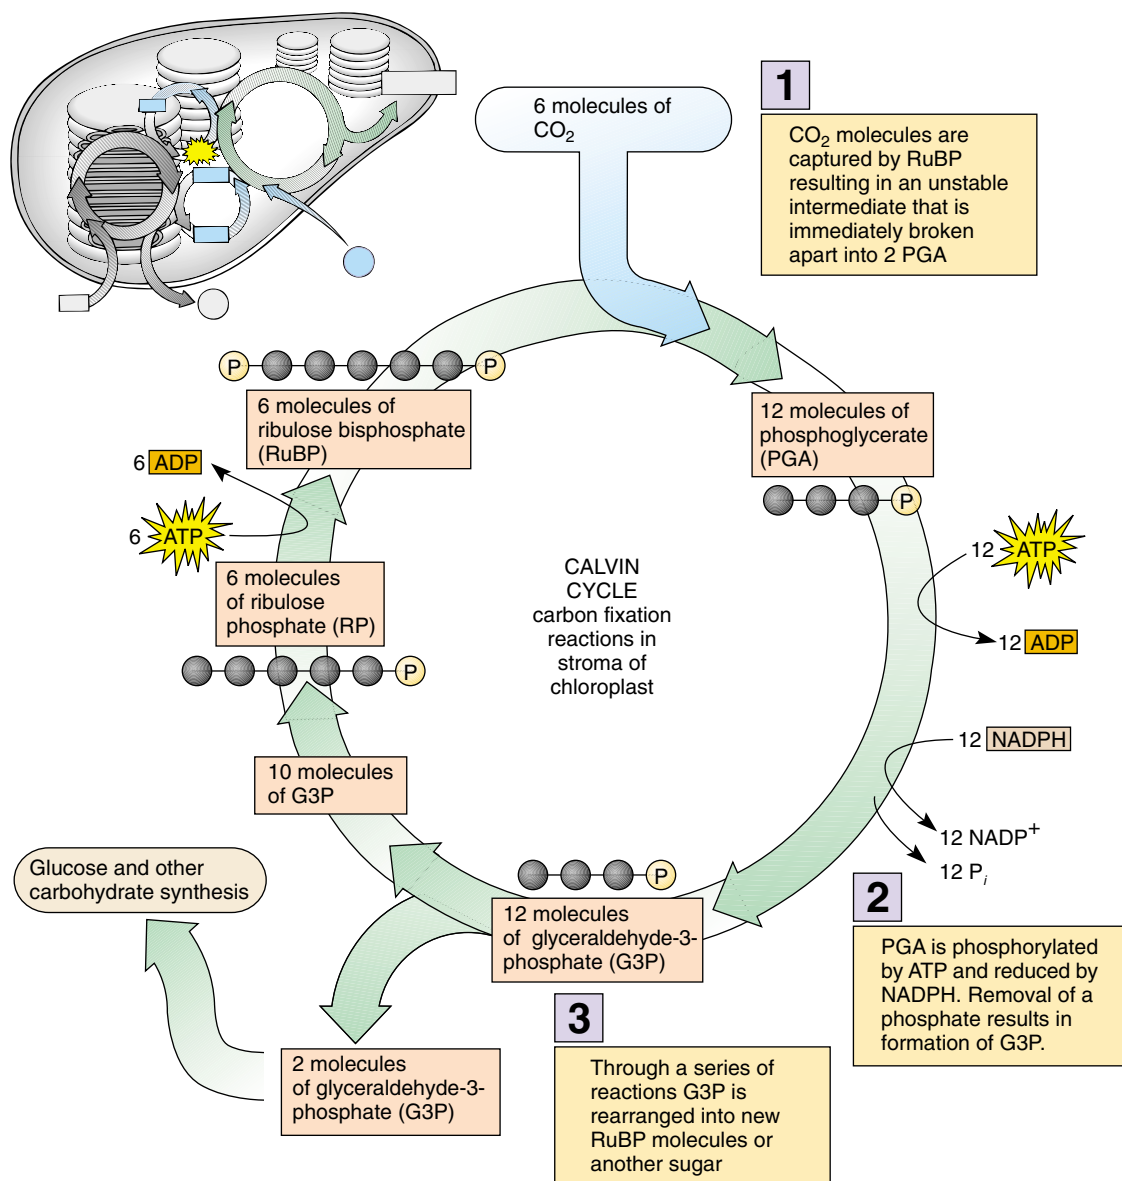

Figure 8–15 A detailed look at the Calvin cycle. This diagram, which shows carbon atoms as black balls, demonstrates that six molecules of CO_2 must be “fixed” (incorporated into preexisting carbon skeletons) to produce one molecule of a six-carbon sugar such as glucose. Two glyceraldehyde-3-phosphate (G3P) molecules “leave” the cycle for every glucose formed. Although these reactions do not require light directly, the energy that drives the Calvin cycle comes from ATP and NADPH, which are the products of the light-dependent reactions.

sugar cane, sugar beets, and maple sap. The plant cell also uses glucose to produce starch or cellulose.

Notice that, although two G3P molecules are removed from the cycle, ten G3P molecules remain; this represents 30 carbon atoms in all. Through a complex series of reactions, these 30 carbons and their associated atoms are rearranged into six molecules of ribulose phosphate, each of which becomes phosphorylated to produce RuBP, the very five-carbon compound with which the cycle started. These RuBP molecules

can begin the process of CO_2 fixation and eventual G3P production once again.

In summary, the inputs required for the carbon fixation reactions are six molecules of CO_2 , phosphates transferred from ATP, and electrons (as hydrogen) from NADPH. In the end, the six carbons from the CO_2 can be accounted for by the harvest of a hexose molecule. The remaining G3P molecules are used to synthesize the RuBP molecules with which more CO_2 molecules may combine.

MAKING THE CONNECTION

NUTRITION AND METABOLIC DIVERSITY

How can we categorize organisms on the basis of their nutritional needs? It is helpful to understand that nutrition has two main components: (1) how the organism obtains the carbon atoms required to make up the carbon skeletons of its organic molecules, and (2) how the organism obtains energy. Organisms obtain carbon in two ways. **Autotrophs** are able to carry out carbon fixation; they use CO_2 as a carbon source. **Heterotrophs** cannot fix carbon; they use preformed organic molecules (produced by other organisms) as a carbon source.

Energy can come from chemical nutrients or from light. **Photoautotrophs** use light as their primary energy source. Plants, algae, and some bacteria are photoautotrophs (see figures *a*, *b*, and *c*); they use light as the source of the energy required to carry out

carbon fixation. **Chemoautotrophs** are bacteria that obtain their energy from the oxidation of reduced inorganic molecules such as hydrogen sulfide (H_2S), nitrite (NO_2^-), or ammonia (NH_3). Some of this energy is then used to carry out carbon fixation. (See *Focus On: Life without the Sun* in Chapter 52 for a discussion of one group of chemoautotrophs.)

All animals, fungi, and most bacteria are **chemoheterotrophs** and use preformed organic molecules as a source of both energy and carbon. A few plants are chemoheterotrophs as well (see figure *d*). A few bacteria are **photoheterotrophs**, organisms able to use light energy but unable to carry out carbon fixation. Photoheterotrophs must obtain carbon from organic sources (as “food”).

(a)

Photoautotrophs. (a) The prayer plant (*Maranta* sp.). Plants are the main photoautotrophs on land. (b) A kelp (*Macrocystis integrifolia*), a type of alga. Algae range in size from those that are microscopic to large seaweeds. They are important photoautotrophs in aquatic environments. (c) A photoautotrophic cyanobacterium (*Nostoc* sp.) that photosynthesizes like plants and algae. (d) Although the vast majority of plants are photoautotrophs, there are exceptions. This plant, commonly known as Indian pipes (*Monotropa uniflora*), lives underground (except for its flowers, which are shown) and has lost the capacity to perform photosynthesis. It is a chemoheterotroph that obtains energy and carbon from organic molecules produced by other plants and supplied by soil-dwelling fungi. The initial carbon fixation step differs in C_4 plants and in CAM plants

Because CO_2 is not a very abundant gas (comprising only about 0.03% of the atmosphere), it is not easy for plants to obtain the CO_2 they need. This problem is complicated by the fact that gas exchange can occur only across a moist surface. The surfaces of leaves and other exposed plant parts are covered with a waterproof layer that helps prevent excess loss of water vapor. Entry and exit of gases is therefore limited to tiny pores, called **stomata** (sing., *stoma*), usually concentrated on

the undersides of the leaves. These openings lead to the interior of the leaf, which is made up of chloroplast-containing cells, known as the **mesophyll**, with many air spaces and a very high concentration of water vapor. The stomata open and close in response to such environmental factors as water content and light intensity. When conditions are hot and dry, the stomata close to reduce the loss of water vapor. As a result, the supply of CO_2 is greatly diminished. Ironically, CO_2 is potentially less available at the very times when maximum sunlight is available to power the light-dependent reactions.

Many plant species living in hot, dry environments have

(a) Arrangement of cells in a C_3 leaf

(b) Arrangement of cells in a C_4 leaf

Figure 8-16 Comparison of C_3 and C_4 anatomy. (a) In C_3 plants, such as soybeans, the Calvin cycle takes place in the mesophyll cells. (b) In C_4 plants, such as crabgrass, reactions that fix CO_2 into four-carbon compounds take place in the mesophyll cells. The four-carbon compounds are transferred from the mesophyll cells to the bundle sheath cells, where the Calvin cycle takes place. (a and b, Dennis Drenner)

adaptations that allow them initially to fix CO_2 through one of two pathways that help minimize water loss. These pathways, known as the C_4 pathway and the CAM pathway, take place in the cytosol. Both the C_4 and CAM pathways merely *precede* the Calvin cycle (C_3 pathway); they do not replace it.

The C_4 pathway efficiently fixes CO_2 at low concentrations

Some plants, known as **C_4 plants**, first fix CO_2 into a four-carbon compound, **oxaloacetate**, prior to the C_3 pathway. The C_4 pathway not only occurs before the C_3 pathway, it also occurs in different cells.

Leaf anatomy is usually distinctive in C_4 plants. In addition to having mesophyll cells, C_4 leaves have prominent chloroplast-containing **bundle sheath cells** (Fig. 8–16). These cells tightly encircle the veins of the leaf. The mesophyll cells in C_4 plants are closely associated with the bundle sheath cells. The **C_4 pathway** (also called the **Hatch-Slack pathway**, after M. D. Hatch and C. R. Slack, who worked out many of its steps) occurs in the mesophyll cells, whereas the Calvin cycle takes place within the bundle sheath cells.

The key component of the C_4 pathway is a remarkable enzyme that has an extremely high affinity for CO_2 , binding it effectively even at unusually low concentrations. This enzyme, **PEP carboxylase**, catalyzes the reaction by which CO_2 reacts with the three-carbon compound **phosphoenolpyruvate (PEP)**, forming oxaloacetate (Fig. 8–17).

In a step that requires NADPH, oxaloacetate is converted to some other four-carbon compound, usually malate. The malate then passes to chloroplasts within bundle sheath cells, where a different enzyme catalyzes the decarboxylation of malate to yield pyruvate (which has three carbons) and CO_2 . NADPH is formed, replacing the one used earlier.

The CO_2 released in the bundle sheath cell combines with ribulose biphosphate and goes through the Calvin cycle in the usual manner. The pyruvate formed in the decarboxylation reaction returns to the mesophyll cell, where it reacts with ATP to regenerate phosphoenolpyruvate.

The role of the C_4 pathway is to efficiently capture CO_2 and ultimately increase its concentration within the bundle sheath cells. The concentration of CO_2 within the bundle sheath cells is about 10 to 60 times greater than the concentration in the mesophyll cells of plants having only the C_3 pathway.

The combined C_3 – C_4 pathway involves the expenditure of 30 ATPs per hexose, rather than the 18 ATPs used by the C_3 pathway alone. The extra energy expense is worthwhile at high light intensity because it ensures a high concentration of CO_2 in the bundle sheath cells and permits them to carry on photosynthesis at a rapid rate. The C_4 pathway is present in addition to the C_3 pathway in many plant species and apparently has evolved independently several times. Because PEP

Figure 8–17 Summary of the C_4 pathway. CO_2 combines with phosphoenolpyruvate (PEP) in the chloroplasts of mesophyll cells, forming a four-carbon compound that is converted to malate. Malate goes to the chloroplasts of bundle sheath cells, where it is decarboxylated. The CO_2 thus released in the bundle sheath cell is used to make carbohydrate by way of the Calvin cycle.

carboxylase fixes CO_2 so efficiently, C_4 plants do not need to have their stomata open as much; they therefore tolerate higher temperatures and higher light intensities, lose less water by transpiration (evaporation), and have higher rates of photosynthesis and growth than plants that use only the Calvin cycle. Among the many quick-growing and aggressive plants that use the C_4 pathway are sugar cane, corn, and crabgrass. If sunlight is abundant, the yields of C_4 crop plants can be two to three times greater than those of C_3 plants. If this pathway could be incorporated into more of our crop plants by genetic manipulation, we might be able to greatly increase food production in some parts of the world.

When light is abundant, the rate of photosynthesis is limited by the concentration of CO_2 , so C_4 plants, with their higher levels of CO_2 in bundle sheath cells, have the advantage. At lower light intensities and temperatures, C_3 plants are favored. For example, winter rye, a C_3 plant, grows lavishly in cool weather when crabgrass cannot because it requires more energy to fix CO_2 .

CAM plants fix CO₂ at night

Plants living in very dry, or *xeric*, conditions have a number of structural adaptations that enable them to survive. Many xeric plants have physiological adaptations as well. For example, their stomata may open during the cooler night and close during the hot day to reduce water loss from transpiration. This is in contrast to most plants, which have stomata that are open during the day and closed at night. But xeric plants that have their stomata closed during the day cannot exchange gases for photosynthesis. (Recall that other plants typically fix CO₂ during the day, when sunlight is available.)

Many xeric plants evolved a special carbon fixation pathway called **crassulacean acid metabolism (CAM)** that in effect solves this dilemma. The name comes from the stonecrop plant family (the Crassulaceae), which possesses the CAM pathway, although it has evolved independently in some members of more than 25 other plant families, including the cactus family (Cactaceae), the lily family (Liliaceae), and the orchid family (Orchidaceae) (Fig. 8–18).

CAM plants use the enzyme PEP carboxylase to fix CO₂ during the night when stomata are open, forming oxaloacetate, which is converted to malate and stored in cell vacuoles. During the day, when stomata are closed and gas exchange cannot occur between the plant and the atmosphere, CO₂ is removed from malate by a decarboxylation reaction. Now the CO₂ is available *within the leaf tissue* to be fixed into sugar by the Calvin cycle (C₃ pathway).

The CAM pathway is very similar to the C₄ pathway but with important differences. C₄ plants initially fix CO₂ into four-carbon organic acids in mesophyll cells. The acids are later decarboxylated to produce CO₂, which is fixed by the C₃ pathway in the bundle sheath cells. In other words, the C₄ and C₃

pathways occur in *different locations* within the leaf of a C₄ plant. In CAM plants, the initial fixation of CO₂ occurs at night. Decarboxylation of malate and subsequent production of sugar from CO₂ by the normal C₃ photosynthetic pathway occur during the day. In other words, the CAM and C₃ pathways occur at *different times* within the same cell of a CAM plant.

Although it does not promote rapid growth the way that the C₄ pathway does, the CAM pathway is a very successful adaptation to xeric conditions. CAM plants are able to exchange gases for photosynthesis and to reduce water loss significantly. Plants with CAM photosynthesis survive in deserts where neither C₃ nor C₄ plants can.

Photorespiration reduces photosynthetic efficiency

Many C₃ plants, including certain agriculturally important crops such as soybeans, wheat, and potatoes, do not yield as much carbohydrate from photosynthesis as might be expected. This reduction in yield is especially significant during very hot spells in summer. On hot, dry days plants close their stomata to conserve water. Once the stomata close, photosynthesis rapidly uses up the CO₂ remaining in the leaf and produces O₂, which accumulates in the chloroplasts. Recall that the enzyme RuBP carboxylase (Rubisco) is responsible for CO₂ fixation in the Calvin cycle by attaching CO₂ to RuBP. O₂ competes with CO₂ for binding to the active site of Rubisco. Therefore, when chloroplast oxygen levels are high and CO₂ levels are low, Rubisco is more likely to catalyze the reaction of RuBP with O₂ instead of with CO₂. When this occurs, some of the intermediates involved in the Calvin cycle are degraded to CO₂ and H₂O. This process is called **photorespi-**

Figure 8–18 A typical CAM plant. Painted lady (*Echeveria derenbergii*), a member of the family Crassulaceae, is a CAM plant that originated in xeric habitats in Mexico. (Michel Viard/Peter Arnold, Inc.)

ration because (1) it occurs in the presence of light; (2) it requires oxygen, like aerobic respiration; and (3) it produces CO₂ and H₂O, like aerobic respiration. Unlike aerobic respiration, however, ATP is not produced during photorespiration. Photorespiration reduces photosynthetic efficiency because it removes some of the intermediates used in the Calvin cycle.

The reasons for photorespiration are incompletely understood, although it is thought to possibly reflect the origin of Rubisco at an ancient time when CO₂ levels were high and molecular oxygen levels were low.

Photorespiration is negligible in C₄ plants because the concentration of CO₂ in bundle sheath cells (where Rubisco is present) is always high. However, many important crop plants are C₃ plants that carry out photorespiration. This is yet another reason that some scientists are attempting to transfer genes for the C₄ pathway to C₃ crops such as soybeans and wheat. If this genetic transfer is accomplished, these plants should be able to produce much more carbohydrate during hot weather.

SUMMARY WITH KEY TERMS

- I. Most producers are **photoautotrophs** and use light as an energy source for manufacturing organic compounds from CO₂ and H₂O.
- II. Light behaves as both a wave and a particle. Particles of light energy, called **photons**, can excite biological molecules. The resulting energized electrons may be accepted by electron acceptor compounds.
- III. In plants, **photosynthesis** occurs in **chloroplasts**, which are located mainly within **mesophyll** cells inside the leaf. During photosynthesis, light energy is captured and converted to the chemical energy of carbohydrates; oxygen is released as a byproduct.
 - A. Chloroplasts are organelles bounded by a double membrane; the inner membrane encloses the **stroma** in which membranous, saclike **thylakoids** are suspended. Thylakoids arranged in stacks are called **grana**.
 - B. **Chlorophyll** and other photosynthetic pigments are components of the thylakoid membranes of chloroplasts. Each thylakoid encloses a **thylakoid interior space**.
 - C. The **absorption spectra** of chlorophylls *a* and *b* are very similar to the **action spectrum** for photosynthesis.
 - D. **Photosystems I** and **II** are the two types of photosynthetic units involved in photosynthesis. Each photosynthetic unit includes an antenna complex and a reaction center.
 1. Chlorophyll molecules and accessory pigments are organized into **antenna complexes**.
 2. Only a special chlorophyll *a* in the **reaction center** actually gives up its energized electrons to a nearby electron acceptor.
- IV. During the noncyclic **light-dependent reactions**, known as **noncyclic photophosphorylation**, ATP and NADPH are formed.
 - A. The electrons in Photosystem I are energized by the absorption of light and passed through a chain of electron acceptors to NADP⁺.
 - B. Electrons given up by P700 in Photosystem I are replaced by electrons from P680 in Photosystem II.
 - C. Electrons given up by P680 in Photosystem II are replaced by electrons made available by the **photolysis** of H₂O; oxygen is released in the process.
 - D. A series of redox reactions takes place as energized electrons are passed along a chain of electron acceptors from Photosystem II to Photosystem I. Some of the energy is used to pump protons across the thylakoid membrane, providing the energy to generate ATP by **chemiosmosis**.
- V. During the cyclic light-dependent reactions, known as **cyclic photophosphorylation**, electrons from Photosystem I are eventually returned to Photosystem I.
 - A. ATP is produced by chemiosmosis.
 - B. No NADPH or oxygen is generated.
- VI. During the **carbon fixation reactions**, the energy of ATP and NADPH

is used to manufacture carbohydrate molecules from CO₂.

- A. The carbon fixation reactions proceed by way of the **Calvin cycle**, also known as the **C₃ pathway**.
 1. CO₂ is combined with **ribulose biphosphate (RuBP)**, a five-carbon sugar, by the enzyme **ribulose biphosphate carboxylase (Rubisco)**.
 2. For every six CO₂ molecules fixed, two molecules of **glyceraldehyde-3-phosphate (G3P)** can leave the cycle.
 3. Two G3P molecules are required to produce the equivalent of one molecule of glucose; the remaining G3P molecules are modified to regenerate RuBP.
- B. In the **C₄ pathway**, the enzyme **PEP carboxylase** binds CO₂ effectively, even when CO₂ is at a low concentration.
 1. C₄ reactions take place within mesophyll cells. The CO₂ is fixed in **oxaloacetate**, which is then converted to **malate**.
 2. The malate moves into a **bundle sheath cell**, and CO₂ is removed from it. The released CO₂ then enters the Calvin cycle.
- C. The **crassulacean acid metabolism (CAM)** pathway is similar to the C₄ pathway. PEP carboxylase fixes carbon at night in the mesophyll cells, and the Calvin cycle occurs during the day in the same cells.
- VII. In **photorespiration**, C₃ plants consume oxygen and generate CO₂ but do not produce ATP. Photorespiration, which decreases photosynthetic efficiency, occurs on bright, hot, dry days when plants close their stomata, conserving water but preventing the passage of CO₂ into the leaf.

Summary Equations for Photosynthesis

The light-dependent reactions (noncyclic photophosphorylation):

The carbon fixation reactions (Calvin cycle):

By canceling out the common items on opposite sides of the arrows in these two coupled equations, we obtain the simplified overall equation for photosynthesis:

POST-TEST

- Where is chlorophyll located in the chloroplast? (a) thylakoid membranes (b) stroma (c) mitochondrial matrix (d) thylakoid interior space (e) between the inner and outer membranes
- In photolysis, some of the energy captured by chlorophyll is used to split (a) CO_2 (b) ATP (c) NADPH (d) H_2O (e) both b and c
- Light is composed of particles of energy called (a) carotenoids (b) reaction centers (c) photons (d) antenna complexes (e) photosystems
- The relative effectiveness of different wavelengths of light in photosynthesis is demonstrated by (a) an action spectrum (b) photolysis (c) carbon fixation reactions (d) a photoheterotroph (e) an absorption spectrum
- In plants, the final electron acceptor in the light-dependent reactions is: (a) NADP^+ (b) CO_2 (c) H_2O (d) $\frac{1}{2} \text{O}_2$ (e) G3P
- In addition to chlorophyll, most plants contain accessory photosynthetic pigments such as (a) PEP (b) G3P (c) carotenoids (d) PGA (e) NADP^+
- In _____, electrons that have been energized by light contribute their energy to add phosphate to ADP, producing ATP. (a) crassulacean acid metabolism (b) the Calvin cycle (c) photorespiration (d) C_4 pathways (e) photophosphorylation
- In _____, there is a one-way flow of electrons to NADP^+ , forming NADPH. (a) crassulacean acid metabolism (b) the Calvin cycle (c) photorespiration (d) cyclic photophosphorylation (e) noncyclic photophosphorylation
- The mechanism by which electron transport is coupled to ATP production is called (a) chemiosmosis (b) crassulacean acid metabolism (c) fluorescence (d) the C_3 pathway (e) the C_4 pathway
- In photosynthesis in eukaryotes, the transfer of electrons through a sequence of electron acceptors provides energy to pump protons across the (a) chloroplast outer membrane (b) chloroplast inner membrane (c) thylakoid membrane (d) inner mitochondrial membrane (e) plasma membrane
- The inputs for _____ are CO_2 , NADPH, and ATP. (a) cyclic photophosphorylation (b) the carbon fixation reactions (c) noncyclic photophosphorylation (d) Photosystems I and II (e) chemiosmosis
- The Calvin cycle begins when CO_2 reacts with (a) phosphoenolpyruvate (b) glyceraldehyde-3-phosphate (c) ribulose biphosphate (d) oxaloacetate (e) phosphoglycerate
- The enzyme directly responsible for almost all carbon fixation on Earth is (a) Rubisco (b) PEP carboxylase (c) ATP synthase (d) phosphofructokinase (e) ligase
- In C_4 plants, C_4 and C_3 pathways occur at different _____, whereas in CAM plants, CAM and C_3 pathways occur at different _____. (a) times of day; locations within the leaf (b) seasons; locations within the leaf (c) locations within the leaf; times of day (d) locations within the leaf; seasons (e) times of day; seasons

REVIEW QUESTIONS

- Why does photosynthesis require light energy?
- What is the role of chlorophyll in photosynthesis?
- What is the significance of the fact that the combined absorption spectra of chlorophyll *a* and *b* roughly parallel the action spectrum of photosynthesis? Why do they not coincide exactly?
- How is oxygen produced during photosynthesis?
- In noncyclic photophosphorylation, what molecule becomes phosphorylated? Why is the phosphorylation process referred to as *photophosphorylation*? Why is it said to be noncyclic?
- How are ATP and NADPH produced and used in the process of photosynthesis?
- How are carbohydrates produced from CO_2 in photosynthesis?
- How do the C_4 and CAM pathways improve photosynthesis in hot, dry environments?
- Label the following figure. Use Figure 8–8 to check your answers.

YOU MAKE THE CONNECTION

1. Only some plant cells have chloroplasts, but *all* actively metabolizing plant cells have mitochondria. Why?
2. Explain why the proton gradient formed during chemiosmosis represents a state of low entropy. (You may have to refer to the discussion of entropy in Chapter 6.)
3. The electrons in glucose have relatively high free energies. How did they become so energetic?
4. Rubisco has been described as “the most abundant protein in the world.” Explain how an enzyme, which is used repeatedly and is therefore present in very small amounts in cells, could be the world’s most abundant protein.
5. What strategies might be employed in the future to increase world food supply? Base your answer on your knowledge of photosynthesis and related processes.

Sue Karr is a renal dietitian who works in an outpatient dialysis clinic in Boulder, Colorado. She manages the nutritional care of kidney disease patients who come to the clinic for their dialysis treatments. She attended the University of Colorado at Boulder and received her B.A. in Environmental, Population, and Organismic Biology in 1993. Because she had always wanted to work with people in an area of health care that had a strong scientific basis, she went on to complete a Master's Degree in Nutrition from the University of Minnesota, where she also completed her registered dietitian credential.

Did you know what you wanted to major in when you entered college?

I had no idea. I took enough prerequisites for any degree my first year. Then I decided I wanted to work in health care but I was not quite sure what area. That's when I thought I would major in biology because no matter what health care career route I eventually took, it was a way to get the basic coursework.

At what point did you choose nutrition?

What sparked me most was a nutrition course. Although the University of Colorado did not offer a nutrition program, Colorado did offer one very good introductory nutrition course, which brought together areas that I had been interested in like wellness, fitness, and eating healthy foods. I saw it also as an area where I could work with people within a strong scientific framework.

Renal Dietitian

SUE KARR

I spent some time speaking with the professor of that nutrition course, and with people who work in the community in different areas of nutrition. We had a career center that I used as well. In addition, I did some volunteer work related to health care and nutrition: I was a driver for Meals on Wheels; I volunteered in an assisted living facility helping with some of the nutritional considerations of the elderly; I also had a part-time job at a nursing home.

What is the difference between a dietitian and a nutritionist?

A dietitian is someone who has met the requirements of the American Dietetic Association to be a registered dietitian (R.D.). To become a registered dietitian, one must have at least a Bachelor's Degree and have taken required courses such as human anatomy and physiology, chemistry, clinical nutrition, food science, and food service management, among others. A registered dietitian also must complete a clinical internship, usually six months to a year, under the supervision of registered dietitians in the community. After completing the internship, one is then eligible to take the national credentialing exam for registered dietitians. The term "nutritionist" does not necessarily specify any particular training. I could call myself a nutritionist, but the title "dietitian" is more specific for me.

Do you believe that your biology background helped you get into graduate school?

Absolutely. I came to my graduate program already having a good background in the basic sciences.

How does understanding basic biology concepts such as energy transfer and metabolism help you on a daily basis?

In my practice, one of the most important things I do is to make sure that my clients are at a weight that is appropriate. I have overweight and underweight clients. Understanding what factors influence their energy needs helps me assess what their nutritional needs may be. Also, knowing how the body uses the different energy

components of proteins, carbohydrates, and fats helps me develop an individualized plan for them that has the right nutrient distribution.

How do you calculate the energy needs of your patients?

I calculate the energy needs for my patients based on their activity level, height, and weight. For practical reasons, BMR (basal metabolic rate) calculations are rarely available. I have all my new clients complete a three-day diet record so I can estimate how closely they are meeting their energy and protein needs. I may modify energy intake recommendations to help my clients reach goals for weight loss or weight gain.

What exactly is your job and how long have you been doing it?

Since August 1997 I have been working at an outpatient dialysis clinic, which is for people who have kidney failure. We work with about sixty clients who are on hemodialysis. They come to the clinic three days a week to get a dialysis treatment, which functions as an artificial kidney that removes metabolic wastes, excess ions, and other substances from their blood.

Is there some kind of nutritional problem common to kidney disease?

There are many issues that come up when the kidney is not working because the kidney is an important filter in our body. The kidney rids the body of excess minerals and metabolic waste products, such as the breakdown products of proteins, and controls fluid balance. I look at certain minerals like potassium and phosphorus, which can be problematic if they build up in the body.

What advice would you give to someone who is considering your career?

Talk to as many professionals as possible who are actually in the field. I did talk to a few people, but I had no idea how many different areas of nutrition are available. There are nutritionists who work in private practice, in the community, in industry, and apart from health care. I recommend volunteering, too. Volunteer work is valuable not only for experience in an area to see if it interests you, but also to strengthen any application to a graduate program.

CHAPTER 9

Chromosomes, Mitosis, and Meiosis

Every organism, even the simplest, contains a massive amount of information in the form of DNA. The DNA is organized into informational units called **genes** that ultimately control all aspects of the life of the organism.

A eukaryotic nucleus contains multiple DNA molecules, each of which is packaged with proteins and assembled into a structure called a **chromosome**. This organization, which prevents the tangling of the long, thin molecules, is essential to the highly organized processes by which DNA is distributed during cell division.

All cells are formed by the division of preexisting cells. When a cell divides, the information contained in the DNA first must be precisely duplicated and the copies then transmitted to each daughter cell through a complex series of processes. Most cell divisions in the body cells of eukaryotes involve a process called **mitosis**, which ensures that each daughter cell, such as the human cells in this false-color SEM, receives one copy of every chromosome (and therefore one copy of every gene) from the parent cell.

Prokaryotic cells contain much less DNA, which is usually circular and packaged with very few associated proteins. Although the distribution of genetic material in dividing prokaryotic cells is a simpler process, it nevertheless must be very precise if the daughter cells are to be genetically identical to the parent cell. Bacterial reproduction is described in Chapter 23.

In eukaryotes, sexual reproduction occurs when two sex cells, or **gametes**, fuse to form a single cell called a **zygote**. In higher plants and animals, the gametes are the eggs and sperm. Each gamete contains only half the number of parental chromosomes, thereby preventing the zygotes from having twice as many chromosomes as the parents. For this reason, sexual life cycles include a special type of cell division, called **meiosis**, which reduces the chromosome number by half.

(CNRI/Science Photo Library/Photo Researchers, Inc.)

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Discuss the significance of chromosomes in terms of their information content.
2. Identify the stages in the eukaryotic cell cycle, describe the principal events characteristic of each, and point out some ways in which the cycle is controlled.
3. Illustrate the structure of a duplicated chromosome, labeling the sister chromatids, sister centromeres, and sister kinetochores.
4. Explain the significance of mitosis and diagram the process.
5. Discriminate between asexual and sexual reproduction.
6. Distinguish between haploid and diploid cells and define homologous chromosomes.
7. Explain the significance of meiosis and diagram the process.
8. Contrast mitosis and meiosis, emphasizing how differences in events lead to different outcomes.
9. Compare the roles of mitosis and meiosis and of haploidy and diploidy in various generalized life cycles.

EUKARYOTIC CHROMOSOMES CONTAIN DNA AND PROTEIN

The major carriers of genetic information in eukaryotes are the **chromosomes** contained within the cell nucleus. Although the term *chromosome* means “colored body,” chromosomes are virtually colorless; the name refers to their ability to be stained by certain dyes.

Chromosomes are made up of **chromatin**, a complex material that consists of fibers containing protein and deoxyribonucleic acid (DNA). When a cell is not dividing, the chromosomes are present but in an extended, partially unraveled form. The chromatin consists of long, thin threads that are somewhat aggregated, which gives them a granular appearance when viewed with the electron microscope (see Fig. 4–12). At the time of cell division, the chromatin fibers condense and the chromosomes become visible as distinct structures (Fig. 9–1). The structure of chromatin is described in more detail in Chapter 11.

Figure 9–1 Chromosomes. The human chromosomes shown in this confocal fluorescence LM have been stained with a fluorescent antibody that binds to the centromere regions (yellow). (Courtesy of Oncor, Inc.)

DNA is organized into informational units called genes

Each chromosome may contain hundreds or even thousands of **genes**. For example, humans are thought to have 70,000 to 100,000 genes. The precise number is not known, although scientists are engaged in a massive coordinated effort to make this determination as part of the Human Genome Project (see Chapter 15). As will be evident in succeeding chapters, our concept of the gene has changed considerably since the beginnings of the science of genetics, but our definitions have always centered on the gene as an informational unit. By providing information needed to carry out one or more specific cellular functions, a gene ultimately affects some characteristic of the organism. For example, we speak of genes controlling eye color in humans, wing length in flies, seed color in peas, and so on.

Chromosomes of different species differ in number and informational content

Every individual of a given species has a characteristic number of chromosomes in most nuclei of its body cells. For example, most human body cells have exactly 46 chromosomes.

Humans are not unique in having 46 chromosomes; some other species of animals and plants also have 46, whereas others have different chromosome numbers. A certain species of roundworm has only two chromosomes in each cell, while some crabs have as many as 200 and some ferns have more than 1000. Most animal and plant species have between 10 and 50 chromosomes. Numbers above and below this are uncommon.

Humans are not humans merely because they have 46 chromosomes; in fact, some humans have abnormal karyotypes (chromosome assortments) with more or fewer than 46 (see Chapter 15). The *number* of chromosomes is not what makes each species unique but rather the *information* specified by the genes in the chromosomes.

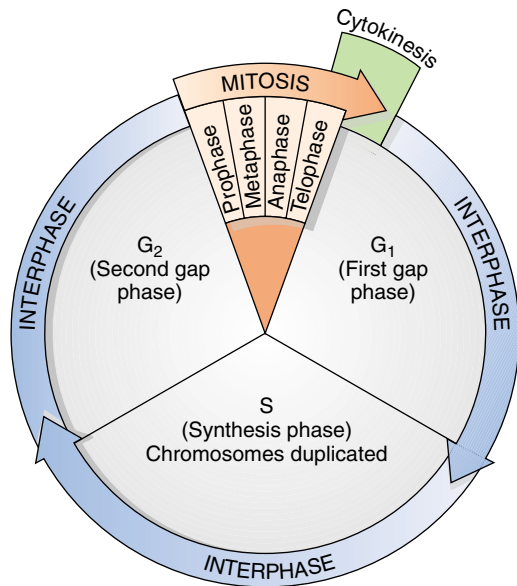

Figure 9–2 The cell cycle. The generation time, the time required to complete one cycle, includes cell division (mitosis and cytokinesis) and interphase. Actual times vary with the species, cell type, and growth conditions.

THE CELL CYCLE IS A SEQUENCE OF CELL GROWTH AND DIVISION

Usually when cells reach a certain size, they must either stop growing or divide. Some cells, such as nerve, skeletal muscle, and red blood cells, do not normally divide once they are mature. The activities of growing and dividing cells can be described in terms of the life cycle of the cell, or the **cell cycle**.

In cells capable of dividing, the cell cycle is the period from the beginning of one division to the beginning of the next and is represented in diagrams as a circle (Fig. 9–2). The time it takes to complete one cell cycle is the **generation time**. The generation time can vary widely, but in actively growing plant and animal cells it is often about 8 to 20 hours.

Cell division involves two main processes, mitosis and cytokinesis. **Mitosis**, a complex process involving the nucleus, ensures that each new nucleus receives the same number and types of chromosomes as were present in the original nucleus. **Cytokinesis**, which generally begins before mitosis is complete, is the division of the cytoplasm of the cell to form two cells. Multinucleate cells are formed if mitosis is not followed by cytokinesis; this is a normal condition for some kinds of cells.

Chromosomes become duplicated during interphase

Most of the life of the cell is spent in **interphase**, the stage between successive cell divisions. The cell is very active during this time, synthesizing needed materials and growing. Most

Figure 9–3 The S phase. The silver grains (black dots) lying on top of the bean chromosomes in this autoradiogram mark locations where the chromosomes incorporated ^3H -labeled thymidine, a DNA precursor, during the S phase of the interphase that preceded mitosis. (Professor J. H. Taylor, *Proceedings of the National Academy of Science*, 43:122,1957, courtesy of New York Academy of Medicine)

proteins and other materials are synthesized throughout interphase. In the early 1950s, researchers demonstrated that the chromosomes are synthesized at a relatively restricted interval during interphase and not during early mitosis, as had been previously thought. They used isotopes such as ^3H , to synthesize radioactive thymidine, a nucleotide (see Chapter 3) that is incorporated specifically into DNA as it is synthesized. After the radioactive thymidine had been supplied for a brief period to actively growing cells, a fraction of the cells could be shown by autoradiography (see Chapter 2) to have silver grains over their nuclei (Fig. 9–3). These labeled cells were those that had been engaged in DNA replication (known as the **synthesis phase**, or **S phase**) during the experiment. The S phase provides the major landmark that is the basis for subdividing interphase, (see Fig. 9–2). Other chromosomal constituents, such as the chromosomal proteins, are also synthesized during the S phase. Chromosome duplication is a complex process discussed in Chapter 11.

The time between mitosis and the beginning of the S phase is termed the **G₁ phase** (G stands for *gap*, an interval during which no DNA synthesis occurs). Growth takes place during the G₁ phase, which is usually the most variable in length and

also the longest. Toward the end of G_1 there is increased activity of enzymes required for DNA synthesis; these enzymes, along with many other factors, make it possible for the cell to enter the S phase. Cells that are not dividing usually become arrested prior to the onset of the S phase. They are said to be in a state called G_0 , which is not part of the cell cycle per se.

After it completes the S phase, the cell enters a second gap phase, the **G_2 phase**. At this time, increased protein synthesis occurs as the final steps in the cell's preparation for division take place. The completion of the G_2 phase is marked by the beginning of mitosis. The sequence of the substages of interphase is therefore:

G_1 phase \rightarrow S phase \rightarrow G_2 phase

Mitosis ensures orderly distribution of chromosomes

Each mitotic division is a continuous process. However, for descriptive purposes mitosis has been divided into stages. Refer to Figure 9–4 as you read the descriptions of these stages as they would occur in a typical plant or animal cell:

Prophase \rightarrow Metaphase \rightarrow Anaphase \rightarrow Telophase

During prophase duplicated chromosomes become visible with the microscope

The first stage of mitosis, **prophase**, begins when the long chromatin threads begin to condense and appear as mitotic chromosomes. This condensation is accomplished mainly by a coiling process in which chromosomes become simultaneously shorter and thicker. The chromatin can then be distributed to the daughter cells without tangling.

When stained with certain dyes and viewed through the light microscope, chromosomes are visible as darkly staining bodies during prophase. Each chromosome has been duplicated during the preceding S phase and consists of a pair of identical units, termed **sister chromatids**. Each chromatid includes a constricted region called the **centromere**. Sister chromatids are tightly associated in the vicinity of their centromeres (Fig. 9–5). Although the chemical basis for this close association is not completely understood, evidence suggests that special DNA sequences and special proteins that bind to those DNA sequences are involved. Attached to each centromere is a **kinetochore**, a structure formed from proteins to which microtubules can bind.

A dividing cell is usually described as a globe, with an equator that determines the midplane, or equatorial plane, and two opposite poles. This terminology is used for all cells regardless of their actual shape.

Microtubules radiate from each pole and some of these protein fibers elongate toward the chromosomes, forming a complex structure known as the **mitotic spindle** (Fig. 9–6).

The mitotic spindle is responsible for the separation of the chromosomes during anaphase.

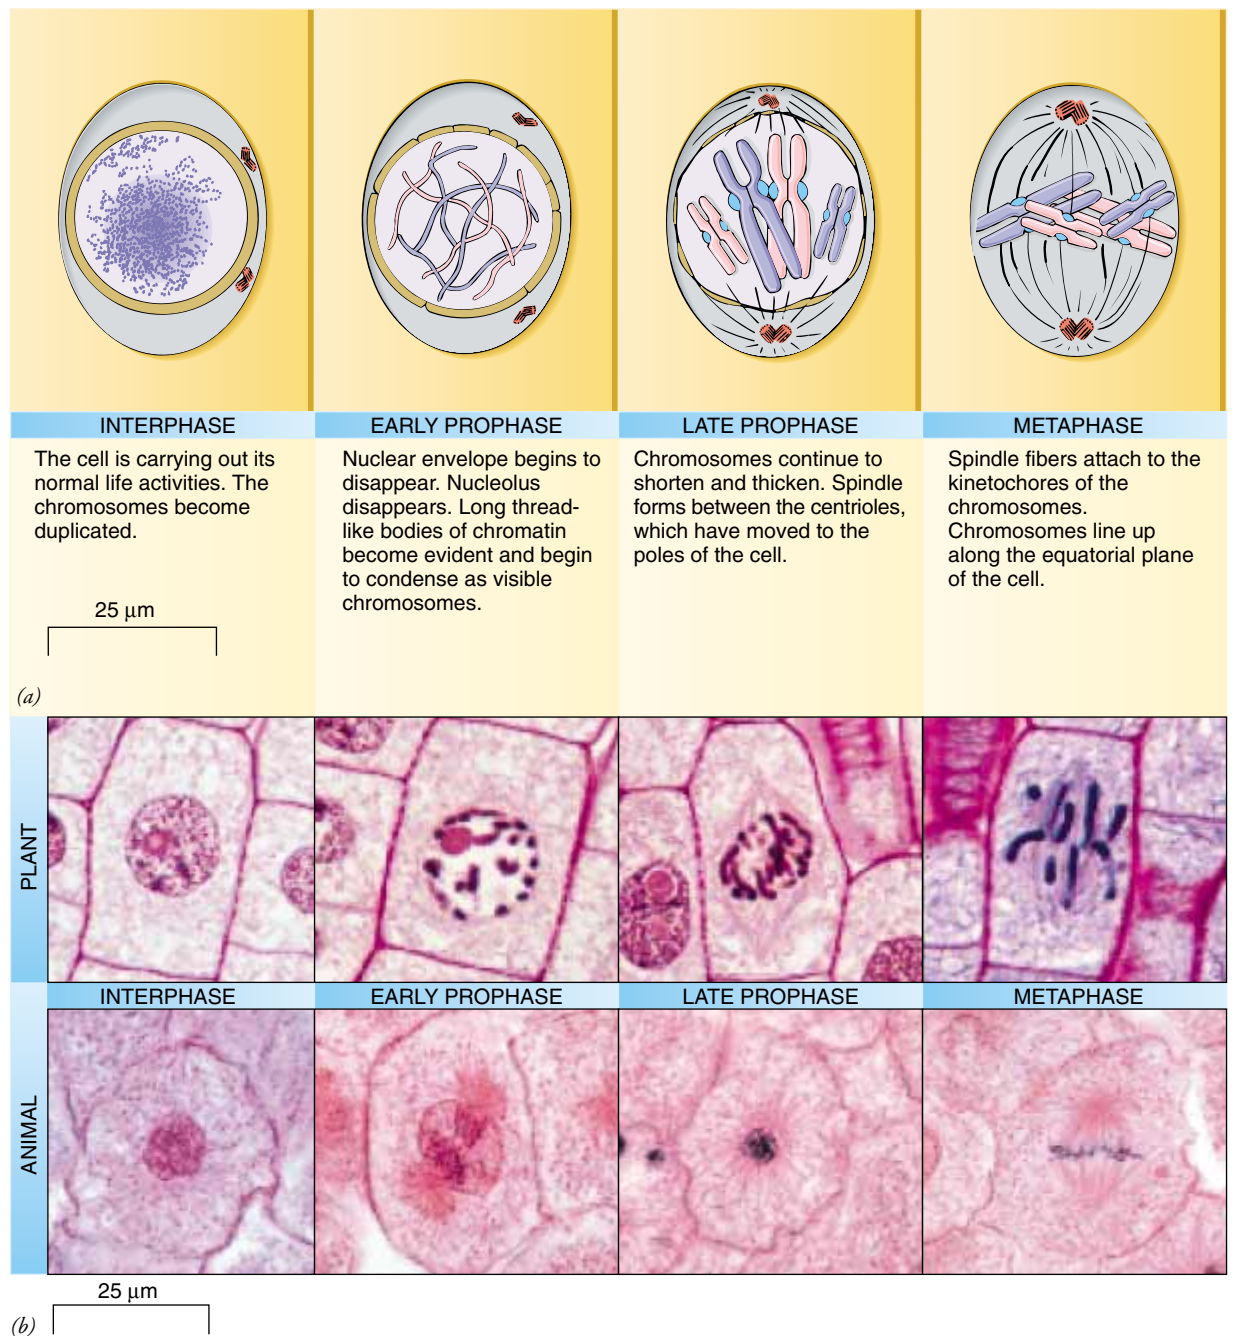

Animal cells differ from the cells of complex plants in the details of mitotic spindle formation. In both types of dividing cells, each pole contains a region, referred to as a **microtubule-organizing center**, from which the microtubules grow outward. When viewed with the electron microscope, microtubule-organizing centers in the cells of higher plants consist of rather dense fibrillar matter with little or no discernible structure.

In contrast, animal cells have a pair of **centrioles** (see Chapter 4) in the middle of each microtubule-organizing center. The centrioles are surrounded by fibrils that make up the **pericentriolar material**. The ends of the spindle microtubules are found in the pericentriolar material, but they do not actually touch the centrioles themselves. Evidence that the pericentriolar material may be functionally similar to the material in the microtubule organizing centers of plants derives from the fact that they are similar in appearance and in the specific types of proteins present.

Each of the two centrioles becomes duplicated during interphase, yielding two pairs of centrioles. Late in prophase, microtubules radiate from the pericentriolar material surrounding the centrioles, and one pair of centrioles migrates to each pole. The migration of the centrioles to the poles essentially marks the migration of the microtubule organizing centers. Additional microtubules form clusters extending outward in many directions from the microtubule organizing centers at the poles; these structures are called **asters** (Fig. 9–6). The function of the asters is not well understood, although there is evidence that these structures play a role in cytokinesis.

It is likely that both plant and animal spindles are organized by similar microtubule organizing centers. Although centrioles were long thought to be required for spindle formation in animal cells, their apparent involvement is probably coincidental. Because centrioles usually arise in association with preexisting centrioles, the localization of the centrioles in the microtubule organizing center may have evolved to provide for the orderly distribution of these organelles to the daughter cells. Centrioles are important to animal cells because they are involved in the formation of the basal bodies of cilia and flagella (see Chapter 4). (New basal bodies can also form if preexisting basal bodies are present, as in the cells of some protists.) Centrioles are not found in the cells of flowering plants and more advanced gymnosperms. Both of these groups lack flagellated sperm and other flagellated or ciliated cells (see Chapter 27). On the other hand, the sperm cells of mosses and ferns (see Chapter 26) are flagellated and possess centrioles.

During prophase, the nucleolus (see Chapter 4) diminishes in size and usually disappears. Toward the end of prophase, the nuclear envelope breaks down, and each chromatid becomes attached to some of the spindle microtubules at its kinetochore. The chromosomes then move back and forth from pole to pole and finally become aligned along the equatorial plane of the cell, midway between the two poles.

At metaphase duplicated chromosomes line up on the midplane

The period during which the chromosomes are lined up along the equatorial plane of the cell constitutes **metaphase**. The mitotic spindle is complete. It is composed of two types of microtubules: **polar microtubules** extend from each pole to the

equatorial region, where they generally overlap. **Kinetochores** **microtubules** extend from each pole and attach to the kinetochores of the chromosomes (see Fig. 9–6). At mitotic metaphase the individual sister kinetochores are attached by kinetochores microtubules to *opposite* poles of the cell.

During metaphase each chromatid is completely condensed and appears quite thick and distinct. Because individ-

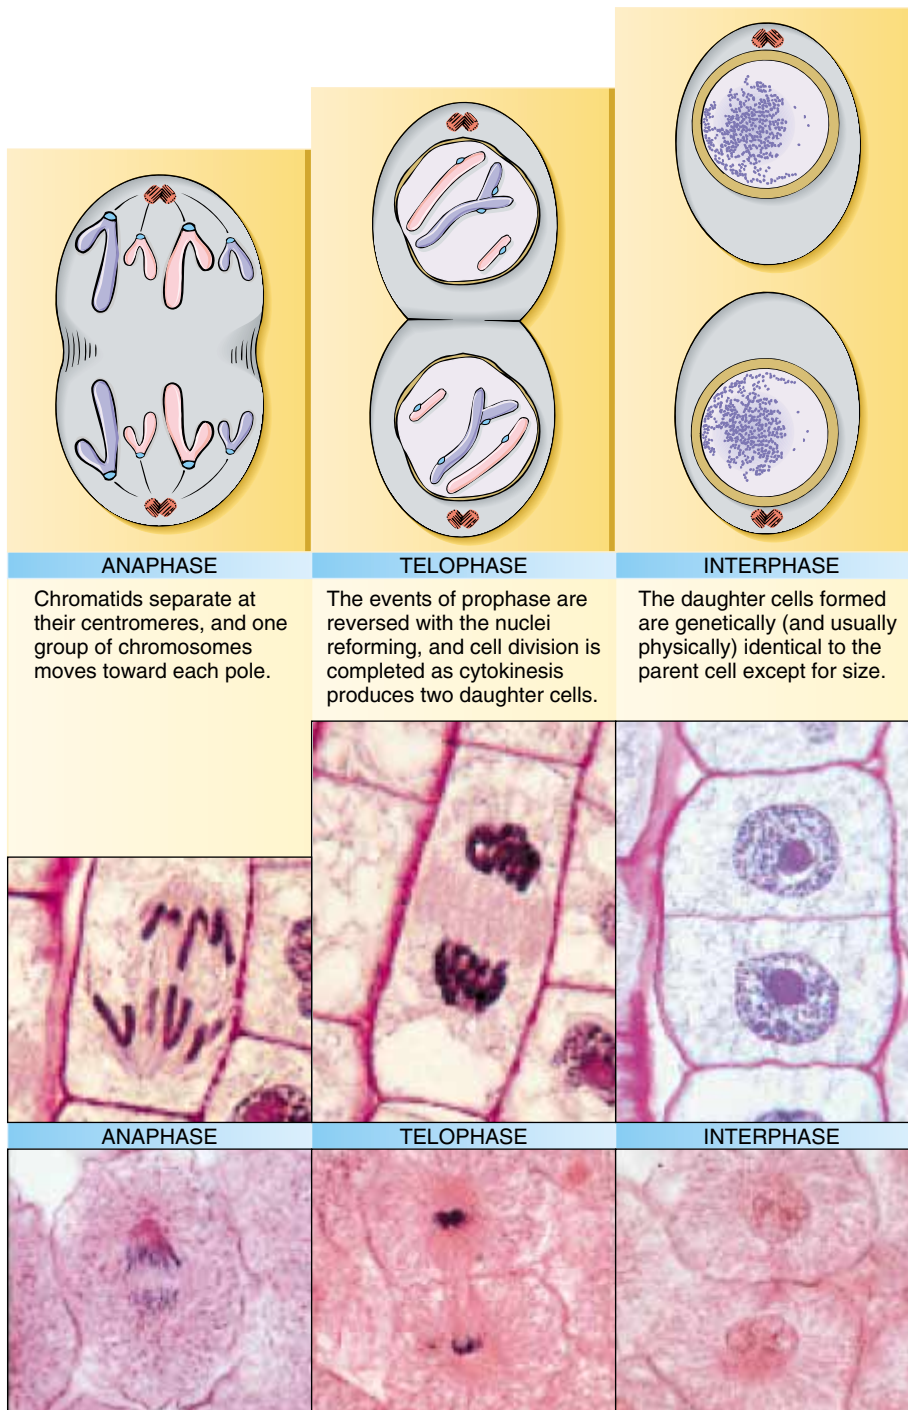

Figure 9-4 Cell division. Interphase and the stages of mitosis are similar in plant and animal cells. Although both types have microtubule organizing centers, the plant cells lack centrioles. (a) The drawings depict generalized animal cells with a diploid chromosome number of four. The sizes of the nuclei and chromosomes are exaggerated to show the structures more clearly. (b) The upper row of LMs depicts stained chromosomes in sectioned cells of the onion, *Allium cepa*. Cells of an animal (the whitefish) are shown in the lower row. The chromosomes have been stained and the cells flattened on microscope slides. (Plant cells, 1st interphase through telophase, Ed Reschke; 2nd interphase, Carolina Biological Supply Company/Phototake. Animal cells, Michael Abbey/Science Source/Photo Researchers, Inc.)

ual chromosomes can be seen more distinctly at metaphase than at any other time, they are usually photographed at this stage to be studied for certain chromosome abnormalities (see Chapter 15).

During anaphase chromosomes move toward the poles

Anaphase begins as the protein tethers holding the sister chromatids together in the vicinity of their centromeres are released.

Each chromatid is now referred to as an independent chromosome. The now separate chromosomes slowly move to opposite poles. The kinetochores of the chromosomes, still attached to kinetochore microtubules, lead the way, with the chromosome arms trailing behind. Anaphase ends when all the chromosomes have reached the poles.

The overall mechanism of chromosome movement in anaphase is still poorly understood, although significant progress is being made in this area. Microtubules lack elastic or contractile properties. So how do the chromosomes move

Figure 9-5 A metaphase chromosome. An SEM (*bottom*) is paired with an interpretive drawing. The sister chromatids, each consisting of tightly coiled chromatin fibers, are tightly associated at their centromere regions, indicated by the brace. Associated with each centromere is a structure known as a kinetochore, which serves as a microtubule attachment site. The kinetochores and microtubules are not evident in the SEM. (E.J. DuPraw)

apart? Are they pushed or pulled, or do other forces operate?

Chromosome movements are studied in a variety of ways. Numbers of microtubules present at a particular stage or after certain treatments can be determined through careful analysis of electron micrographs. It is possible to physically perturb living cells that are dividing, using laser beams or mechanical devices known as micromanipulators. Skilled researchers can move chromosomes, break their connections to microtubules, and even remove them from the cell entirely.

There is a considerable body of evidence that kinetochore microtubules shorten during anaphase. Because microtubules are constantly changing structures, with tubulin subunits being constantly removed and others being added, many current hypotheses to explain anaphase movement are based on suggestions that chromosomes move poleward as tubulin subunits disassemble from the ends of the microtubules. One suggestion has been that kinetochore microtubules are disassembled

Figure 9-6 The mitotic spindle. Kinetochore microtubules and polar microtubules are found in both plant and animal cells, whereas most plant cells lack centrioles and astral microtubules. (a) One end of each microtubule of this animal cell is associated with one of the poles. Astral microtubules (*green*) radiate in all directions, forming the aster. Kinetochore microtubules (*red*) connect the kinetochores to the poles, and polar microtubules (*blue*) overlap at the midplane. (b) Fluorescent-stained LM of animal cell at metaphase with well defined spindle and asters (chromosomes *orange*, microtubules *green*). (b, CNRI/Phototake, NYC).

at the kinetochores themselves, implying that chromosomes play an active role in their own movements. However, this idea is not supported by recent findings. It has been shown that if all the chromosomes are removed from a living cell after the spindle has formed, the kinetochore microtubules shorten just as they would if the chromosomes were present. One possible interpretation is that microtubule shortening takes place at the poles and that the chromosomes are transported passively.

A second phenomenon also plays a role in chromosome separation. During anaphase the spindle as a whole elongates, at least partly because polar microtubules originating at opposite poles are associated with motors that enable them to slide past one another at the equator, decreasing the degree to which they are overlapped and thereby “pushing” the poles apart. This mechanism indirectly causes the chromosomes to move apart because they are attached to the poles.

During telophase two separate nuclei are formed

The final stage of mitosis, telophase, is characterized by a return to interphase-like conditions. The chromosomes decondense by uncoiling. A new nuclear envelope forms around each set of chromosomes, made at least in part from small vesicles and other components derived from the old nuclear envelope. The spindle microtubules disappear, and the nucleoli reorganize.

Cytokinesis is the formation of two separate daughter cells

Cytokinesis, the division of the cytoplasm to yield two daughter cells, usually overlaps mitosis, generally beginning during telophase. Cytokinesis of an animal cell begins as a ring of actin microfilaments forms at right angles to the spindle, encircling the cell in the equatorial region (Fig. 9–7*a*). The ring contracts, producing a furrow that gradually deepens and separates the cytoplasm into two daughter cells, each with a complete nucleus.

In plant cells, cytokinesis occurs by the formation of a **cell plate** (Fig. 9–7*b*), a partition constructed in the equatorial region of the spindle and growing laterally to the cell wall. The cell plate forms as a line of vesicles that originate in the Golgi complex (see Chapter 4). The vesicles contain materials to construct both a primary cell wall for each daughter cell and a middle lamella that will cement the primary cell walls together. The vesicle membranes fuse to become the plasma membrane of each daughter cell.

Mitosis typically produces two cells genetically identical to the parent cell

The remarkable regularity of the process of cell division ensures that each of the daughter nuclei receives exactly the same number and kinds of chromosomes that the parent cell had. Thus, with a few exceptions, every cell of a multicellular organism has exactly the same genetic makeup. If a cell receives

more or fewer than the characteristic number of chromosomes through some malfunction of the cell division process, the resulting cell may show marked abnormalities and be unable to survive.

Most cytoplasmic organelles are distributed randomly to the daughter cells

Mitosis provides for the orderly distribution of chromosomes (and of centrioles, if present), but what about the various cytoplasmic organelles? For example, all eukaryotic cells, including plant cells, require mitochondria. Likewise, photosynthetic plant cells cannot carry out photosynthesis without chloroplasts. These organelles contain their own DNA and appear to form by the division of previously existing mitochondria or plastids or their precursors. However, they generally divide during interphase, not when the cell divides. Because many copies of each organelle are present in each cell, organelles are apportioned more or less equally between the daughter cells at cytokinesis.

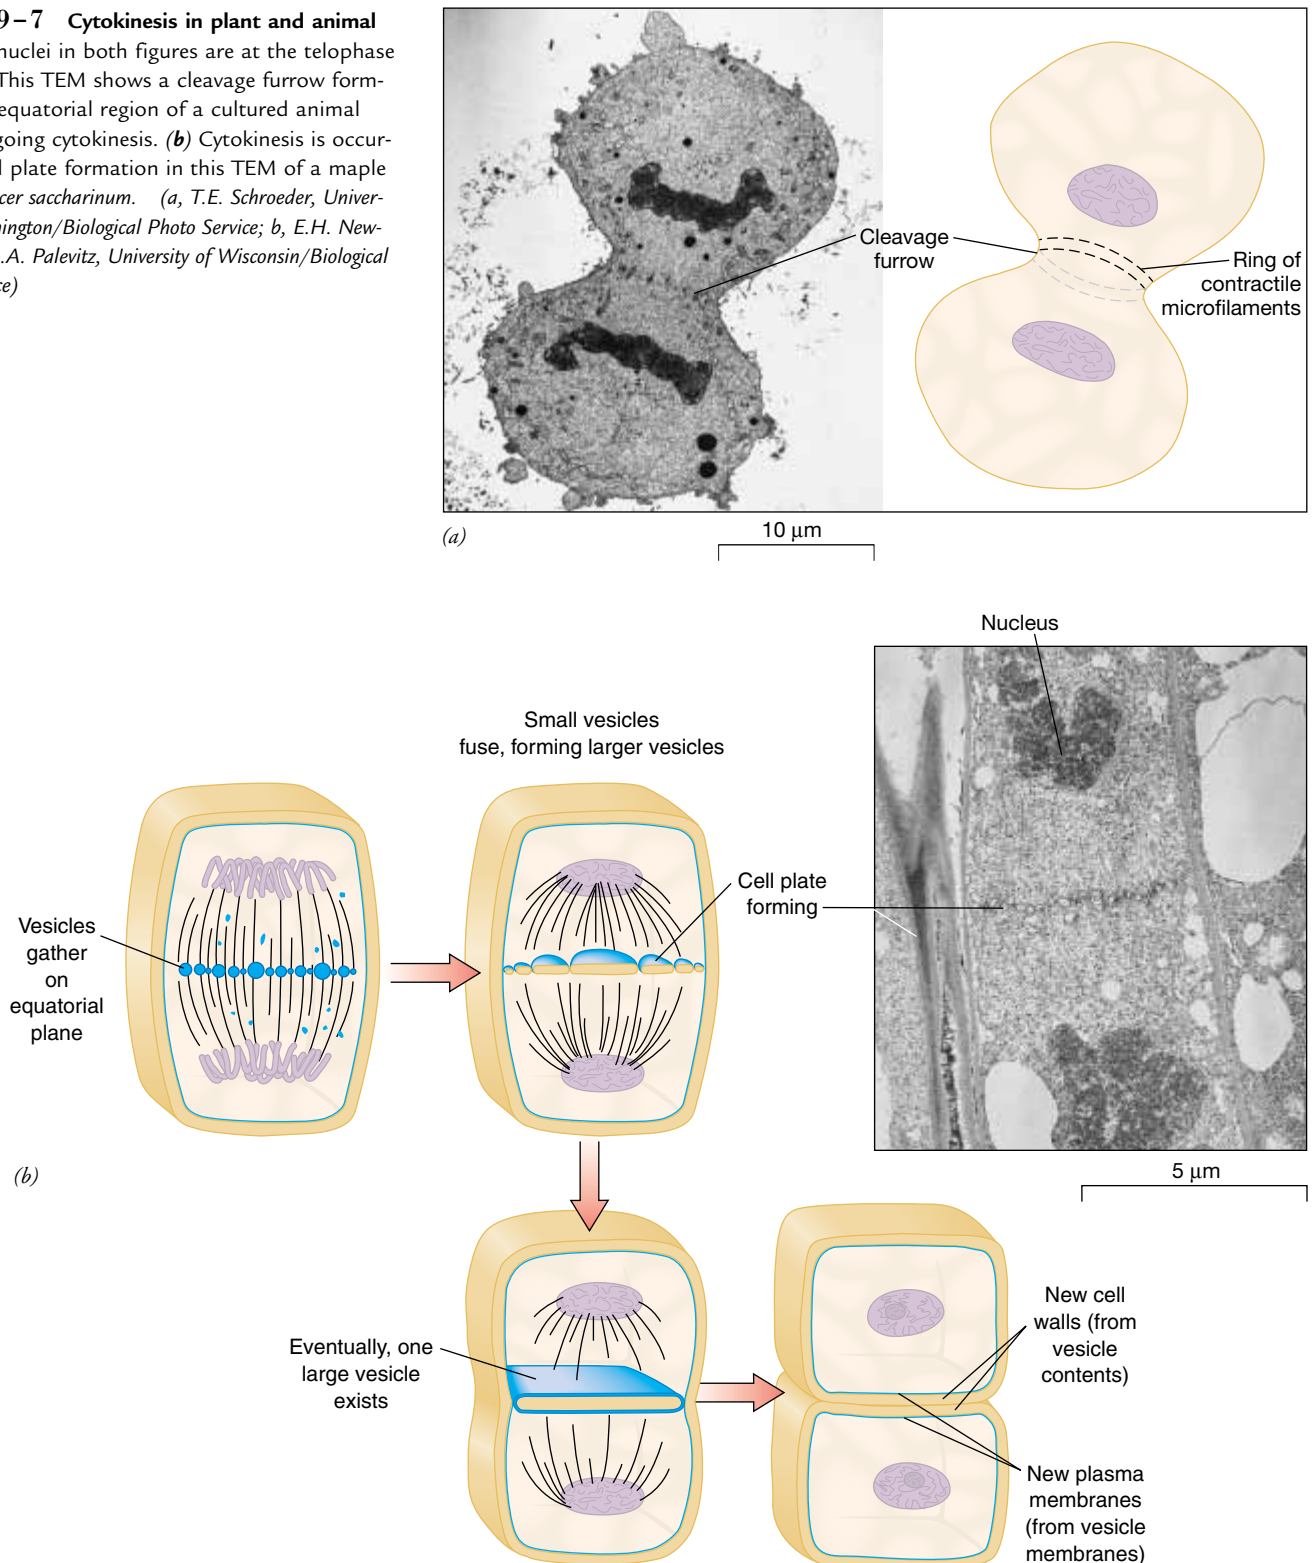

The cell cycle is controlled by an internal genetic program interacting with external signals

When conditions are optimal, some prokaryotic cells (which divide nonmitotically; see Chapter 23) can divide every 20 minutes. The generation times of eukaryotic cells are generally much longer, although the frequency of cell division varies widely among different species and among different tissues of the same species. Some cells in the central nervous system usually cease dividing after the first few months of life, whereas blood-forming cells, digestive tract cells, and skin cells divide frequently throughout the life of the organism. Under optimal conditions of nutrition, temperature, and pH, the eukaryotic cell cycle length is constant for any cell type. Under less favorable conditions, however, the generation time may be longer.

According to a considerable body of evidence that has accumulated in recent years, certain fundamental mechanisms of genetic control of the cell cycle are common to all eukaryotes. Among the key components of the regulatory system are **protein kinases**, enzymes that activate or inactivate other proteins by adding phosphate groups (phosphorylation). The particular protein kinases involved in controlling the cell cycle are called cyclin-dependent protein kinases because they are only active when complexed with regulatory proteins called **cyclins**. The cyclins are so-named because their levels fluctuate predictably during the cell cycle (i.e., they “cycle”).

When a specific cyclin-dependent protein kinase (Cdk) forms a complex with a specific cyclin, it actively phosphorylates certain cellular proteins. Some of these proteins, including certain enzymes, become activated when they are phosphorylated. Conversely, phosphorylation inactivates some other enzymes and proteins. As some enzymes are activated and others are inactivated by phosphorylation, the activities of

Figure 9–7 Cytokinesis in plant and animal cells. The nuclei in both figures are at the telophase stage. **(a)** This TEM shows a cleavage furrow forming in the equatorial region of a cultured animal cell undergoing cytokinesis. **(b)** Cytokinesis is occurring by cell plate formation in this TEM of a maple leaf cell, *Acer saccharinum*. (a, T.E. Schroeder, University of Washington/Biological Photo Service; b, E.H. Newcomb and B.A. Palevitz, University of Wisconsin/Biological Photo Service)

the cell (as they relate to the steps of the cell cycle) change (Fig. 9–8). Although not all of the details are understood, these systems of regulating the cell cycle have been highly conserved during the evolution of eukaryotes; they are found in organ-

isms as diverse as yeast (a unicellular fungus), clams, frogs, and plants.

Certain drugs can stop the cell cycle. Some of these prevent DNA synthesis, whereas others inhibit the synthesis of

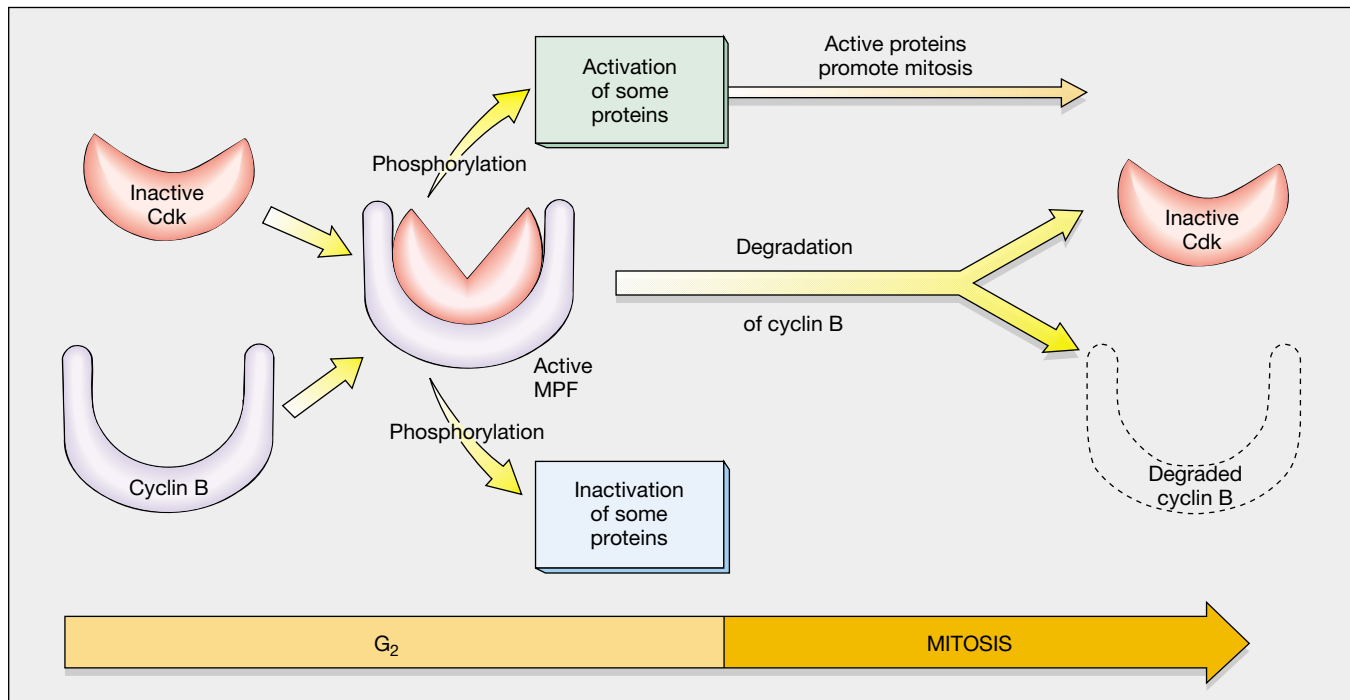

Figure 9–8 Genetic control of the cell cycle. In this example, *mitosis-promoting factor (MPF)* is required for the cell to make the transition from G₂ to mitosis. Active MPF is produced when an inactive cyclin-dependent protein kinase enzyme (Cdk) becomes complexed with cyclin B. MPF then phosphorylates many proteins, thereby activating those needed for mitosis and inactivating those that would impede mitosis. Later in mitosis, MPF becomes inactive as cyclin B is degraded. These events are repeated when cyclin B levels rise again in G₂ of the next cell cycle.

proteins that control the cycle, as well as the synthesis of structural proteins that contribute to the mitotic spindle. Because cancer cells often divide much more rapidly than most normal body cells, they can be most affected by these drugs. Many of the side effects of certain anticancer drugs (e.g., nausea, hair loss) are due to the drugs' effects on rapidly dividing cells in the digestive system, hair follicles, and so forth.

Colchicine, a drug used to block cell division in eukaryotic cells, binds with unpolymerized tubulin subunits, preventing them from being added to the spindle microtubules. Under these conditions, the rate of microtubule breakdown far exceeds the rate of microtubule assembly, resulting in the disappearance of the spindle. Although the sister chromatids eventually become detached from one another and each becomes a chromosome, they cannot move to the poles in the absence of the spindle. As a result, a cell may end up with extra sets of chromosomes (a condition known as **polyploidy**, which is discussed in the next section).

In plant cells, certain hormones are known to stimulate mitosis. These include the **cytokinins**, a group of plant hormones that promote mitosis both in normal growth and in wound healing (see Chapter 36).

Protein **growth factors**, which are active at extremely low concentrations, stimulate mitosis in certain animal cells. Of the approximately 50 protein growth factors known, some act

only on specific cell classes, while others work over a broader range. For example, the effects of erythropoietin are limited to cells that will develop into red blood cells, whereas epidermal growth factor stimulates many cell types to divide. In addition, hormones such as certain steroid hormones can act as growth factors (see Chapter 47).

SEXUAL LIFE CYCLES REQUIRE A MECHANISM TO REDUCE THE CHROMOSOME NUMBER

Although the details of the reproductive process vary greatly among different kinds of eukaryotes, we can distinguish two basic types of reproduction: asexual and sexual. In **asexual reproduction** a single parent usually splits, buds, or fragments to produce two or more individuals (Fig. 9–9). In most forms of asexual reproduction, all the cells are produced by mitosis, so their genes and inherited traits are identical to those of the parent. Such a group of genetically identical organisms is termed a **clone**. Asexual reproduction is usually a rapid process; it permits organisms well adapted to their environment to produce new generations of similarly adapted organisms.

Figure 9-9 Binary fission. This cell of *Paramecium caudatum*, a ciliate protozoan, is reproducing asexually by binary fission. Binary fission in *Paramecium* includes mitosis. (M. Abbey/Photo Researchers, Inc.)

In contrast, **sexual reproduction** involves the union of two specialized sex cells, or **gametes**, to form a single cell called a **zygote**. Usually the gametes are contributed by two different parents, but in some cases a single parent furnishes both gametes. In the case of animals and plants, the egg and the sperm cells are the gametes, and the fertilized egg is the zygote. Offspring produced sexually are not genetically identical to their parents, so some may be able to survive environmental changes or other stresses better than either parent, whereas others, with a different combination of traits, may be less likely to survive.

Because you now understand the roles of chromosomes in inheritance, you may recognize a problem in eukaryotic sexual reproduction: if each gamete has the same number of chromosomes as did the parental cell that produced it, then the zygote would be expected to have twice as many chromosomes. This doubling would occur generation after generation. How do organisms avoid producing zygotes with ever-increasing chromosome numbers? To answer this question, we need more information about the types of chromosomes found in cells.

Each chromosome found in a somatic (body) cell of a higher plant or animal normally has a partner chromosome. The two partners, known as **homologous chromosomes**, are similar in size, shape, and the position of their centromeres. When stained by special techniques, the members of a pair generally share a characteristic pattern of bands. In most species, chromosomes vary enough in their morphological features that cytologists can distinguish the different homologous pairs and match up the partners. The 46 chromosomes in human cells constitute 23 different homologous pairs (Fig. 9-10). The most important feature of homologous chromosomes is that they carry similar, but not necessarily identical, genetic information. For example, members of a pair of homologous chromosomes might each carry a gene that specifies hemoglo-

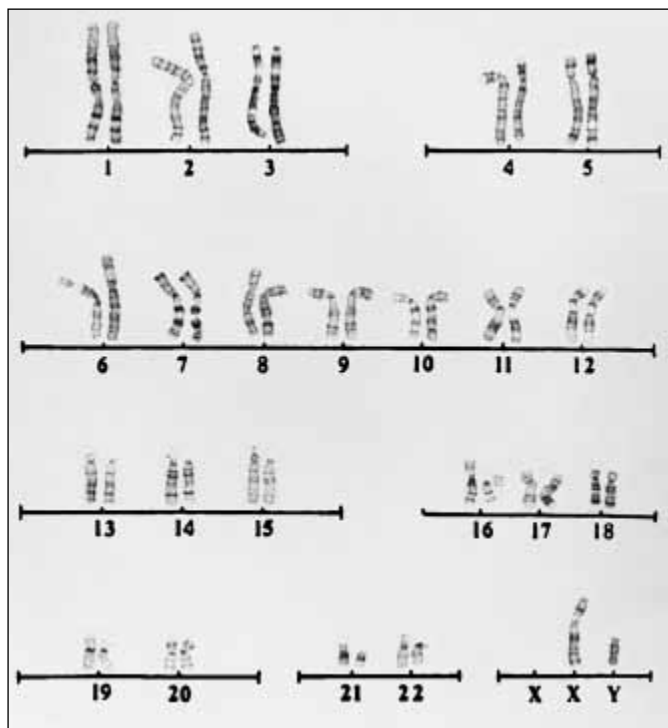

Figure 9-10 A human karyotype. Although these are duplicated chromosomes (late prophase), the sister chromatids are not clearly evident because they are closely aligned throughout their lengths. As discussed in Chapter 10, the X and Y chromosomes of this normal male are not strictly homologous; normal females have two X chromosomes and no Y chromosome. The process of karyotyping is discussed in Chapter 15. (Courtesy of Dr. Leonard Sciorra)

bin structure; however, one member might have the information for normal hemoglobin, whereas the other might specify the abnormal form of hemoglobin associated with sickle cell anemia (see Chapter 15). Homologous chromosomes can therefore be contrasted with the two members of a pair of sister chromatids, which are precisely identical to each other.

A **set** of chromosomes has one of each kind of chromosome; in other words, it contains one member of each homologous pair. If a cell or nucleus contains two sets of chromosomes, it is said to have a **diploid** chromosome number. If it has only a single set of chromosomes, it has the **haploid** number. In humans the diploid chromosome number is 46 and the haploid number is 23. When a sperm and egg fuse at fertilization, each gamete is haploid, contributing one set of chromosomes; the diploid number is thereby restored in the fertilized egg (zygote). When the zygote divides by mitosis to form the first two cells of the embryo, each daughter cell receives the diploid number of chromosomes, and this is repeated in subsequent mitotic divisions. Thus, most human body cells are diploid.

If a cell or an individual has three or more sets of chromosomes, we say that it is **polyploid**. Polyploidy is relatively rare among animals but quite common among plants (see

Figure 9–11 Polyploidy. Modern bread wheat is a hexaploid plant. (Sharon Cummings/Dembinsky Photo Associates)

Chapter 19). In fact, polyploidy has been an important factor in plant evolution. As many as 80% of all flowering plants are polyploid. Polyploid plants are often larger and hardier than diploid members of the same group. Many commercially important plants are polyploid. Modern bread wheat, *Triticum aestivum* (Fig. 9–11), is a hexaploid with 42 chromosomes, derived from three different diploid species with 14 chromosomes each.

The abbreviation for the chromosome number found in the gametes of a particular species is n , and the zygotic chromosome number is given as $2n$. If the organism is not polyploid, the haploid chromosome number is equal to n and the diploid number is equal to $2n$. For example, in humans $n = 23$ and $2n = 46$. For simplicity, in the rest of this chapter we assume that the organisms used as examples are not polyploid. We therefore use the designations diploid and $2n$, and haploid and n , interchangeably, although these terms are not strictly synonymous.

DIPLOID CELLS UNDERGO MEIOSIS TO FORM HAPLOID CELLS

We have examined the process of mitosis, which ensures that each daughter cell receives exactly the same number and kinds of chromosomes that the parent cell had. A diploid cell that undergoes mitosis produces two diploid cells; similarly a mitotic haploid cell produces two haploid cells. A division resulting in a reduction in chromosome number is called **meiosis**. The term *meiosis* means “to make smaller,” referring to the fact that the chromosome number is reduced by one-half. In meiosis a diploid cell undergoes two cell divisions, potentially yielding four haploid cells.

The position of meiosis in the life cycle varies among groups

Because sexual reproduction is characterized by the fusion of two haploid sex cells to form a diploid zygote, it follows that, in a sexual life cycle, meiosis must occur before gametes can be produced.

In animals and a few other organisms meiosis leads directly to gamete formation (Figure 9–12*a*). The body (somatic) cells of an individual organism multiply by mitosis and are diploid; the only haploid cells produced are the gametes. These are formed when certain **germ line** cells undergo meiosis. The formation of gametes is known as **gametogenesis**. Male gametogenesis, termed **spermatogenesis**, results in the formation of four haploid sperm cells for each cell that enters meiosis.

In contrast, female gametogenesis, termed **oogenesis**, results in the formation of a single egg cell, or **ovum**, for every cell that enters meiosis. This is accomplished by a process that apportions virtually all of the cytoplasm to only one of the two nuclei at each of the meiotic divisions. At the end of the first meiotic division, one nucleus is retained and the other, called the first **polar body**, is excluded from the cell and ultimately degenerates. Similarly, at the end of the second division, one nucleus becomes the second polar body and the other nucleus survives. In this way, one haploid nucleus becomes the recipient of most of the accumulated cytoplasm and nutrients from the original meiotic cell. (See Figure 48–13 for a more detailed description.)

However, although meiosis occurs at some point in a sexual life cycle, it does not always *immediately* precede gamete formation. Many simple eukaryotes (including some fungi and algae) remain haploid (their cells dividing mitotically) throughout most of their lives, with individuals being unicellular or multicellular. Two haploid gametes (produced by mitosis) fuse to produce a diploid zygote that undergoes meiosis to restore the haploid state (Figure 9–12*b*). Examples of these types of life cycles can be found in Chapters 24 and 25.

The most complex life cycles are displayed by plants and some algae (Figure 9–12*c*). These life cycles, characterized by an **alternation of generations**, consist of a multicellular diploid stage, termed the **sporophyte generation**, and a mul-

Figure 9-12 Representative life cycles.

ticellular haploid stage, termed the **gametophyte generation**. Diploid sporophyte cells undergo meiosis to form haploid spores, each of which then divides mitotically to produce a multicellular haploid gametophyte. Gametophytes produce gametes by mitosis. The female and male gametes (eggs and sperm cells) then fuse to form a diploid zygote that divides mitotically to produce a multicellular, diploid sporophyte.

In higher plants, including flowering plants, the diploid sporophyte—which includes the roots, stems, and leaves of the plant body—is the dominant form. The gametophytes are small and inconspicuous. For example, a pollen grain contains a haploid male gametophyte that forms haploid sperm by mitosis. More detailed descriptions of alternation of generations can be found in Chapters 26 and 27.

Figure 9-13 **Meiosis.** Two nuclear divisions, meiosis I and meiosis II, are required. In this illustration, the process begins with a cell that has a diploid chromosome number of four and ends with the formation of four haploid cells with two chromosomes each. The maternal chromosomes are shown in pink; the paternal chromosomes are purple.

Meiosis produces haploid cells with unique gene combinations

The events of meiosis are similar to the events of mitosis, with four important differences: (1) Meiosis involves two successive nuclear and cytoplasmic divisions, producing up to four cells. (2) Despite two successive nuclear divisions, the DNA and other chromosomal components are duplicated only once, during the interphase preceding the first meiotic division. (3) Each of the four cells produced by meiosis contains the haploid chromosome number, that is, only one set with only one representative of each homologous pair. (4) During meiosis, the genetic information from both parents is shuffled, so each resulting haploid cell has a virtually unique combination of genes.

In meiosis homologous chromosomes become distributed into different daughter cells

Meiosis typically consists of two nuclear and cytoplasmic divisions, designated the *first* and *second meiotic divisions*, or simply **meiosis I** and **meiosis II**. Each includes prophase,

metaphase, anaphase, and telophase stages. During meiosis I, the members of each homologous pair of chromosomes first join together and then separate and move into different nuclei. In meiosis II the sister chromatids that make up each chromosome separate and are distributed to the nuclei of the daughter cells. The following discussion describes meiosis in an animal with a diploid chromosome number of four. Refer to Figures 9–13 and 9–14 as you read.

Prophase I includes synapsis and crossing-over

As in mitosis, the chromosomes are duplicated during the S phase of interphase, before meiosis actually begins. Each duplicated chromosome consists of two chromatids. During *prophase I*, while the chromatids are still elongated and thin, the homologous chromosomes come to lie lengthwise side by side. This process is called **synapsis**, which means “fastening together.” In our example, because the diploid number is four, there are two homologous pairs.

It is customary when discussing higher organisms to refer to one member of each homologous pair as a **maternal homologue** because it was originally inherited from the female parent, and to the other as a **paternal homologue** because it

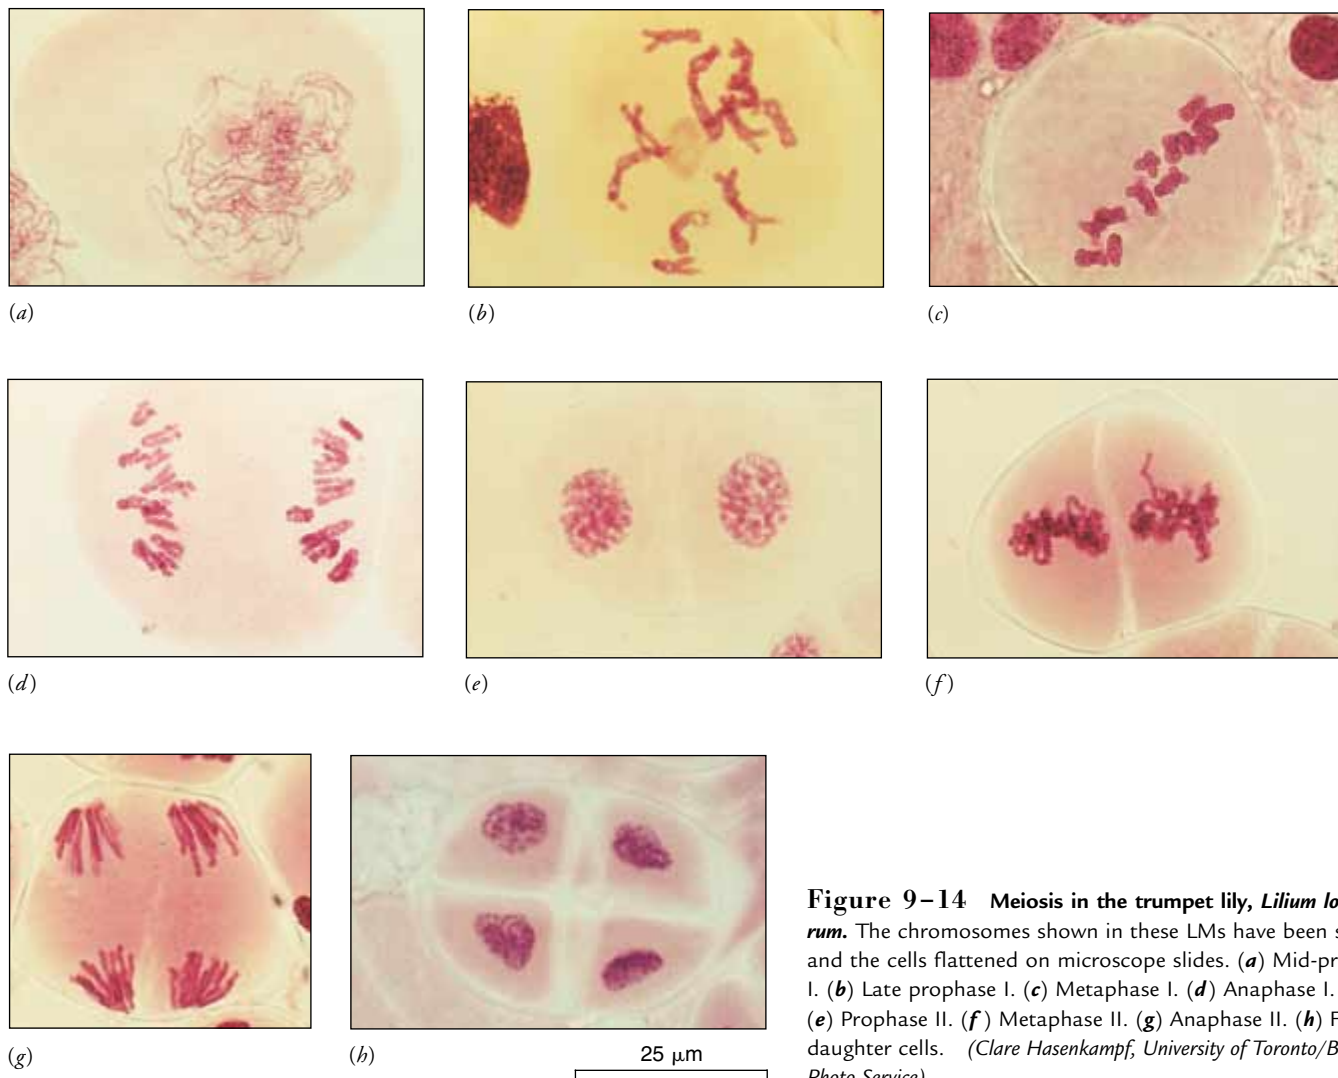

Figure 9–14 Meiosis in the trumpet lily, *Lilium longiflorum*. The chromosomes shown in these LMs have been stained and the cells flattened on microscope slides. (a) Mid-prophase I. (b) Late prophase I. (c) Metaphase I. (d) Anaphase I. (e) Prophase II. (f) Metaphase II. (g) Anaphase II. (h) Four daughter cells. (Clare Hasenkampf, University of Toronto/Biological Photo Service)

was contributed by the male parent during the formation of the zygote. Because each chromosome was duplicated during the premeiotic interphase and now consists of two chromatids, synapsis results in the association of *four* chromatids. The resulting complex is known as a **bivalent** or a **tetrad**. The term bivalent, in which the prefix *bi-* refers to the two homologous chromosomes, is commonly used by cytogeneticists (scientists who study inheritance at the cellular level, particularly through the analysis of chromosomes). The term tetrad (*tetra* means “four”) is preferred by some geneticists interested in following the fates of the four chromatids. We will use tetrad in further discussions.

The number of tetrads per prophase I cell is equal to the haploid chromosome number. In our example there are two tetrads; in a human cell at prophase I there are 23 tetrads (and a total of 92 chromatids).

Homologous chromosomes become closely associated during synapsis. Electron microscopic observations reveal that a characteristic structure, known as the **synaptonemal complex**, forms between the synapsed homologues (Fig. 9–15). This structure holds the synapsed homologues together and is

thought to play a role in **crossing-over**, a process in which genetic material is exchanged between homologous (nonsister) chromatids. In crossing-over, enzymes break homologous chromatids and then join them to produce new combinations of genes. The resulting **genetic recombination** greatly enhances the amount of genetic variation among sexually produced offspring. This process is discussed in more detail in Chapter 10.

In many species, prophase I is a lengthy phase during which the cell grows and synthesizes nutrients. This is especially true during the formation of some egg cells because materials need to be made for the benefit of the future embryo. In many types of meiotic cells, the chromosomes assume unusual shapes during this phase. For example, lampbrush chromosomes, found in the female meiotic cells (oocytes) of some amphibians, are composed of hundreds of pairs of loops of chromatin projecting from the chromatid axis. They owe their name to their resemblance to the brushes used to clean old-fashioned oil lamps (Fig. 9–16). The loops are sites of intense synthesis of RNA, which is used to direct the synthesis of specific proteins.

In addition to the unique processes of synapsis and cross-

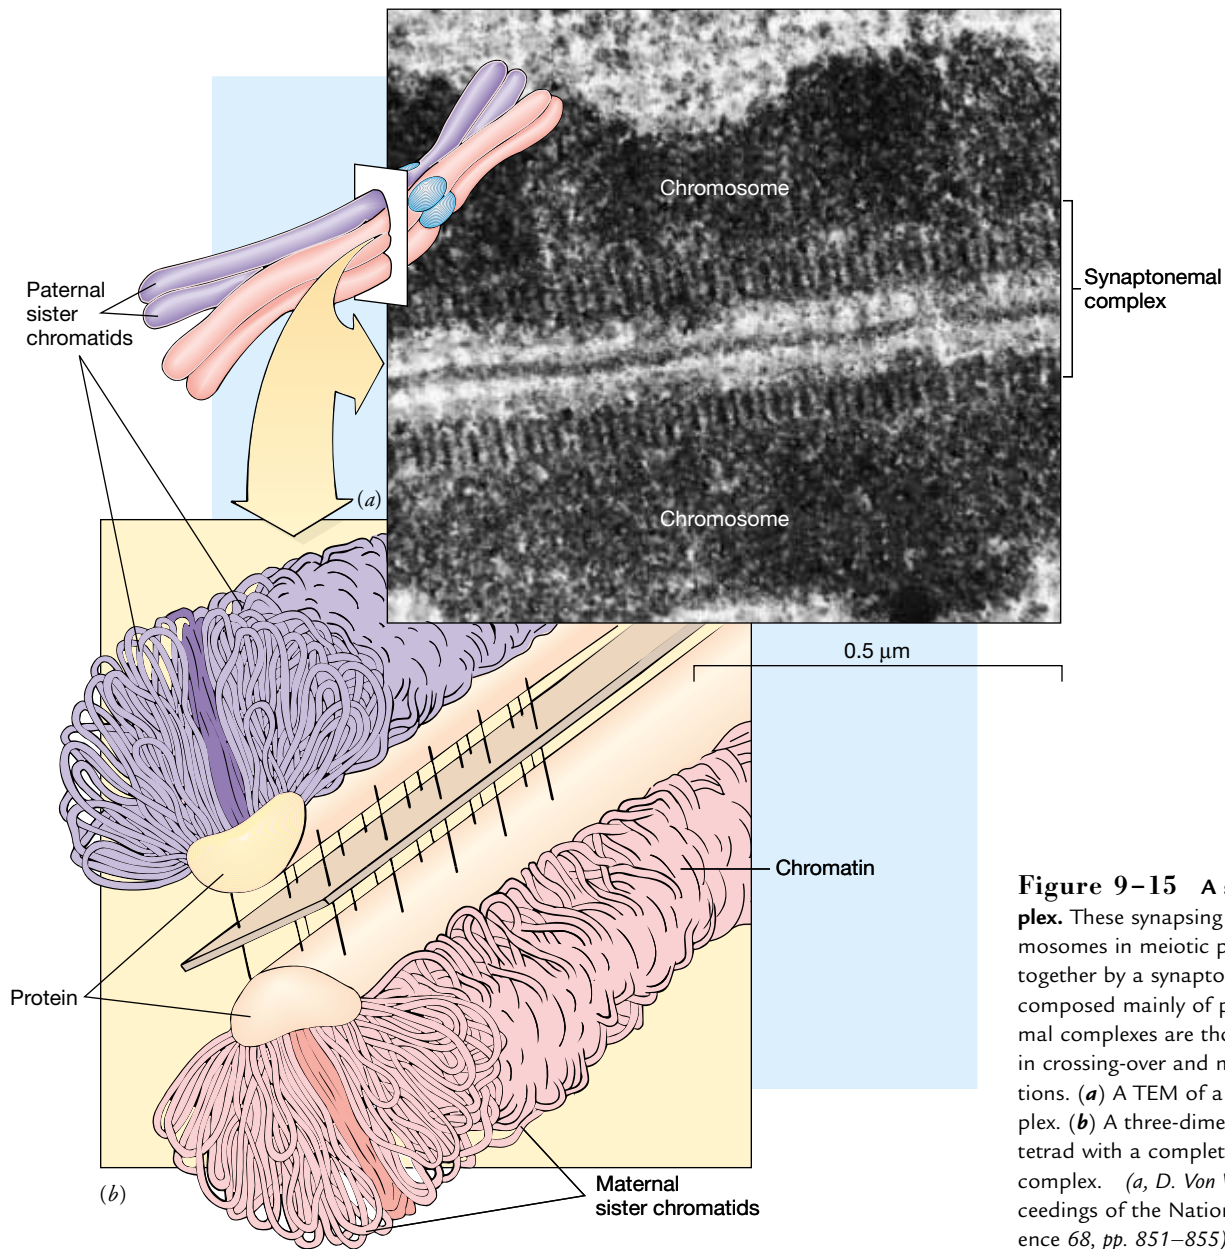

Figure 9–15 A synaptonemal complex. These synapsing homologous chromosomes in meiotic prophase I are held together by a synaptonemal complex, composed mainly of protein. Synaptonemal complexes are thought to be involved in crossing-over and may have other functions. (a) A TEM of a synaptonemal complex. (b) A three-dimensional model of a tetrad with a complete synaptonemal complex. (a, D. Von Wettstein, 1971 *Proceedings of the National Academy of Science* 68, pp. 851–855)

Figure 9–16 Lampbrush chromosomes. This LM shows parts of several tetrads from a female meiotic cell (oocyte) of the newt *Triturus viridescens*. The loops, composed of chromatin, are sites of intense RNA synthesis. (Dennis Gould)

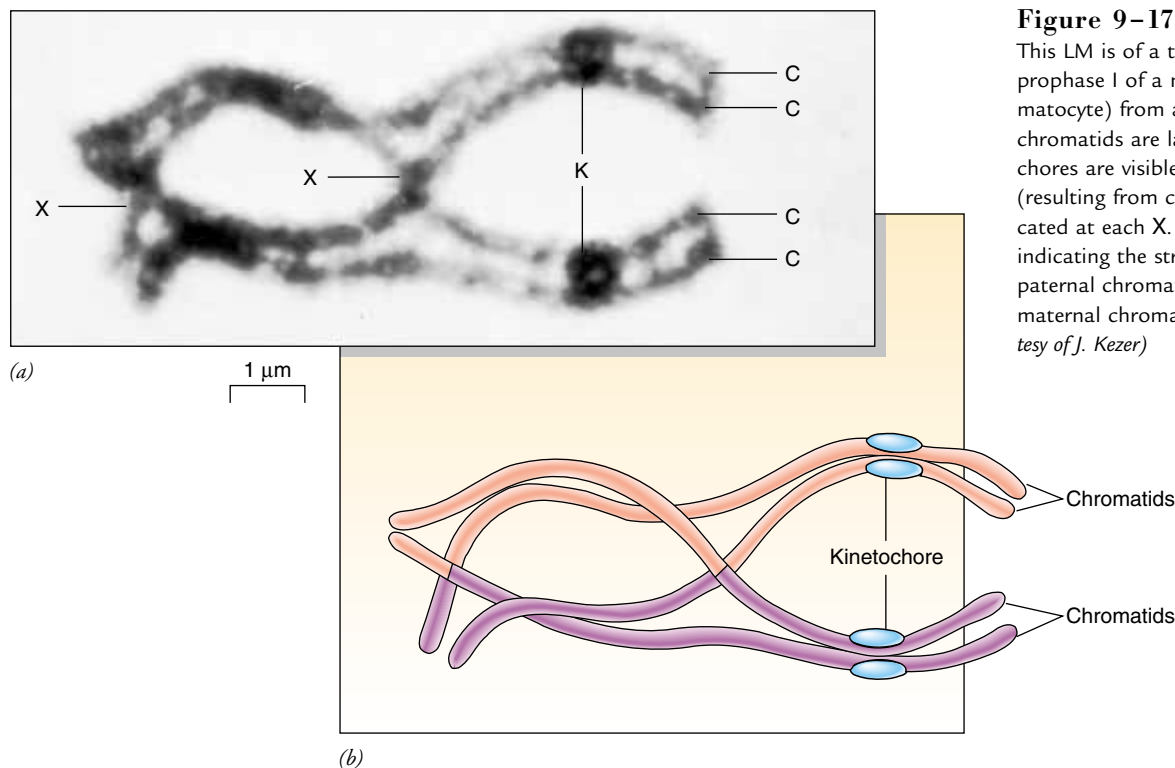

Figure 9-17 A meiotic tetrad. (a)

This LM is of a tetrad during late prophase I of a male meiotic cell (spermatocyte) from a salamander. The four chromatids are labelled C, the kinetochores are visible at K, and chiasmata (resulting from crossing-over) are indicated at each X. (b) Interpretive drawing indicating the structure of the tetrad. The paternal chromatids are purple, and the maternal chromatids are pink. (a, Courtesy of J. Keizer)

ing-over, events similar to those seen during mitotic prophase also take place. A spindle composed of microtubules and other components forms. If centrioles are present (as in animal cells), one pair moves to each pole, and astral microtubules are formed. The nuclear envelope disappears in late prophase I, and in favorable material the structure of the tetrads can be seen clearly with the microscope (Fig. 9-17). The sister chromatids continue to be closely aligned along their lengths, but the homologous chromosomes are no longer closely associated, and their centromeres (and kinetochores) are separated from one another. In late prophase I, the homologous chromosomes are held together only at specialized regions, termed **chiasmata** (sing., *chiasma*). Each chiasma originates at a site of crossing-over, that is, a site at which homologous chromatids previously broke, exchanged genetic material, and rejoined, producing an X-shaped configuration.

During meiosis I homologous chromosomes separate

Prophase I ends when the tetrads become aligned on the equatorial plane; the cell is now said to be at **metaphase I**. Both sister kinetochores of one chromosome are attached by spindle fibers to the same pole, and both kinetochores of the homologous chromosome are attached to the opposite pole. (By contrast, in mitosis, sister kinetochores are attached to opposite poles.) During **anaphase I**, the homologous chromosomes of each pair separate, or disjoin, and move toward opposite poles. Each pole receives a random mixture of maternal and paternal chromosomes, but only one member of each homologous pair is present at each pole. The sister chromatids are

united at their centromere regions. Again, this differs from mitotic anaphase, in which the sister chromatids pass to opposite poles.

During **telophase I**, the chromatids generally decondense somewhat, the nuclear envelope may reorganize, and cytokinesis may take place. Each telophase I nucleus contains the haploid number of chromosomes, but each chromosome is a duplicated chromosome. In our example, there are two duplicated chromosomes at each pole, for a total of four chromatids; in humans there are 23 duplicated chromosomes (46 chromatids) at each pole.

An interphase-like stage usually follows. Because it is not a true interphase (i.e., there is no S phase) it is given the name **interkinesis**. Interkinesis is very brief in most organisms and absent in some.

Chromatids separate in meiosis II

Because the chromosomes usually remain partially condensed between divisions, the prophase of the second meiotic division is brief. **Prophase II** is similar to mitotic prophase in many respects. There is no pairing of homologous chromosomes (indeed, only one member of each pair is present in each nucleus) and no crossing-over.

During **metaphase II**, the chromosomes line up on the equatorial planes of their cells. The first and second metaphases can be easily distinguished in diagrams; at metaphase I the chromatids are arranged in bundles of four (tetrads), and at metaphase II they are in groups of two (as in mitotic metaphase). This is not always so obvious in living cells.

During **anaphase II** the chromatids, attached to spindle

Figure 9–18 Mitosis and meiosis. The diagram compares the events and the outcomes of mitosis and meiosis, in each case beginning with a diploid cell with four chromosomes (i.e., two pairs of homologous chromosomes). Because the chromosomes were duplicated in the previous interphase, each chromosome consists of two sister chromatids. The chromosomes derived from one parent are shown in purple, and those from the other parent are pink. The homologous partner chromosomes can be recognized because they are similar in size and shape. Some of the stages have been omitted for simplicity.

fibers at their kinetochores, separate and move to opposite poles, just as they would at mitotic anaphase. As in mitosis, each former chromatid is now referred to as a chromosome. Thus, at **telophase II** there is one representative for each homologous pair at each pole. Each is an unduplicated chromosome. Nuclear envelopes then re-form, the chromosomes gradually elongate to form chromatin threads, and cytokinesis occurs.

The two successive divisions yield four haploid nuclei, each containing *one* of each kind of chromosome. Each resulting haploid cell has a different combination of genes. This genetic variation has two sources: (1) During meiosis the maternal and paternal chromosomes are “shuffled” so that one member of each pair becomes randomly distributed to the poles at anaphase I. (2) DNA segments are exchanged between maternal and paternal homologues during crossing-over. The genetic consequences of these events are discussed in more detail in Chapter 10.

THE EVENTS OF MITOSIS AND MEIOSIS LEAD TO CONTRASTING OUTCOMES

Although mitosis and meiosis share many similar features, specific distinctions between these processes result in the formation of different types of cells (Fig. 9–18).

Mitosis is a single division in which *sister chromatids* sep-

arate from each other. These are distributed to the two daughter cells, which are genetically identical to each other and to the original cell. Homologous chromosomes do not associate physically at any time in mitosis.

In meiosis, a diploid cell undergoes two successive divisions, meiosis I and meiosis II. In prophase I of meiosis the homologous chromosomes undergo synapsis to form tetrads. If we ignore crossing-over, we can say that *homologous chromo-*

somes separate during meiosis I, and *sister chromatids* separate during meiosis II. It is also correct to say that homologous centromeres (or kinetochores) separate during meiosis I, and sister centromeres (or kinetochores) disjoin during meiosis II. Meiosis ends with the formation of four, genetically different, haploid daughter cells. The fates of these cells depend on the type of life cycle; in animals they differentiate as gametes, while in plants they become spores.

S U M M A R Y W I T H K E Y T E R M S

- I. In the production of a new generation, cells transfer genetic information from parent to offspring.
- II. **Genes** are made of DNA, which is complexed with protein to form the **chromatin** fibers that make up **chromosomes**.
 - A. A **diploid** organism of a given species has a characteristic number of chromosome pairs per cell.
 - B. The two members of each chromosome pair, called **homologous chromosomes**, are similar in length, shape, and other structural features, and carry genes affecting the same kinds of attributes of the organism.
- III. The eukaryotic **cell cycle** is the period from the beginning of one division to the beginning of the next; the time required to complete one cycle is the **generation time**.
 - A. **Interphase** can be divided into the first gap phase (G_1), the chromosomal synthesis phase (S), and the second gap phase (G_2).
 1. During the **G_1 phase**, the cell grows and prepares for the S phase.
 2. During the **S phase**, DNA and the chromosomal proteins are synthesized.
 3. During the **G_2 phase**, protein synthesis increases in preparation for cell division.
 - B. During **mitosis**, identical chromosomes are distributed to each pole of the cell, and a nuclear envelope forms around each set.
 1. During **prophase**, duplicated chromosomes, each composed of a pair of **sister chromatids** associated with each other in the vicinity of their **centromeres**, become visible with the microscope. The nucleolus disappears, the nuclear envelope breaks down, and the **mitotic spindle** begins to form.
 2. During **metaphase** the chromosomes are aligned on the equatorial plane of the cell; the mitotic spindle is complete and the **kinetochores** of the sister chromatids are attached by microtubules to opposite poles of the cell.
 3. During **anaphase** the sister chromatids become separated and move to opposite poles. Each former chromatid is now referred to as a chromosome.
 4. During **telophase** a nuclear envelope re-forms around each set of chromosomes, nucleoli become apparent, the chromosomes uncoil, and the spindle disappears.
 - C. During **cytokinesis**, which generally begins in telophase and therefore overlaps mitosis, the cytoplasm divides to form two individual cells.
 1. In animal cells a ring of microfilaments contracts, producing a furrow that divides the cytoplasm.
 2. In plant cells the **cell plate** provides materials for new plasma membranes and cell walls.
- IV. There are two major forms of reproduction: asexual and sexual.
 - A. Offspring produced by **asexual reproduction** usually have hereditary traits identical to those of the single parent. These offspring constitute a **clone**. Usually all the cells involved are produced by mitosis.
 - B. In **sexual reproduction** two haploid sex cells, or **gametes**, fuse to form a single diploid **zygote**. This process is balanced by **meiosis** at some point in the life cycle.
 1. The somatic cells of animals are diploid; the only haploid cells are the gametes (produced by **gametogenesis**, which in animals includes meiosis.)
 2. Simple eukaryotes may be regularly haploid; the only diploid stage is the zygote, which undergoes meiosis to restore the haploid state.
 3. Plants and some algae have **alternation of generations**. A multicellular diploid **sporophyte** forms haploid spores by meiosis. Each spore divides mitotically to form a multicellular haploid **gametophyte**, which produces gametes by mitosis. Two haploid gametes then fuse to form a diploid zygote, which divides mitotically to produce a new diploid sporophyte.
- V. A diploid cell undergoing meiosis completes two successive cell divisions to give rise to four haploid cells.
 - A. **Meiosis I** begins with **prophase I**; the members of a homologous pair of chromosomes become physically joined by a process known as **synapsis** and undergo **crossing-over**, a process of **genetic recombination** during which segments of DNA strands are exchanged between homologous (nonsister) chromatids.
 - B. At metaphase I **tetrads**, each composed of a pair of homologous chromosomes held together by one or more **chiasmata**, line up on the equatorial plane.
 - C. The members of each pair of homologous chromosomes separate during meiotic **anaphase I** and are distributed to different nuclei. Each nucleus contains the haploid number of chromosomes; each chromosome consists of two chromatids.
 - D. During **meiosis II** the two chromatids of each chromosome separate and one is distributed to each daughter cell. Each former chromatid is now referred to as a chromosome.

P O S T - T E S T

1. Chromatin fibers include (a) DNA and structural polysaccharides (b) RNA and phospholipids (c) protein and carbohydrate (d) DNA and protein (e) triacylglycerol and steroids
2. The term *S phase* refers to (a) DNA synthesis during interphase (b) synthesis of chromosomal proteins during prophase (c) active RNA synthesis in lampbrush chromosomes (d) synapsis of homologous chromosomes (e) fusion of gametes in sexual reproduction
3. At which of the following stages do human skin cell nuclei have the same

- DNA content? (a) early mitotic prophase; mitotic telophase (b) G_1 ; G_2 (c) G_1 ; early mitotic prophase (d) G_1 ; mitotic telophase (e) G_2 ; mitotic telophase
4. In a cell at _____ each chromosome consists of a pair of attached chromatids. (a) mitotic prophase (b) meiotic prophase II (c) meiotic prophase I (d) meiotic anaphase I (e) all of the above
 5. In an animal cell at mitotic metaphase, you would expect to find (a) two pairs of centrioles located on the metaphase plate (b) a pair of

- centrioles inside the nucleus (c) a pair of centrioles within each microtubule organizing center (d) a centriole within each centromere (e) no centrioles
- Cell plate formation usually begins during (a) telophase in a plant cell (b) telophase in an animal cell (c) G_2 in a plant cell (d) G_2 in an animal cell (e) a and b are correct
 - The life cycle of a sexually reproducing organism includes (a) mitosis (b) meiosis (c) fusion of sex cells (d) b and c (e) a, b, and c
 - Which of the following are genetically identical? (a) two cells resulting from meiosis I (b) two cells resulting from meiosis II (c) four cells resulting from meiosis I followed by meiosis II (d) two cells resulting from a mitotic division (e) all of the above
 - You would expect to find a synaptonemal complex in a cell at (a) mitotic prophase (b) meiotic prophase I (c) meiotic prophase II (d) mei-

- otic anaphase I (e) meiotic anaphase II
- A particular plant species has a diploid chromosome number of 20. A haploid cell of that species at mitotic prophase contains a total of _____ chromosomes and _____ chromatids. (a) 20; 20 (b) 20; 40 (c) 10; 10 (d) 10; 20 (e) none of the above because haploid cells cannot undergo mitosis
 - A diploid nucleus at early mitotic prophase has _____ set(s) of chromosomes; a diploid nucleus at mitotic telophase has _____ chromosome set(s). (a) 1; 1 (b) 1; 2 (c) 2; 2 (d) 2; 1 (e) not enough information has been given.
 - A chiasma links a pair of (a) homologous chromosomes at meiotic metaphase II (b) homologous chromosomes at meiotic metaphase I (c) sister chromatids at meiotic metaphase II (d) sister chromatids at mitotic metaphase (e) sister chromatids at meiotic metaphase I

REVIEW QUESTIONS

- Two species may have the same chromosome number and yet have very different attributes. Explain.
- Sketch a duplicated chromosome and label the sister chromatids, the centromeres, and the kinetochores. What are the functions of centromeres and of kinetochores?
- How does the DNA content of the cell change from the beginning of interphase to the end of interphase? Does the number of chromatids change? Does the number of chromosomes change?
- Are homologous chromosomes present in a diploid cell? Are they present in a haploid cell?
- How does meiosis differ from mitosis? Are there any points of similarity

between these two processes? Explain.

- What kinds of life cycles include a multicellular haploid stage? Can haploid cells divide by mitosis? By meiosis?
- Assume that an animal has a diploid chromosome number of ten. (a) How many chromosomes would it have in a typical body cell, such as a skin cell? (b) How many chromosomes would be present in a cell at mitotic prophase? How many chromatids? (c) How many chromosomes would be present in each daughter cell produced by mitosis? Are these duplicated chromosomes? (d) How many tetrads would form in prophase I of meiosis? (e) How many chromosomes would be present in each gamete? Are these duplicated chromosomes?

YOU MAKE THE CONNECTION

- Decide whether each of the following is an example of sexual or asexual reproduction and state why. (a) A diploid queen honeybee produces haploid eggs by meiosis. Some of these eggs are never fertilized and develop into haploid male honeybees (drones). (b) Haploid male honeybees produce haploid sperm by mitosis. These sperm fertilize haploid eggs produced by the queen, resulting in the development of diploid female worker

bees. (c) Seeds develop after a flower has been pollinated with pollen from a different plant of the same species. (d) Seeds develop after a flower has been pollinated with pollen from the same plant. (e) A cutting from a plant develops roots after it has been placed in water. The plant survives and grows after it is transplanted to soil.

CHAPTER 10

The Basic Principles of Heredity

Heredity, the transmission of genetic information from parent to offspring, is generally a very regular process, following predictable patterns. The basic rules of inheritance in eukaryotes were first discovered by Gregor Mendel (1822–1884), an abbot who bred pea plants, depicted here in his monastery garden at Brunn, Austria (now Brno, Czech Republic). Mendel was the first scientist to effectively apply quantitative methods to the study of inheritance. He did not merely describe his observations; he planned his experiments carefully, recorded the data, and subjected the results to mathematical analysis. Although his work was unappreciated in his lifetime, it was rediscovered in 1900. His major findings, including those now known as Mendel's principles of segregation and independent assortment, became the foundation of the science of **genetics**.

During the decades following the rediscovery of Mendel's findings, geneticists initially extended Mendel's principles by correlating the transmission of genetic information from generation to generation with the behavior of chromosomes during meiosis. They also refined his methods and, through their studies on a variety of organisms, both verified Mendel's findings and added to a growing list of so-called exceptions to his principles. These include such phenomena as linkage, sex linkage, and polygenic inheritance.

Some geneticists were very active in the development of the emerging science of statistical analysis (which had been in its infancy in Mendel's time), thereby providing scientists with increasingly sophisticated ways to analyze and interpret experimental data. These statistical methods were also essential to the study of the genetic makeup of natural populations of organisms. The results of these investigations on the genetics of populations were combined with Charles Darwin's theory of evolution by natural selection to develop a unified modern theory of evolution, firmly based on genetic principles (see Chapters 17 and 18).

Geneticists study not only the transmission of genes, but also the expression of genetic information. As you will see in this and succeeding chapters, our understanding of the relationship between an organism's genes and its characteristics has become increasingly sophisticated as we have learned more about the flow of information in cells.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Define and use correctly the terms *allele*, *locus*, *genotype*, *phenotype*, *dominant*, *recessive*, *homozygous*, *heterozygous*, and *test cross*.
2. Apply Mendel's principles to solve genetics problems involving monohybrid and dihybrid crosses.
3. Apply the product rule and sum rule appropriately when predicting the outcomes of genetic crosses.
4. Solve genetics problems involving incomplete dominance, epistasis, polygenes, multiple alleles, and X-linked inheritance.
5. Explain some of the ways in which genes may interact to affect the phenotype; discuss how it is possible for a single gene to affect many features of the organism simultaneously.
6. Analyze data from a test cross involving alleles of two loci.
7. Discuss the genetic determination of sex and the role of the Y chromosome in determining male sex in humans; contrast the mechanism of sex determination in humans and other mammals with that in various other animals and some plants; compare dosage compensation of X-linked genes in mammals and *Drosophila*.
8. Assess the effects of inbreeding versus outbreeding on a population; discuss the genetic basis of hybrid vigor.

MENDEL FIRST DEMONSTRATED THE PRINCIPLES OF INHERITANCE

Gregor Mendel was not the first plant breeder; at the time he began his work, **hybrid** plants and animals (offspring of two genetically dissimilar parents) had been known for a long time. When Mendel began his breeding experiments in 1856, two main facts about inheritance were widely recognized: (1) All hybrid plants that are offspring of the same kinds of parents are similar in appearance. (2) When these hybrids are mated to each other they do not breed true; their offspring show a mixture of traits. Some look like their parents, and some have features like their grandparents. Mendel's genius lay in his ability to recognize a pattern in the way the parental traits reappear in the offspring of hybrids. No one before had categorized and counted the offspring and analyzed these regular patterns over several generations.

Just as geneticists do today, Mendel chose the organism for his experiments very carefully. The garden pea, *Pisum sativum*, had a number of advantages. Pea plants are easy to grow, and many varieties were available through commercial sources. It is impossible to study inheritance without such genetic **variation**. (If every person in the population had blue eyes, it would be impossible to study the inheritance of eye color.) Another advantage of pea plants is that controlled pollinations are relatively easy to conduct. Pea flowers (Fig. 10–1) have both male and female parts, and are naturally self-pollinated. However, the male anthers (pollen-producing parts of the flower) can be removed to prevent self-fertilization. Pollen from a different source can then be applied to the stigma (receptive surface of the female part). Pea flowers are easily protected from other sources of pollen because the reproductive structures are completely enclosed by the petals. Although Mendel did not mention having done this, plant hybridizers usually cover the flowers with small bags to provide additional protection from pollinating insects.

Although his original pea seeds were obtained from commercial sources, Mendel did some important preliminary work

before he started his actual experiments. For several years he worked to develop genetically pure, or **true-breeding**, lines for a number of inherited features. Today we use the term **phenotype** to refer to the physical appearance of an organism. A true-breeding line produces only offspring expressing the same phenotype (e.g., round seeds or tall plants), generation after generation. During this time he apparently chose those characteristics of his pea strains that could be studied most easily, and probably discarded or ignored a number of others. He probably made the initial observations that would later form the basis of his theories.

Mendel eventually chose strains representing seven clearly contrasting pairs of phenotypes: yellow versus green seeds, round versus wrinkled seeds, green versus yellow pods, tall versus short plants, inflated versus constricted pods, white seed coats versus gray seed coats, and flowers borne on the ends of the stems versus flowers appearing all along the stems. Other plant breeders typically studied hybrids between parents that differed in many, often not clearly defined, ways. Mendel's re-

Figure 10–1 Reproductive structures of a pea flower. This cut-away view shows the pollen-producing anthers and the stigma, that portion of the female part of the flower that receives the pollen.

Figure 10–2 One of Gregor Mendel’s many pea plant crosses. Crossing a tall pea plant with a short pea plant yielded only tall offspring in the F_1 generation. However, when these F_1 individuals self-pollinated, or when two F_1 individuals were crossed, the resulting F_2 generation included tall and short plants in a ratio of about 3:1.

sults were much easier to analyze because he chose easily distinguishable phenotypes and limited the genetic variation studied in each experiment.

Mendel began his experiments by crossing plants from two different true-breeding lines with contrasting phenotypes; these genetically pure individuals constituted the **parental**, or **P, generation**. In every case, the members of the first generation of offspring all looked alike and resembled one of the two parents. For example, when he crossed tall plants with short plants, all the progeny were tall (Fig. 10–2). These offspring were the **first filial** (*filial* comes from Latin for “sons and daughters”) generation, or **F₁ generation**. The second filial generation, or

F₂ generation, was produced by a cross between F_1 individuals, or by self-pollination of F_1 individuals. Mendel’s F_2 generation in this experiment included 787 tall plants and 277 short plants.

Most breeders of Mendel’s time thought that inheritance was controlled by fluids that blended together when hybrids were formed. One implication of this idea is that a hybrid should be intermediate between the two parents. However, in Mendel’s experiments, hereditary factors from one of the parents apparently masked expression of the hereditary factors from the other parent in an F_1 hybrid. The factor expressed in the F_1 generation (tallness in our example) is said to be **dominant**; the one hidden (shortness) is said to be **recessive**. Although we know today that dominance is not always observed (exceptions are considered later in this chapter), the fact that dominance can occur conflicted with the notion of blending inheritance.

Mendel’s results argued against blending inheritance in yet another way. Once two fluids have blended, it is very difficult to imagine how they can be separated. However, in the example just discussed, the hereditary factor(s) that controlled shortness clearly had not been lost or blended inseparably with the hereditary factor(s) that controlled tallness in the F_1 generation, because shortness reappeared in the F_2 generation. Mendel therefore proposed that each kind of inherited feature of an organism is controlled by two factors that behave like particles and are present in every individual. To Mendel these “hereditary factors” were abstractions, because he knew nothing of chromosomes and DNA. They are essentially what we call **genes** today, so we will use that term in our discussion. Today we know that genes are not particles, but treating them as such allowed Mendel to develop precise mathematical models, testable by experiment, to predict the patterns by which genes are transmitted from generation to generation.

Mendel’s experiments led to his discovery and explanation of the major principles of heredity, which we now know as the principles of segregation and independent assortment. We consider the first now and the second later in the chapter.

The principle of segregation states that alleles separate before gametes are formed

Today we use the term **alleles** to refer to the alternative forms of a gene. In the example in Figure 10–2, each F_1 -generation tall plant had two different alleles that control plant height: one for tallness (which we designate T) and one for shortness (which we designate t), but because the tall gene was dominant, these plants were tall. To explain his experimental results, Mendel proposed an idea that we now refer to as the principle of segregation. Using modern terminology, the **principle of segregation** states that, in order for sexual reproduction to occur, the two alleles carried by an individual parent must become separated (segregated). As a result, each sex cell (egg or sperm) formed contains only one allele of each pair. An essential feature of the process is that the alleles remain intact (one does not “contaminate” or eliminate the other); thus, re-

Figure 10–3 The chromosomal basis for segregation. The separation of homologous chromosomes during meiosis results in the segregation of alleles. Note that one-half of the gametes will carry *T* and one-half will carry *t*.

cessive alleles are not lost and so can reappear in the F_2 generation.

In our example, before the F_1 plants formed gametes, the allele for tallness separated (segregated) from the allele for shortness, so that half of the gametes contained a *T* allele and the other half a *t* allele. The random process of fertilization led to three possible combinations of alleles in the F_2 offspring: one-fourth with two tallness alleles (*TT*), one-fourth with two shortness alleles (*tt*), and one-half with one allele for tallness and one for shortness (*Tt*). Because both *TT* and *Tt* plants are tall, on average Mendel expected approximately three-fourths (787/1064) to express the phenotype of the dominant allele (tall) and about one-fourth (277/1064) the phenotype of the recessive allele (short). (The mathematical reasoning behind these predictions will be explained shortly.)

Today we know that segregation of alleles is a direct result of the separation of homologous chromosomes during

meiosis (Fig. 10–3). (Recall from Chapter 9 that in all sexual life cycles, meiosis must occur at some point prior to gamete formation.) Later, at the time of fertilization, each haploid gamete contributes one chromosome from each homologous pair and therefore one gene for each gene pair (either *T* or *t* in our example). Although gametes and fertilization were known at the time Mendel carried out his research, mitosis and meiosis had not yet been discovered. It is truly remarkable that Mendel was able to formulate his ideas mainly on the basis of mathematical abstractions. Today his principles are much easier to understand because we are able to think about them in concrete terms by relating the transmission of genes to the behavior of chromosomes.

Mendel reported these and other findings (discussed later in this chapter) at a meeting of the Brunn Society for the Study of Natural Science; he published his results in the transactions of that society in 1866. At that time biology was largely a descriptive science, and biologists had little interest in applying quantitative and experimental methods such as Mendel had used. The importance of his results and his interpretations of those results was not appreciated by other biologists of the time, and his findings were neglected for nearly 35 years.

In 1900 Hugo DeVries in Holland, Karl Correns in Germany, and Erich von Tschermak in Austria each rediscovered Mendel's paper and found that it provided explanations for their own research findings. They gave credit to Mendel by naming the basic laws of inheritance after him. By this time biologists had a much greater appreciation of the value of quantitative experimental methods. The details of mitosis, meiosis, and fertilization had been described, and in 1903 W. S. Sutton pointed out the connection between Mendel's segregation of genes and the separation of homologous chromosomes during meiosis. The time was right for wider acceptance and extension of these ideas and their implications.

Alleles occupy corresponding loci on homologous chromosomes

Today we know that each chromatid is made up of one long DNA molecule and that each gene is actually a segment of that DNA molecule. We also know that homologous chromosomes usually have similar genes located in corresponding positions. The term **locus**¹ (pl., *loci*) was originally coined to designate the location of a particular gene on the chromosome (Fig. 10–4). Of course we are actually referring to a segment of the DNA that has the information required to control some aspect of the organism. One locus may be involved in determining seed color, another seed shape, still another the shape of the pods, and so on. The existence of a particular locus can be inferred (by traditional genetic methods at least) only if at least two allelic variants of that locus, producing contrasting phenotypes (e.g., yellow peas versus green peas) are available

¹In mathematics a locus is a dimensionless point; a genetic locus, being a segment of DNA, is obviously not dimensionless!

Figure 10–4 Loci and their alleles.

for study. In the simplest cases an individual can express one (yellow) or the other (green) but not both.

Thus alleles are genes that govern variations of the same feature (yellow versus green seed color) and occupy corresponding loci on homologous chromosomes. Each allele (variant) of a locus is assigned a single letter (or group of letters) as its symbol. Although more complicated forms of notation are often used by geneticists, it is customary when working simple genetics problems to indicate a dominant allele with a capital letter and a recessive allele with the same letter in lowercase. The choice of the letter is generally determined by the first allelic variant found for that locus. For example, the dominant allele that governs the yellow color of the seed might be

designated Y , and the recessive allele responsible for the green color would then be designated y . Because discovery of the yellow allele made identification of this locus possible, we refer to the locus as the *yellow* locus, although pea seeds are most commonly green.

Remember that the term *locus* designates not only a position on a chromosome but also a type of gene controlling a particular kind of characteristic; thus, Y (yellow) and y (green) represent a specific pair of alleles of a locus involved in determining seed color in peas. *Although you may initially be uncomfortable with the fact that geneticists sometimes use the term gene to specify a locus and at other times to specify one of the alleles of that locus, the meaning is usually clear from the context.*

A MONOHYBRID CROSS INVOLVES INDIVIDUALS WITH DIFFERENT ALLELES OF A GIVEN LOCUS

The basic principles of genetics and the use of genetic terms are best illustrated by examples. In the simplest case, a **monohybrid cross**, the inheritance of two alleles of a single locus is studied. Our first example in this section deals with the expected ratios in the F_2 generation, as did our previous example of Mendel's work on tall and short pea plants.

Heterozygotes carry two different alleles of a locus; homozygotes carry identical alleles

Figure 10–5 illustrates a monohybrid cross featuring a locus that governs coat color in guinea pigs. The female comes from a true breeding line of black guinea pigs. We say that she is **homozygous** for black because the two alleles she carries for this locus are identical. The brown male is also from a true breeding line and is homozygous for brown. What color would you expect the F_1 offspring to be? Dark brown? Spotted? It is impossible to make such a prediction without more information.

In this particular case, the F_1 offspring are black, but they are **heterozygous**, meaning that they carry two different alleles for this locus. The allele for brown coat color can be expressed only in a homozygous brown individual; it is referred to as a recessive allele. The allele for black coat color can be expressed in both homozygous black and heterozygous individuals; it is a dominant allele. On the basis of this information, we can use standard notation to designate the dominant black allele as B and the recessive brown allele as b .

During meiosis in the female parent (BB), the two B alleles separate according to Mendel's principle of segregation so that each egg has only one B allele. In the male (bb), the two b alleles separate so that each sperm has only one b allele. The fertilization of each B egg by a b sperm results in heterozygous F_1 offspring, each with the alleles Bb . That is, each individual has one allele for brown coat and one for black coat. Because this is the only possible combination of alleles present in the eggs and sperm, all the F_1 offspring are Bb .

A Punnett square predicts the ratios of genotypes and phenotypes of the offspring of a cross

During meiosis in heterozygous black guinea pigs (Bb), the chromosome containing the B allele becomes separated from its homologue (the chromosome containing the b allele), so each normal sperm or egg contains B or b , but never both. Gametes containing B alleles and those containing b alleles are formed in equal numbers by heterozygous Bb individuals. Because no special attraction or repulsion occurs between an egg

Figure 10–5 A monohybrid cross. In this example, a homozygous black guinea pig is mated with a homozygous brown guinea pig. The F_1 generation includes only black individuals. However, the mating of two of these offspring yields F_2 generation offspring in the expected ratio of 3 black:1 brown, indicating that the F_1 individuals are heterozygous. The corresponding F_2 genotypic ratio is $1BB:2Bb:1bb$.

and a sperm containing the same allele, fertilization is a random process.

As illustrated in Figure 10–5, the possible combinations of eggs and sperm at fertilization can be represented in the form of a “checkerboard” known as a **Punnett square**, devised by an early geneticist, Sir Reginald Punnett. The types of gametes (and their expected frequencies) from one parent are represented across the top, and those from the other parent are indicated along the left side. The squares are then filled in with the resulting F_2 zygote combinations. Three-fourths of all F_2 offspring have the genetic constitution BB or Bb and are phe-

not typically black; one-fourth have the genetic constitution bb and are phenotypically brown. The genetic mechanism responsible for the approximate 3:1 F_2 ratios (called *monohybrid F_2 phenotypic ratios*) obtained by Mendel in his pea-breeding experiments is again evident.

The phenotype of an individual does not always reveal its genotype

An organism's phenotype is its appearance (in a given environment) with respect to a certain inherited feature. However, because some alleles may be dominant and others recessive, we cannot always determine which alleles are carried by an organism simply by looking at it. The *genetic constitution* of that organism, most often expressed in symbols, is its **genotype**. In

the cross we have been considering, the genotype of the female parent is homozygous dominant, BB , and her phenotype is black. The genotype of the male parent is homozygous recessive, bb , and his phenotype is brown. The genotype of all the F_1 offspring is heterozygous, Bb , and their phenotype is black. To prevent confusion we always indicate the genotype of a heterozygous individual by writing the symbol for the dominant allele first and the recessive allele second (always Bb , never bB).

The phenomenon of dominance partly explains why an individual may resemble one parent more than the other, even if the two parents make equal contributions to their offspring's genetic constitution. Dominance is not predictable and can be determined only by experiment. In one species of animal, black coat may be dominant to brown; in another species, brown may be dominant to black.

Figure 10-6 A test cross. In this illustration, a test cross is used to determine the genotype of a black guinea pig. (a) If a black guinea pig is mated with a brown guinea pig and all the offspring are black, the black parent probably has a homozygous genotype. (b) If any of the offspring are brown, the black guinea pig must be heterozygous. The expected ratio is 1 black:1 brown.

A test cross can detect heterozygosity

Guinea pigs with the genotypes BB and Bb are alike phenotypically; they both have black coats. How, then, can we know the genotype of a black guinea pig? Geneticists can accomplish this by performing a **test cross**, in which an individual of unknown genotype is crossed with a homozygous recessive individual (Fig. 10–6). In a test cross, the alleles carried by the gametes from the parent of unknown genotype are never “hidden” in the offspring by dominant alleles contributed by the other parent. Therefore, one can deduce the genotypes of all the classes of offspring directly from their phenotypes. If all the offspring were black, what inference would you make about the genotype of the black parent? If any of the offspring were brown, what conclusion would you draw regarding the genotype of the black parent? Would you be more certain about one of these inferences than the other?

Mendel did just these sorts of experiments, breeding F_1 (tall) pea plants with homozygous recessive (tt) short ones. If his ideas were correct, the F_1 individuals were expected to be heterozygous, producing equal numbers of T and t gametes. Because the homozygous short parents were expected to produce only t gametes, Mendel predicted that he would obtain equal numbers of tall (Tt) and short (tt) offspring. His results agreed with his predictions, thereby providing additional evidence supporting the hypothesis that there is 1:1 segregation of the alleles of a heterozygous parent. Thus, Mendel’s principle of segregation not only explained the known facts, such as the 3:1 monohybrid F_2 phenotypic ratio, but also enabled him to successfully anticipate the results of other experiments, in this case the 1:1 test cross phenotypic ratio.

THE RULES OF PROBABILITY PREDICT THE LIKELIHOOD OF GENETIC EVENTS

All genetic ratios are properly expressed in terms of probabilities. In the examples just discussed, among the offspring of two individuals heterozygous for the same gene pair, the ratio of the phenotypes of the dominant and recessive alleles is 3:1. The probability of an event is its expected frequency; therefore we can say that there are 3 chances in 4 ($3/4$) that any particular individual offspring of two heterozygous individuals will express the dominant allele phenotype and 1 chance in 4 ($1/4$) that it will express the recessive allele phenotype. Although we sometimes speak in terms of percentages, probabilities must always be calculated as fractions (e.g., $3/4$) or decimal fractions (e.g., 0.75). If an event is certain to occur, its probability is 1; if it is certain not to occur, its probability is 0. A probability can be 0, 1, or some number between 0 and 1.

Often we wish to *combine* two or more probabilities. The Punnett square, which we use to predict the results of genetic

		Second toss		
		 Probability is $\frac{1}{2}$	 Probability is $\frac{1}{2}$	
First toss	Heads	 Probability is $\frac{1}{2}$	 $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$	 $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$
	Tails	 Probability is $\frac{1}{2}$	 $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$	 $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$

Figure 10–7 The rules of probability. For each coin toss the probability of heads is $1/2$ and the probability of tails is also $1/2$. Because the outcome of the first toss is independent of the outcome of the second, the combined probabilities of the outcomes of successive tosses are calculated by multiplying their individual probabilities (according to the product rule: $1/2 \times 1/2 = 1/4$). These same rules of probability are used to predict genetic events.

crosses, is a device that allows us to combine probabilities. When we use a Punnett square we are intuitively following two important rules known as the **product rule** and the **sum rule**.

The product rule predicts the combined probabilities of independent events

Events are independent if the occurrence of one does not affect the probability that the other will occur. For example, the probability of obtaining heads on the first toss of a coin is $1/2$; the probability of obtaining heads on the second toss (an independent event) is also $1/2$. If two or more events are *independent* of each other, the probability of their both occurring is the *product* of their individual probabilities. If this seems strange to you, keep in mind that when we multiply two numbers that are less than 1, the product is a smaller number. Therefore, the probability of obtaining heads two times in a row is $1/2 \times 1/2 = 1/4$, or 1 chance in 4 (Fig. 10–7).

Similarly, we can apply the product rule to genetic events. If both parents are Bb , what is the probability that they will produce a child who is bb ? For the child to be bb , he or she must receive a b gamete from each parent. The probability of a b egg is $1/2$ and the probability of a b sperm is also $1/2$. Like the outcomes of the coin tosses, these probabilities are independent, so we combine them by the product rule ($1/2 \times 1/2 = 1/4$). You may wish to check this result using a Punnett square.

The sum rule predicts the combined probabilities of mutually exclusive events

In some cases there is more than one way to obtain a specific outcome. These different ways are called *mutually exclusive* events because no more than one of them can happen; i.e., if one of them occurs, the other(s) cannot. For example, if both parents are Bb , what is the probability that their first child will also have the Bb genotype? There are two different ways these parents can have a Bb child: either a B egg combines with a b sperm (probability $1/4$), or a b egg combines with a B sperm (probability $1/4$).

Naturally, if there is more than one way to obtain a result, the chances of its being obtained are improved; we therefore combine the probabilities of mutually exclusive events by *summing* (adding) their individual probabilities. The probability of obtaining a Bb child in our example is therefore $1/4 + 1/4 = 1/2$. (Because there is only one way these heterozygous parents can produce a homozygous recessive child, bb , that probability is only $1/4$. The probability of a homozygous dominant child, BB , is likewise $1/4$.)

The rules of probability can be applied to a variety of calculations

The rules of probability have wide applications. For example, what are the probabilities that a family with two (and only two) children will have two girls, two boys, or one girl and one boy? For purposes of discussion we will assume that male and female births are equally probable. The probability of having a girl first is $1/2$, and the probability of having a girl second is also $1/2$. These are independent events, so we combine their probabilities by multiplying: $1/2 \times 1/2 = 1/4$. Similarly, the probability of having two boys is also $1/4$.

In families with both a girl and a boy, the girl can be born first or the boy can be born first. The probability that a girl will be born first is $1/2$, and the probability that a boy will be born second is also $1/2$. We use the product rule to combine the probabilities of these two independent events: $1/2 \times 1/2 = 1/4$. Similarly, the probability that a boy will be born first and a girl second is also $1/4$. These two kinds of families represent mutually exclusive outcomes, that is, two different ways of obtaining a family with one boy and one girl. Having two different ways of obtaining the desired result improves our chances, so we use the sum rule to combine the probabilities: $1/4 + 1/4 = 1/2$. Notice that the probabilities of the three types of families—both boys ($1/4$), both girls ($1/4$), and one girl, one boy ($1/2$)—add up to 1. This serves as a useful check that the calculations have been done correctly. You may also wish to confirm these results by making a Punnett square.

In working with probabilities, it is important to keep in mind a point that many gamblers forget: chance has no memory. This means that if events are truly random, past events have no influence on the probability of the occurrence of independent future events. For example, if two brown-eyed people have a child, what is the probability that it will have blue

eyes? If their first child has blue eyes, what is the probability that their second child will also have blue eyes? The color of the iris of the human eye is controlled by alleles at several loci, but alleles at one locus are primarily responsible. The allele for brown eye color, B , is usually dominant to the allele for blue, b . If the two brown-eyed parents are heterozygous, there is 1 chance in 4 that any child of theirs will have blue eyes. Each fertilization is a separate, independent event; its result is not affected by the results of any previous fertilizations. If these two, heterozygous, brown-eyed parents already have three brown-eyed children and are expecting their fourth child, what is the probability that the child will have blue eyes? The uninformed might guess that this one *must* have blue eyes, but in fact there is still only 1 chance in 4 that the child will have blue eyes and 3 chances in 4 that the child will have brown eyes.

If two heterozygous people marry and *plan* to have four children, what is the probability that all four will have brown eyes? The probability of brown eyes for each child is $3/4$, so we combine these independent events by the product rule: $3/4 \times 3/4 \times 3/4 \times 3/4 = 81/256$ or 0.32. Why is the answer to this question so different from the answer to the previous question? Remember that for the brown-eyed children that were already born, chance ($3/4$) is replaced by certainty (1), so the calculation becomes $1 \times 1 \times 1 \times 3/4 = 3/4$. The chance that the fourth (as yet unborn) child will have brown eyes is therefore $3/4$ (and the chance of blue eyes is $1/4$).

When working probability problems, common sense is more important than blindly memorizing rules. Examine your results to see if they appear reasonable; if they do not, you should reevaluate your assumptions.

A DIHYBRID CROSS INVOLVES INDIVIDUALS THAT HAVE DIFFERENT ALLELES OF TWO LOCI

Simple monohybrid crosses each involve a pair of alleles of a single locus. Mendel also analyzed crosses involving alleles of two or more loci. A mating between individuals with different alleles at two loci is called a **dihybrid cross**. Consider the case when two pairs of alleles are located in nonhomologous chromosomes (i.e., one pair of alleles is located in one pair of homologous chromosomes, and the other pair of alleles is located in a *different* pair of homologous chromosomes). Each pair of alleles is inherited independently; that is, each pair segregates during meiosis independently of the other.

An example of a dihybrid cross carried through the F_2 generation is illustrated in Figure 10–8. When a homozygous, black, short-haired guinea pig ($BBSS$, because black is dominant to brown and short hair is dominant to long hair) and a homozygous, brown, long-haired guinea pig ($bbss$) are mated, the $BBSS$ animal produces gametes that are all BS , and the $bbss$ individual produces gametes that are all bs . Each gamete contains one and only one allele for each of the two loci. The

Figure 10–8 A dihybrid cross. When a black, short-haired guinea pig is crossed with a brown, long-haired one, all the offspring are black and have short hair. However, when two members of the F₁ generation are crossed, the ratio of phenotypes is 9:3:3:1. Note that the two pairs of alleles considered here assort independently.

union of the *BS* and *bs* gametes yields only individuals with the genotype *BbSs*. All these F₁ offspring are heterozygous for hair color and for hair length, and all are phenotypically black and short-haired.

The principle of independent assortment states that the alleles of different loci on nonhomologous chromosomes are randomly distributed into gametes

Each F₁ guinea pig produces four kinds of gametes with equal probability: *BS*, *Bs*, *bS*, and *bs*. Hence, the Punnett square has 16 (4²) squares representing the zygotes, some of which are genotypically or phenotypically alike. There are 9 chances in 16 of obtaining a black, short-haired individual; 3 chances in 16 of obtaining a black, long-haired individual; 3 chances in 16 of obtaining a brown, short-haired individual; and 1 chance in 16 of obtaining a brown, long-haired individual. This

9:3:3:1 phenotypic ratio is expected in a dihybrid F₂ if the hair color and hair length loci are on nonhomologous chromosomes.

On the basis of similar results, Mendel formulated the principle of inheritance now called Mendel's **principle of independent assortment**, which states that members of any gene pair segregate from one another independently of the members of the other gene pairs. This occurs in a regular way that ensures that each gamete contains one allele for each locus, but the alleles of different loci are assorted at random with respect to each other in the gametes. (Mendel only reported on the results of crosses in which the genes assorted independently. As you will soon see, independent assortment does not always occur.)

Procedures used in solving genetics problems that illustrate Mendel's principles of segregation and independent assortment are summarized at the end of the chapter in *Focus On: Solving Genetics Problems* on page 240 and *Focus On: Deducing Genotypes* on page 241.

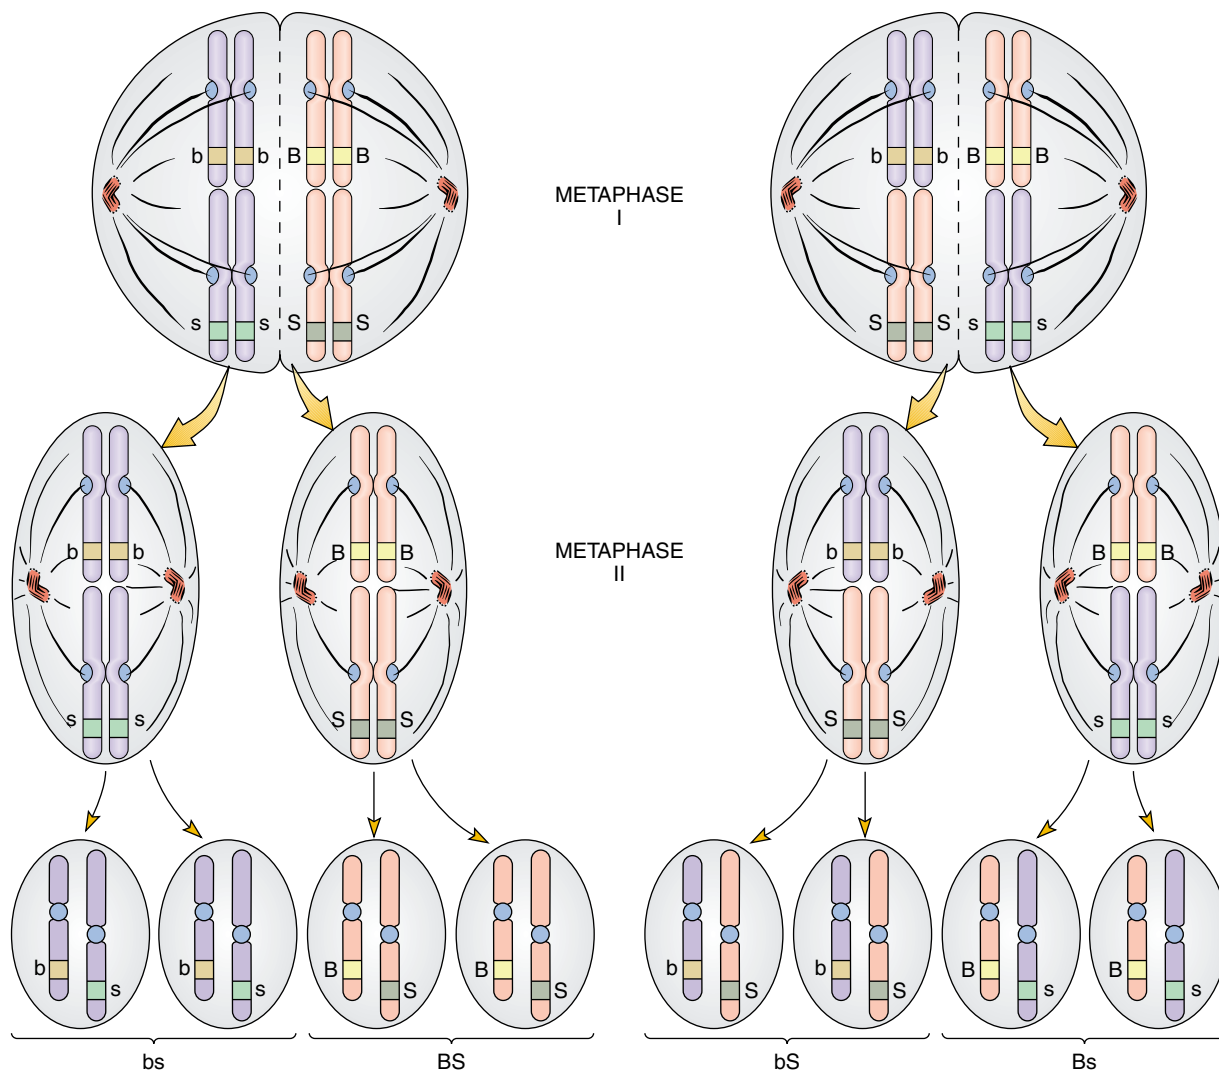

Figure 10–9 Meiosis and independent assortment. There are two equally likely ways that two different pairs of homologous chromosomes can line up at metaphase I and be subsequently distributed. A cell with the orientation shown at the left produces half *BS* and half *bs* gametes. Conversely, the cell at the right produces half *Bs* and half *bS* gametes. Because approximately half of the meiotic cells are of each type, the ratio of the four possible types of gametes is 1:1:1:1.

The mechanics of meiosis are the basis for independent assortment

Today we recognize that independent assortment is related to the events of meiosis. It occurs because there are two different ways in which two pairs of homologous chromosomes can be arranged at metaphase I of meiosis. These occur randomly, with approximately half the meiotic cells having one orientation, and the other half having the opposite orientation. The orientation of the homologous chromosomes on the metaphase plate then determines the way they subsequently separate and are distributed into the haploid cells (Fig. 10–9).

Linked genes do not assort independently

Independent assortment does not apply if the two loci are located in the same pair of homologous chromosomes. In fruit flies there is a locus controlling wing shape (the dominant allele *V* for normal wings and the recessive allele *v* for vestigial wings) and another locus controlling body color (the dominant allele *B* for gray and the recessive allele *b* for black). If a homozygous *BBVV* fly is crossed with a homozygous *bbvv* fly, the F_1 flies all have gray bodies and normal wings, and their genotype is *BbVv* (Fig. 10–10).

Because these loci happen to be located in the *same pair*

Figure 10–10 A two-point test cross to detect linkage. In fruit flies, loci for wing length (vestigial versus normal wings) and for body color (black versus gray body) are linked; they are located on a homologous chromosome pair. Linkage can be recognized when an excess of parental type offspring and a deficiency of recombinant type offspring are produced.

of homologous chromosomes, their alleles do not assort independently; instead they tend to be inherited together and are said to be **linked**. Linkage is most readily observed by analyzing the results of a test cross in which heterozygous F₁ flies (*BbVv*) are mated with homozygous recessive (*bbvv*) flies (see bottom of Fig. 10–10). Because heterozygous individuals are mated to homozygous recessive individuals, this test cross is similar to the test cross described previously. However, it is called a **two-point test cross** because alleles of two loci are involved.

If the loci governing these characteristics were on different chromosomes (unlinked), the heterozygous parent in a test cross would produce four kinds of gametes (*BV*, *Bv*, *bV*, and *bv*) in equal numbers. As a result of this independent assortment, offspring with new gene combinations not present in the parental generation would be produced. Any process that leads to new gene combinations is called **recombination**. In our example, *Bv* and *bV* are both **recombinant** gametes. The other two kinds of gametes, *BV* and *bv*, are called **parental gametes** because they are identical to the gametes produced by the P generation. Of course, the homozygous recessive parent produces only one kind of gamete, *bv*. Thus, if independent assortment were to occur in the F₁ flies, approximately 1/4 of

the test-cross offspring would be gray-bodied and normal-winged (*BbVv*), 1/4 black-bodied and normal-winged (*bbVv*), 1/4 gray-bodied and vestigial-winged (*Bbvv*), and 1/4 black-bodied and vestigial-winged (*bbvv*). Notice that the two-point test cross allows us to determine the genotypes of the offspring directly from their phenotypes.

By contrast, the loci in our example behave differently because they are linked. Alleles at different loci on a given chromosome tend to be inherited together because chromosomes pair and separate during meiosis as units and therefore tend to be inherited as units. If linkage were complete, only parental type flies, with gray bodies and normal wings (*BbVv*), or black bodies and vestigial wings (*bbvv*), would be produced. However, in our example, the progeny also include some gray-bodied, vestigial-winged flies and some black-bodied, normal-winged flies. These are recombinant type flies, having received a recombinant gamete from the heterozygous F₁ parent. Each recombinant gamete arose by crossing-over between these loci in a meiotic cell of a heterozygous female² fly. Recall from

²Fruit flies are unusual in that crossing-over occurs only in females and not in males. It is far more common for crossing-over to occur in both sexes of a species.

Chapter 9 that when chromosomes pair and undergo synapsis, **crossing-over** occurs as homologous (nonsister) chromatids exchange segments of chromosomal material by a process of breakage and rejoining (Fig. 10–11).

Figure 10–11 Crossing-over. The exchange of segments between chromatids of homologous chromosomes permits the recombination of linked genes. Genes located far apart on a chromosome have a greater probability of being separated by an exchange of segments than do genes that are closer together.

The linear order of linked genes on a chromosome is determined by calculating the frequency of crossing-over

In our example, about 20% of the offspring are recombinant types: gray flies with vestigial wings, *Bbvv* (approximately 10% of the total); and black flies with normal wings, *bbVv* (also about 10% of the total). The remaining 80% are parental types. These data can be used to calculate the percentage of crossing-over between the loci. This is done by adding the number of individuals in the two recombinant classes of offspring (10 + 10), dividing by the *total number of offspring* (40 + 40 + 10 + 10), and multiplying by 100. Thus, the *V* locus and the *B* locus have 20% recombination between them.

During a single meiotic division, several exchanges may occur at different points along the length of each homologous chromosome pair. In general, a crossover is more likely to occur between two loci if they are far apart on the chromosome and less likely to occur if they are close together. Because this rough correlation exists between the frequency of recombination between two loci and the linear distance between them, a genetic map of the chromosome can be generated by converting the percentage of recombination to **map units**. By convention, 1% recombination between two loci equals a distance of 1 map unit, so the loci in our example are 20 map units apart.

The frequencies of recombination between specific linked loci have been measured in a number of species. All of the experimental results are consistent with the hypothesis that

Figure 10–12 Gene mapping. Gene order (i.e., which locus lies between the other two) is determined by the percentage of recombination between each of the possible pairs. In this hypothetical example, the percentage of recombination between locus *A* and locus *B* is 5% (corresponding to 5 map units) and that between *B* and *C* is 3% (3 map units). If the recombination between *A* and *C* is 8% (8 map units), *B* must be in the middle. However, if the recombination between *A* and *C* is 2%, then *C* must be in the middle.

genes are present in a linear order in the chromosomes. Figure 10–12 illustrates the traditional method for determining the order of genes in a chromosome.

More than one crossover between two loci in a single tetrad can occur in a given cell undergoing meiosis. We can observe only the frequency of offspring receiving recombinant gametes from the heterozygous parent, not the actual number of crossovers. In fact, the actual frequency of crossing-over is slightly more than the observed frequency of recombinant gametes. This is because the simultaneous occurrence of two crossovers involving the same two homologous chromatids reconstitutes the original combination of genes (Fig. 10–13). When two loci are relatively close together, this effect is minimized.

The genes in a particular chromosome tend to be inherited together and, therefore, are said to constitute a **linkage group**. The number of linkage groups determined by genetic tests is equal to the number of pairs of chromosomes. By putting together the results of many crosses, scientists painstakingly developed detailed linkage maps for a number of eukaryotes, including the fruit fly (which has four pairs of chromosomes), the mouse, yeast, and *Neurospora* (a fungus). In addition, special genetic methods have made possible the de-

velopment of a detailed map for *Escherichia coli*, a bacterium with a single, circular DNA molecule, and a number of other prokaryotes and viruses. Much more sophisticated maps of chromosomes have been made by means of recombinant DNA technology (see Chapter 14). These methods have been particularly useful in producing maps of human chromosomes through the Human Genome Project (see Chapter 15).

SEX IS COMMONLY DETERMINED BY SPECIAL SEX CHROMOSOMES

Mechanisms of sex determination vary considerably (see *Making the Connection: Mechanisms of Sex Determination*). Most animals have special sex chromosomes. Typically, members of one sex (the **homogametic** sex) have a pair of similar sex chromosomes and produce gametes that are all identical in sex chromosome constitution. The members of the other sex (the **heterogametic** sex) have two different sex chromosomes and produce two kinds of gametes, each bearing a single kind of sex chromosome.

The females of many animal species (including humans) are homogametic; their cells contain two **X chromosomes**. In contrast, the males are **heterogametic**, having a single X chromosome and a smaller **Y chromosome**. Human males have 22 pairs of **autosomes**, which are chromosomes other than the sex chromosomes, plus one X chromosome and one Y chromosome; females have 22 pairs of autosomes plus two X chromosomes.

The Y chromosome determines male sex in most species of mammals

Do human males have a male phenotype because they have only one X chromosome or because they have a Y chromosome? Much of the evidence bearing on this question comes from studies of persons with abnormal sex chromosome constitutions (see Chapter 15). A person with an XXY constitution is a nearly normal male in external appearance but has underdeveloped testes (Klinefelter syndrome). A person with one X but no Y chromosome has the appearance of an immature female (Turner syndrome). An embryo with a Y but no X does not survive. Hence all individuals require at least one X, and the Y is the male-determining chromosome. In fact, several genes on the Y that are involved in male determination have been identified.

The X and Y chromosomes are not truly homologous, that is, they are not similar in size, shape, and genetic constitution. However, they have a short homologous “pairing region” that allows them to synapse and separate from one another during meiosis. Half the sperm contain an X chromosome and half contain a Y chromosome. All normal eggs bear a single X chromosome (Fig. 10–14). Fertilization of an X-bearing egg by an X-bearing sperm results in an XX (female) zygote; fertilization by a Y-bearing sperm results in an XY (male) zygote.

Figure 10–13 Double crossing-over. If the same homologous chromatids undergo double crossing-over between the genes of interest, recombinant gametes are not formed.

MAKING THE CONNECTION

MECHANISMS OF SEX DETERMINATION

What determines the sex of an organism? Genes are the most important sex determinants in most organisms, although in some species sex is controlled mainly by the environment. The major sex-determining genes of most animals are carried by sex chromosomes.

An XX/XY sex chromosome mechanism, similar to that of humans, operates in many species of animals. However, it is not universal, and many of the details may vary. For example, the fruit fly, *Drosophila*, has homogametic (XX) females and heterogametic (XY) males, but the Y is not male-determining; a fruit fly with an X chromosome and no Y chromosome has a male phenotype. In birds and butterflies the mechanism is reversed, with homogametic males (the equivalent of XX) and heterogametic females (the equivalent of XY).

In **hermaphroditic** organisms, organs of both sexes are found in the same individual. Hermaphroditic animals (see Chapters 28, 29, and 48) do not have sex chromosomes. Most flowering plants are hermaphrodites. The male and female sexual organs may be in the same flowers. If they are in separate flowers on the same plant, the plants are said to be **monoecious**; corn, walnuts, and oaks are examples. Far fewer flowering plants are **dioecious**, having male and female floral organs on separate plants. A few dioecious plants, such as asparagus, apparently have sex chromosomes, although they are not necessarily comparable to those of animals.

We would expect to have equal numbers of X- and Y-bearing sperm and a 1:1 ratio of females to males. In fact, however, more males are conceived than females and more males die before birth. Even at birth the ratio is not 1:1; about 106 boys are born for every 100 girls. It is not known why this occurs, but the Y-bearing sperm is assumed to have some competitive advantage.

Figure 10-14 Sex is determined by the sperm. An X-bearing sperm produces a female; a Y-bearing sperm produces a male.

X-linked genes have unusual inheritance patterns

The human X chromosome contains many loci that are required in both sexes, whereas the Y chromosome contains only a few genes, including one or more genes for maleness. Genes located in the X chromosome, such as colorblindness and hemophilia, are sometimes called **sex-linked** genes. It is more appropriate, however, to refer to them as **X-linked** genes because they follow the transmission pattern of the X chromosome and, strictly speaking, are not linked to the sex of the organism per se.

A female receives one X from her mother and one X from her father. A male receives his Y chromosome, which makes him male, from his father. From his mother he inherits a single X chromosome and therefore all of his X-linked genes. In the male, every X chromosome allele present is expressed, whether that allele was dominant or recessive in the female parent. A male is neither homozygous nor heterozygous for his X-linked loci; instead he is always **hemizygous** for every X-linked locus (*hemi* means "half").

We will use a simple system of notation for problems involving X linkage, indicating the X and incorporating specific alleles as superscripts. For example, the symbol X^c signifies a recessive X-linked allele for colorblindness and X^C the dominant X-linked allele for normal color vision. The Y chromosome is written without superscripts because it does not carry the locus of interest. Two recessive X-linked alleles must be present in a female for the abnormal phenotype to be expressed, whereas in the hemizygous male a single abnormal allele is expressed. As a practical consequence, these abnormal alleles are usually expressed only in male offspring, although they may be carried by a female.

To be expressed in a female, a recessive X-linked allele must be inherited from both parents. A colorblind female, for

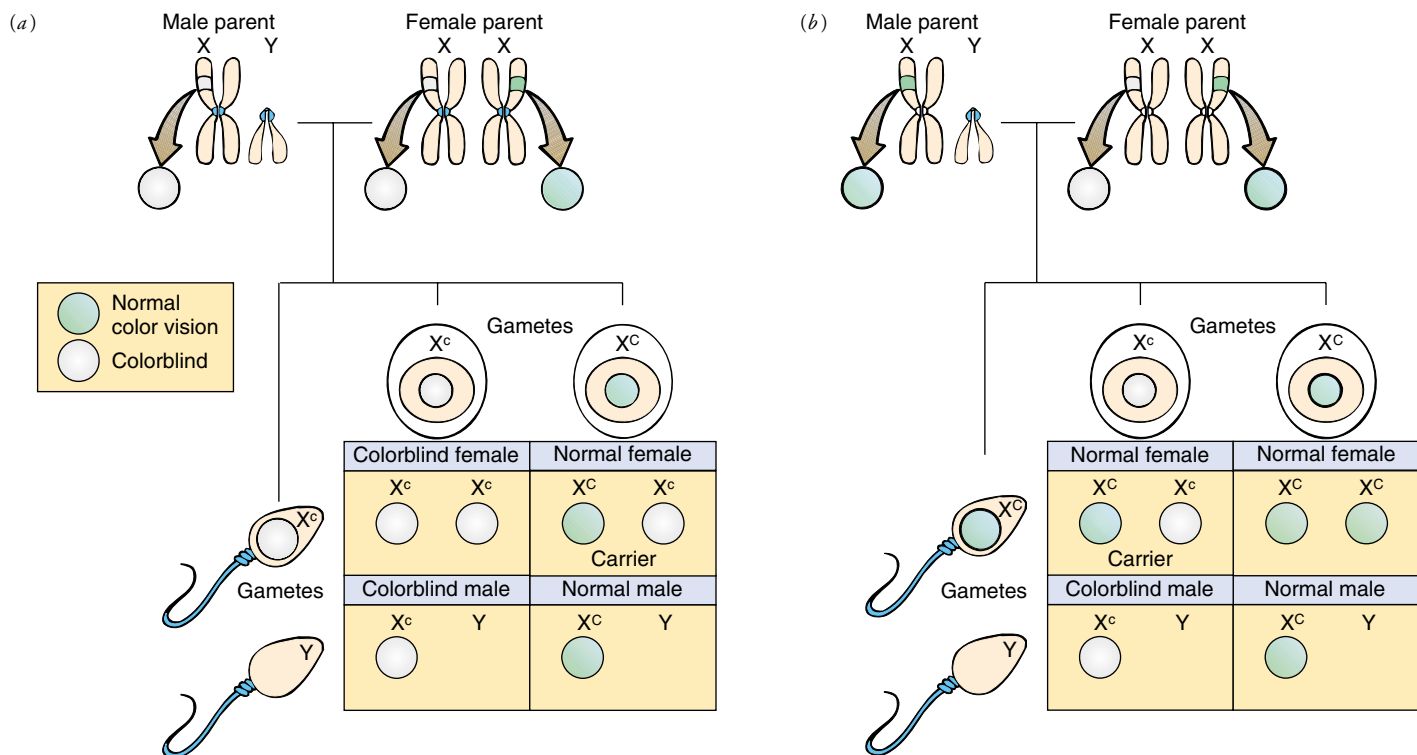

Figure 10–15 X-linked recessive colorblindness. Note that the Y chromosome does not carry a gene for color vision. (a) To be colorblind, a female must inherit alleles for colorblindness from both parents. (b) If a normal male mates with a carrier female, one-half of their sons would be expected to be colorblind and one-half of their daughters would be expected to be carriers.

example, must have a colorblind father and a mother who is heterozygous or homozygous for colorblindness (Fig. 10–15). Such a combination is unusual. In contrast, a colorblind male need only have a mother who is heterozygous for colorblindness; his father can be normal. Hence, X-linked recessive traits are generally much more common in males than in females, a fact that may partially explain why human male embryos are more likely to die.

Dosage compensation equalizes the expression of X-linked genes in males and females

The X chromosome contains numerous genes required by both sexes, yet a normal female has two copies (“doses”) for each locus, whereas a normal male has only one. **Dosage compensation** is a mechanism that makes the two doses in the female and the single dose in the male equivalent. Male fruit flies accomplish this by making their single X chromosome more active. In most tissues the metabolic activity of a single male X chromosome is equal to the combined metabolic activity of the two X chromosomes present in the female.

Dosage compensation in mammals generally involves inactivation of one of the two X chromosomes in the female. During interphase a dark spot of chromatin, called a **Barr**

body, is visible at the edge of the nucleus of each female mammalian cell (Fig. 10–16). The Barr body has been found to represent a dense, dark-staining, and metabolically inactive X chromosome. The other X chromosome resembles the metabolically active autosomes; during interphase it is a greatly extended thread that is not evident by light microscopy. From this and other evidence, the British geneticist Mary Lyon has suggested that in any one cell of a female mammal, only one of the two X chromosomes is active; the other is inactive and

Figure 10–16 A Barr body. The darkly-stained Barr body (arrow) at the edge of the nucleus in this LM is an inactivated X chromosome. The entire cell is not shown. (Omikron/Photo Researchers, Inc.)

Figure 10–17 A calico cat. This cat has X-linked genes for both black and yellow (or orange) pigmentation of the fur, but because of random X chromosome inactivation, black is expressed in some clones of cells and yellow (or orange) is expressed in others. Because other genes affecting fur color are also present, white patches are usually evident as well. (Larime Photographic/Dembinsky Photo Associates)

is visible as a Barr body. (Actually, X chromosome inactivation is never complete; a small fraction of the genes are expressed.)

Because only one X chromosome is active in any one cell and because X chromosome inactivation is a random event, a female mammal that is heterozygous at an X-linked locus expresses one of the alleles in about half her cells and the other allele in the other half. This is sometimes (but not always) evident in the phenotype. Mice and cats have several X-linked genes for certain coat colors. Females that are heterozygous for such genes may show patches of one coat color in the midst of areas of the other coat color. This phenomenon, termed **variegation**, is evident in calico (Fig. 10–17) and tortoiseshell cats. Early in development, when relatively few cells are present, X chromosome inactivation occurs randomly in each cell. When any one of these cells divides by mitosis, the cells of the resulting clone (group of genetically identical cells) all have the same active X chromosome, and, therefore, a patch of cells that all express the same color develops.

Why, you might ask, is variegation not always apparent in females heterozygous at X-linked loci? The answer is that, although variegation usually occurs, we may need to use special techniques to observe it. For example, colorblindness is due to abnormal pigments in the cone cells in the retina of the eye (Chapter 41). In at least one type of red-green colorblindness, the retina of a heterozygous female actually contains patches of abnormal cones, but the patches of normal cones are sufficient to provide normal color vision.

Sex-influenced genes are autosomal, but their expression is affected by the individual's sex

Not all characteristics that differ in the two sexes are X-linked. Certain **sex-influenced** traits are inherited through autosomal genes, but the *expression* of alleles at these loci can be altered or influenced by the sex of the animal. Therefore, males and females with the same genotype with respect to these loci may have different phenotypes.

Pattern baldness in humans, characterized by premature loss of hair on the front and top of the head, but not on the sides, is far more common among males than among females. It has been proposed that a single pair of alleles is involved, with the allele responsible for pattern baldness being dominant in males and recessive in females. Because of this unusual situation, we modify our notation, designating the pattern baldness allele as B_1 and the allele for normal hair growth as B_2 . Individuals with the genotype B_1B_1 show pattern baldness, regardless of sex. Persons with a B_1B_2 genotype are bald if they are male but not bald if they are female. Individuals with the genotype B_2B_2 are not bald, regardless of sex.

Evidence suggests that the expression of most sex-influenced traits is strongly modified by sex hormones. For example, male hormones (see Chapter 48) are strongly implicated in the expression of pattern baldness.

THE RELATIONSHIP BETWEEN GENOTYPE AND PHENOTYPE IS OFTEN COMPLEX

The relationship between a given locus and the characteristic it controls may be simple: a single pair of alleles of a locus may regulate the appearance of a single characteristic of the organism (e.g., tall versus short in garden peas). Alternatively, the relationship may be more complex: a pair of alleles may participate in the control of several characteristics, or alleles of many loci may cooperate to regulate the appearance of a single characteristic. Not surprisingly, these more complex relationships are quite common.

As you will learn in Chapters 11 and 12, each locus is a segment of DNA in which genetic information is stored. Most loci code for specific types of proteins, and it is the presence of a protein, such as an enzyme, that usually provides the chemical basis for the genetic trait. Because most biologically important molecules are synthesized by complex metabolic pathways requiring a number of enzymes, it is not difficult to appreciate why relationships between genes and the characteristics of the organism are complex.

We may assess the phenotype on one or many levels. It may be a morphological characteristic such as shape, size, or color. It may be a physiological characteristic or even a biochemical trait, such as the presence or absence of a specific enzyme required for the metabolism of some specific molecule.

Figure 10–18 Incomplete dominance in Japanese four o’clocks. If a pair of alleles is incompletely dominant to each other, a heterozygote has a phenotype intermediate between its parents. Two incompletely dominant alleles, R^1 and R^2 , are responsible for red, white, and pink flower colors. Red-flowered plants are R^1R^1 ; white-flowered plants are R^2R^2 , and heterozygotes (R^1R^2) are pink. Note that uppercase notation is used for both alleles, because neither is recessive to the other.

In addition, the phenotypic expression of genes may be altered by changes in the environmental conditions under which the organism develops.

Dominance is not always complete

Studies of the inheritance of many traits in a wide variety of organisms have clearly shown that one member of a pair of alleles may not be completely dominant to the other. In such instances it is improper to use the terms *dominant* and *recessive*.

For example, the plants commonly known as Japanese four o’clocks may have red or white flowers. Each color breeds true when these plants are self-pollinated. What flower color might we expect in the offspring of a cross between a red-flowering plant and a white-flowering one? Without knowing which is dominant, we might predict that all would have red flowers or all would have white flowers. This cross was first made by the German botanist Karl Correns (one of the rediscoverers of Mendel’s work), who found that all F₁ offspring have pink flowers! Does this result in any way prove that Mendel’s assumptions about inheritance are wrong? Did the parental characteristics blend inseparably in the offspring? Quite the contrary, for when two of these pink-flowered plants are crossed, red-flowered, pink-flowered, and white-flowered offspring appear in a ratio of 1:2:1 (Fig. 10–18).

In this instance, as in all other aspects of the scientific process, results that differ from those predicted prompt scientists to reexamine and modify their assumptions to account for the exceptional results. The pink-flowered plants are clearly the heterozygous individuals, and neither the red allele nor the white allele is completely dominant. When the heterozygote has a phenotype that is intermediate between those of its two parents, the genes are said to show **incomplete dominance**. In these crosses the genotypic and phenotypic ratios are identical.

Incomplete dominance is not unique to Japanese four o’clocks. Red- and white-flowered sweet pea plants also produce pink-flowered plants when crossed, and numerous additional examples of incomplete dominance are known in both plants and animals.

In both cattle and horses, reddish coat color is not completely dominant to white coat color. Heterozygous individuals have a mixture of reddish colored hairs and white hairs, which is called roan. If you saw a white mare nursing a roan foal, what would you guess was the coat color of the foal’s father? Because the reddish and white colors are expressed independently (hair by hair) in the roan heterozygote, we sometimes refer to this as a case of **codominance**. Strictly speaking, incomplete dominance refers to instances in which the heterozygote is intermediate in phenotype, and codominance refers to instances in which the heterozygote simultaneously

expresses the phenotypes of both types of homozygotes. The human ABO blood group (see Chapter 15) provides a classic example of codominant alleles, as well as an example of a locus with multiple alleles.

Multiple alleles for a locus may exist in a population

The examples given so far have dealt with situations in which each locus was represented by a maximum of two allelic variants, and in most of these examples one of the alleles has been dominant and one recessive. It is true that a single diploid individual has a maximum of two different alleles for a particular locus and that a haploid gamete has only one allele for each locus. However, if we survey a population, we may find more than two alleles for a particular locus. If three or more alleles for a given locus exist within the population, we say that locus has **multiple alleles**. A great many loci can be shown to have multiple alleles if the population is surveyed carefully. Some alleles can be identified by the activity of a certain enzyme or by some other biochemical feature but do not produce an obvious phenotype. Others produce a readily recognizable phenotype, and certain patterns of dominance can be discerned when the alleles are combined in various ways.

In rabbits, for example, a *C* allele causes a fully colored coat. The homozygous recessive genotype, *cc*, causes albino coat color. There are two additional allelic variants of the same locus, *c^b* and *c^{ch}*. The genotype *c^bc^b* causes the “Himalayan” pattern, in which the body is white but the tips of the ears, nose, tail, and legs are colored (similar to the color pattern of a Siamese cat). An individual with the genotype *c^{ch}c^{ch}* has the “chinchilla” pattern, in which the entire body has a light gray color. On the basis of the results of genetic crosses, these alleles can be arranged in the following series: *C* > *c^b* > *c^{ch}* > *c*. Each allele is dominant to those following it and recessive to those preceding it. For example, a *c^bc^{ch}* rabbit has the “Himalayan” pattern, whereas a *c^{ch}c* rabbit has the “chinchilla” pattern. In some other series of multiple alleles, certain alleles may be codominant and others incompletely dominant; hence the heterozygotes commonly have phenotypes intermediate between those of their parents.

A single gene may affect multiple aspects of the phenotype

In the examples presented so far, the relationship between a gene and its phenotype has been direct, precise, and exact, and the loci considered have controlled the appearance of single traits. However, the relationship of gene to characteristic may be quite complex. Most genes probably have many different effects, a quality referred to as **pleiotropy**. This is dramatically evident in many genetic diseases, such as cystic fibrosis and sickle cell anemia (see Chapter 15), in which multiple symptoms are caused by a single pair of alleles. Most cases of pleiotropy can be traced to a single fundamental cause. For example, a defective enzyme may affect the functioning of many types of cells.

Alleles of different loci may interact to produce a phenotype

Several pairs of alleles may interact to affect a single phenotype, or one pair may inhibit or reverse the effect of another pair. More than 12 pairs of alleles interact in various ways to produce coat color in rabbits, and more than 100 pairs are concerned with eye color and shape in fruit flies.

One type of gene interaction is illustrated by the inheritance of combs in poultry, where two genes may interact to produce a novel phenotype (Fig. 10–19). The allele for a rose comb, *R*, is dominant to that for a single comb, *r*. An unlinked gene pair governs the inheritance of a pea comb, *P*, versus a single comb, *p*. A single-combed fowl must therefore be homozygous for the recessive allele at both loci (*pprr*); a pea-combed fowl is either *PPrr* or *Pprr*; and a rose-combed fowl is either *ppRR* or *PpRr*. When an *R* and *P* occur together, the phenotype is neither a pea nor a rose comb but a completely different type, called a *walnut comb*. The walnut comb phenotype is produced whenever a fowl has one or two *R* alleles, plus one or two *P* alleles (that is, *PPRR*, *PpRR*, *PPRr*, or *PpRr*). What would you predict about the types of combs among the offspring of two heterozygous walnut-combed fowl, *PpRr*? How does this form of gene interaction affect the ratio of phenotypes in the *F*₂ generation? Is it the typical Mendelian 9:3:3:1 ratio?

Figure 10–19 Gene interaction. Two gene pairs govern these types of genetically determined combs in roosters. Note that four genotypes—*PPRR*, *PpRR*, *PPRr*, and *PpRr*—all have walnut combs.

Epistasis is a common type of gene interaction in which the presence of certain alleles of one locus can prevent the expression of alleles of a different locus. (Literally, epistasis means “standing upon.”) We have already seen that coat color in guinea pigs can be determined by the *B* and *b* allelic pair, with the *B* allele for black coat dominant to the *b* allele for brown coat. The expression of either phenotype, however, depends on the presence of a dominant allele at yet another locus. This allele, *C*, codes for the enzyme tyrosinase, which converts a colorless precursor to the pigment melanin and hence is required for the production of any kind of pigment. The recessive allele (*c*) codes for an inactive form of the enzyme. Thus, an animal that is homozygous recessive for this allele lacks the enzyme and produces no melanin. It is therefore a white-coated, pink-eyed albino, regardless of the combination of *B* and *b* alleles. Albinism, or lack of melanin pigment, is not restricted to guinea pigs, but is found in humans (see Chapter 15 introduction) and a variety of other animals (Fig. 10–20).

When an albino guinea pig with the genotype *ccBB* is mated to a brown guinea pig with the genotype *CCbb*, the *F*₁ generation is black coated, *CcBb*. When two such animals are mated, their offspring appear black-coated, brown-coated, and albino in a ratio of 9:3:4. (Make a Punnett square to verify this.)

You might wonder why heterozygous *Cc* individuals do not show at least some lightening of the coat color, given the fact that they produce only about half the normal amount of tyrosinase enzyme. It turns out that half the normal amount of enzyme is usually adequate to produce normal amounts of pigment. This type of situation applies to many enzymes, and explains many (although certainly not all) cases of dominance.

Polygenes act additively to produce a phenotype

The inherited components of many human characteristics, such as height, body form, and skin color, are not inherited through alleles at a single locus. The same holds true for many commercially important characteristics in domestic plants and animals, such as milk and egg production. Alleles at several, perhaps many, different loci affect each characteristic. The term **polygenic inheritance** is applied when multiple independent pairs of genes have similar and additive effects on the same characteristic.

Polygenes are responsible for the inheritance of skin color in humans. It is now thought that alleles representing four or more different loci are involved in determining skin color, but for simplicity the principle of polygenic inheritance can be illustrated with pairs of alleles at only three unlinked loci (Fig 10–21). These can be designated *A* and *a*, *B* and *b*, and *C* and *c*. The capital letters represent incompletely dominant alleles producing dark skin. The more capital letters, the darker the skin, because the alleles affect skin color in an additive fashion. A person with the darkest skin would have the genotype *AABBCC*, and a person with the lightest skin would have the genotype *aabbcc*. The *F*₁ offspring of an *aabbcc* person and an

Figure 10–20 Epistasis. Homozygous alleles for albinism exhibit epistasis, masking the expression of alleles of other loci that govern production of melanin pigment. Albino individuals, such as this albino koala, occur occasionally in nature. (Tom McHugh/Photo Researchers, Inc.)

AABBCC person are all *AaBbCc* and have an intermediate skin color. The *F*₂ offspring of two such triple heterozygotes would have skin colors ranging from very dark to very light.

Polygenic inheritance is therefore characterized by an *F*₁ generation that is intermediate between the two completely homozygous parents and by an *F*₂ generation that shows wide variation between the two parental types. Most of the *F*₂-generation individuals have one of the intermediate phenotypes; only a few show the extreme phenotypes of the grandparents (*P* generation). On average, only 1 of 64 is as dark as the very dark grandparent, and only 1 of 64 is as light as the very light grandparent (Fig. 10–22). The alleles *A*, *B*, and *C* each produce about the same amount of darkening of the skin; hence, the genotypes *AaBbCc*, *AABbcc*, *AAbbCc*, *AaBBcc*, *aaBBCC*, *AabbCC*, and *aaBbCC* all produce similar intermediate phenotypes.

The model used here for the inheritance of skin color in humans is a rather simple example of polygenic inheritance because only three major allelic pairs are used. The inheritance of height in humans involves alleles representing ten or more

Figure 10–21 Polygenic inheritance. This simplified model assumes that skin color in humans is governed by alleles of three unlinked loci. The alleles producing dark skin (*A*, *B*, and *C*) are represented by capital letters, but they are not dominant. Instead they have additive effects. If one parent is very dark and the other very light, their children (*F*₁) are intermediate in skin color. A wide range of skin colors are expected in the *F*₂. The number of dark dots (each signifying an allele producing dark skin) is counted to determine the phenotype. The results are summarized in Figure 10–22.

loci. Because many allelic pairs are involved and because height is modified by a variety of environmental conditions, the height of adults ranges from perhaps 125 to 215 cm. If we were to measure the heights of 1000 adult American men selected at random, we would find that only a few are as tall as

215 cm or as short as 125 cm. The heights of most would cluster around the mean, about 170 cm. When the number of men at each height is plotted against height (in centimeters) and the points are connected, the result is a bell-shaped curve, called a **normal distribution curve** (Fig. 10–23).

Figure 10-22 Distribution of phenotypes in polygenic inheritance. The bars indicate the expected phenotypic ratios in the F_2 generation shown in Figure 10-21. This expected distribution of phenotypes is consistent with the superimposed normal curve.

Figure 10-23 Polygenic inheritance in a population. The distribution of heights of 1083 adult males approximates a normal curve, which is consistent with continuous phenotypic variation in the population. The bars indicate the actual number of men whose heights were within the unit range. For example, there were 163 men whose heights were between 170 and 173 cm.

SELECTION, INBREEDING, AND OUTBREEDING ARE USED TO DEVELOP IMPROVED STRAINS

How do geneticists go about establishing a breed of cow that will give more milk, a strain of hens that will lay bigger eggs, or a variety of corn with more kernels per ear? By selecting organisms that manifest the desired phenotype and using these organisms in further matings, a true-breeding strain with the commercially advantageous phenotype is gradually developed. Such a strain is expected to be homozygous for all of the genes involved, whether they be dominant, recessive, or additive in their effects.

There is a limit to the effectiveness of breeding by selection. When a strain becomes homozygous for all of the genes involved, further selective breeding cannot increase the desired quality. Moreover, because of **inbreeding**—the mating of two closely related individuals—the strain may become homozygous for multiple undesirable traits as well. Evidence suggests that human inbreeding increases the frequency of genetic dis-

ease in the population, although the individual risk is relatively small (Chapter 15).

The mating of individuals of totally unrelated strains, termed **outbreeding**, frequently leads to offspring much better adapted for survival than either parent. Such improvement reflects a phenomenon called **hybrid vigor**. A large proportion of the corn, wheat, and other crops grown in the United States consists of hybrid strains. Each year the seed to grow these crops must be obtained by mating the original strains. The hybrids are heterozygous at a great many loci and give rise, even when self-fertilized, to a wide variety of forms, few of which are as good as the original hybrid. (The seeds produced by F_1 hybrid corn plants are not normally planted, but eaten instead!)

The reason for hybrid vigor has long been a matter of debate, and, in fact, there may be multiple causes. One explanation may be that each of the parental strains is homozygous for certain undesirable recessive genes, but any two strains are homozygous for different undesirable genes. Each strain contains dominant genes to make up for the recessive undesirable genes of the other strain. The hybrid offspring would express

FOCUS ON

SOLVING GENETICS PROBLEMS

Simple Mendelian genetics problems are like puzzles. They can be fun and easy to work if you follow certain conventions and are methodical in your approach.

1. Always use standard designations for the generations. The generation with which a particular genetic experiment is begun is called the P, or *parental, generation*. Offspring of this generation (the “children”) are called the F₁, or *first filial, generation*. The offspring resulting when two F₁ individuals are bred constitute the F₂, or second filial, generation (the “grandchildren”).
2. Write down a key for the symbols you are using for the allelic variants of each locus. Use uppercase to designate a dominant allele and lowercase to designate a recessive allele. Use the same letter of the alphabet to designate both alleles of a particular locus. If you are not told which is dominant and which is recessive, the phenotype of the F₁ generation is a good clue.
3. Determine the genotypes of the parents of each cross by making use of the following types of evidence:
 - a. Are they from true-breeding lines? If so, they should be homozygous.
 - b. Can their genotypes be reliably deduced from their phenotypes? This is usually true if they express the recessive phenotype.
 - c. Do the phenotypes of their offspring provide any information? See *Focus On: Deducing Genotypes* for an exam-

ple of how these determinations can be made.

4. Indicate the possible kinds of gametes formed by each of the parents. It is helpful to draw a circle around the symbols for each kind of gamete.
 - a. If it is a monohybrid cross, we must apply the principle of segregation; i.e., a heterozygote *Aa* forms two kinds of gametes: *A* and *a*. Of course a homozygote, such as *aa*, forms only one kind of gamete: *a*.
 - b. If it is a dihybrid cross, we must apply both the principle of segregation *and* the principle of independent assortment. For example, an individual heterozygous for two loci would have the genotype *AaBb*. *A* segregates from *a*, and *B* segregates from *b*. The assortment of *A* and *a* into gametes is independent of the assortment of *B* and *b*. Therefore *A* is equally likely to end up in a gamete with *B* or *b*. The same is true for *a*.

5. Set up a Punnett square, placing the possible types of gametes from one parent down the left side and the possible types from the other parent across the

top.

6. Fill in the Punnett square and read off (and sum up) the genotypic and phenotypic ratios of the offspring. Avoid confusion by consistently placing the dominant allele first and the recessive allele second in heterozygotes (*Aa*, never *aA*). If it is a dihybrid cross, it is very important to always write the two alleles of one locus first and the two alleles of the other locus second. It does not matter which locus you choose to write first, but once you have decided on the order, it is critical that you maintain it consistently. This means that if the individual is heterozygous for both loci you will always use the form *AaBb*. Writing this particular genotype as *aBbA*, for example, would cause confusion.
7. If you do not need to know the frequencies of all of the expected genotypes and phenotypes, you may use the rules of probability as a shortcut. For example, if both parents are *AaBb*, what is the probability of an *AABB* offspring? To be *AA*, the offspring must receive an *A* gamete from each parent. The probability that a given gamete is *A* is 1/2 and each gamete represents an independent event, so we combine their probabilities by multiplying ($1/2 \times 1/2 = 1/4$). The probability of *BB* is calculated similarly and is also 1/4. The probability of *AA* is independent of the probability of *BB*, so again we use the product rule to obtain their combined probabilities ($1/4 \times 1/4 = 1/16$).

all the desirable (dominant) traits and none of the undesirable (recessive) traits of the two parental strains.

Alternatively, hybrid vigor may be due to **heterozygote advantage**, i.e., the superiority of the heterozygous genotype to either homozygous genotype. The key may be that a particular allele may have advantages under one set of conditions, but that a different allele may be favored when conditions change. Therefore an individual with two different alleles for a locus may be able to function over a wider range of conditions. This view is supported by experimental evidence that the metabolism of an individual heterozygous at many loci tends to be more stable and less affected by environmental changes.

A case of heterozygote advantage with a rather specific explanation is seen in humans who are heterozygous for the recessive sickle cell anemia allele (*s*) and the normal dominant allele (*S*). These *Ss* individuals appear to have increased resistance to the parasite that lives inside red blood cells and causes malaria. Such resistance is a significant advantage in areas of the world where malaria is still uncontrolled. Homozygous normal individuals (*SS*) appear to be less resistant to malaria; homozygous sickle cell individuals (*ss*) are at a distinct disadvantage due to severe anemia and other serious effects of the sickle cell allele (see Chapters 15 and 18).

FOCUS ON

DEDUCING GENOTYPES

The science of genetics resembles mathematics in that it consists of a few basic principles, which, once grasped, enable the student to solve a wide variety of problems. Very often the genotypes of the parents can be deduced from the phenotypes of their offspring. In chickens, for example, the allele for rose comb (R) is dominant to the allele for single comb (r). Suppose that a cock is mated to three different hens, as shown in the figure. The cock and hens A and C have rose combs; hen B has a single comb. Breeding the cock with hen A produces a rose-combed chick, with hen B a single-combed chick, and with hen C a single-combed chick. What types of offspring can be expected from further matings of

the cock with these hens?

Because the allele for single comb, r , is recessive, all of the hens and chicks that are phenotypically single-combed must be rr . We can deduce that hen B and the offspring of hens B and C are genotypically rr .

All individuals that are phenotypically rose-combed must have at least one R allele. The fact that the offspring of the cock and hen B was single-combed proves that the cock is heterozygous Rr , because, although the single-combed chick received one r allele from its mother, it must have received the second one from its father.

The fact that the offspring of the cock and hen C had a single comb proves that hen C is heterozygous, Rr . It is impossible

to decide from the data given whether hen A is homozygous RR or heterozygous Rr ; further breeding would be necessary to determine this. (Can you suggest an appropriate mating?)

Additional matings of the cock with hen B should result in half rose-combed and half single-combed individuals; additional matings of the cock with hen C should produce three-fourths rose-combed and one-fourth single-combed chicks.

Using phenotypes to deduce genotypes. In many cases the phenotypes of the offspring can provide information on the genotypes of the parents.

S U M M A R Y W I T H K E Y T E R M S

- I. **Genetics** is the study of the structure, expression, and transmission of genetic information. The transfer of genetic information from parent to offspring is called **heredity**.
- II. Mendel's inferences about inheritance obtained from his garden pea-breeding experiments have been tested repeatedly in all kinds of diploid organisms and found to be generally true. These principles have been extended and now can be stated in a more modern form.
 - A. Today we know that the genes are in chromosomes; the site a gene occupies in the chromosome is its **locus**.
 - B. Different forms of a particular gene are **alleles**; they occupy corresponding loci on homologous chromosomes. Genes therefore exist as pairs of alleles in diploid individuals.
 - C. An individual that carries two identical alleles is said to be **homozygous** for that locus. If the two alleles are different, that individual is said to be **heterozygous** for that locus.
 - D. One allele (the **dominant allele**) may mask the expression of the other allele (the **recessive allele**) in a heterozygous individual. For this reason two individuals with the same appearance (**phenotype**) may differ from each other in genetic constitution (**genotype**).
 - E. Dominance does not always apply, and alleles can be **incompletely dominant**, in which the heterozygote is intermediate in phenotype, or **codominant**, in which the heterozygote simultaneously expresses the phenotypes of both homozygotes.
 - F. According to Mendel's **principle of segregation**, during meiosis the alleles for each locus separate, or segregate, from each other as the homologous chromosomes separate. When haploid gametes are formed, each contains only one allele for each locus.
 - G. According to Mendel's **principle of independent assortment**, alleles of different loci are distributed randomly into the gametes. This can result in recombination, that is, production of new gene combinations that were not present in the parental (P) generation.
 - H. Each chromosome behaves genetically as if it were composed of genes arranged in a linear order. Genes in the same chromosome are **linked**.
 1. Recombination of linked genes can occur as a result of **crossing-over** (breaking and rejoining of homologous chromatids) in meiotic prophase I.
 2. By measuring the frequency of recombination between linked genes, it is possible to construct a genetic map of a chromosome.
 - I. A cross between homozygous parents (**P generation**) that differ from each other with respect to their alleles at one locus is called a **monohybrid cross**; if they differ at two loci, it is a **dihybrid cross**.
 1. The first generation of offspring is heterozygous and is called the first filial, or **F₁ generation**; the generation produced by a cross of two F₁ individuals is the second filial, or **F₂ generation**.
 2. A **test cross** is between an individual of unknown genotype (or an F₁ individual) and a homozygous recessive individual.
- III. Genetic ratios can be expressed in terms of probabilities.
 - A. Any probability is expressed as a fraction or decimal fraction, calculated as the number of favorable events divided by the total number of events. This can range from 0 (an impossible event) to 1 (a certain event).
 - B. According to the **product rule**, the probability of two independent events occurring together can be obtained by multiplying the probabilities of each occurring separately.
 - C. According to the **sum rule**, the probability of an outcome that can be obtained in more than one way can be calculated by adding the separate probabilities.
- IV. The sex of humans and many other animals is determined by the **X** and **Y sex chromosomes** or their equivalents. **Autosomes** are chromosomes other than sex chromosomes.
 - A. Normal female mammals have two X chromosomes; normal males have one X and one Y.
 - B. The fertilization of an X-bearing egg by an X-bearing sperm results in a female (XX) zygote. The fertilization of an X-bearing egg by a Y-bearing sperm results in a male (XY) zygote.
 - C. The Y chromosome is responsible for determining male sex in mammals.
 - D. The X chromosome contains many important genes unrelated to sex determination that are required by both males and females. A male receives all his **X-linked** genes from his mother. A female receives X-linked genes from both parents.
 - E. A female mammal shows **dosage compensation** of X-linked genes. Only one of the two X chromosomes is expressed in each cell; the other is inactive and is seen as a dark-staining **Barr body** at the edge of the interphase nucleus.
- V. **Multiple alleles** (three or more alleles that can potentially occupy a particular locus) may exist in a population. A diploid individual has any two of the alleles; a haploid individual or gamete has only one.
- VI. The relationship between a gene and its phenotype may be quite complex.
 - A. Most genes have many different effects; they are **pleiotropic**.
 - B. Many types of gene interactions are known. In **epistasis**, an allele of one locus can mask the expression of alleles of a different locus.
 - C. In **polygenic inheritance**, multiple independent pairs of genes may have similar and additive effects on the phenotype.
 1. Many human characteristics showing continuous variation, such as height and skin color, as well as many characteristics in other animals and plants, are inherited through polygenes.
 2. In polygenic inheritance, the F₁ generation is intermediate between the two parental types and shows little variation; the F₂ generation shows wide variation.
- VII. **Inbreeding**, the mating of two closely related individuals, greatly increases the probability that an individual offspring will be homozygous for one or more recessive genes. **Outbreeding**, the mating of totally unrelated individuals, increases the probability that the offspring will be heterozygous at many loci and exhibit **hybrid vigor**.

P O S T - T E S T

1. One reason why Mendel was able to discover the basic principles of inheritance is that he (a) understood the behavior of chromosomes in mitosis and meiosis (b) studied a wide variety of experimental organisms (c) began by establishing true-breeding lines (d) studied various types of linkage (e) all of the above
- 2.–5. Use the following information to answer questions 2 through 5:
In peas, the allele for round seeds (*R*) is dominant to that for wrinkled seeds (*r*); the allele for yellow seeds (*Y*) is dominant to that for green seeds (*y*). These loci are unlinked. Plants from a true-breeding line with round, green seeds are crossed with plants from a true-breeding line with wrinkled, yellow seeds. These parents constitute the P generation.
2. The genotypes of the P generation are: (a) *RRrr* and *YYyy* (b) *RrYy* (c) *RRYY* and *rryy* (d) *RRyy* and *rrYY* (e) *RR* and *YY*
3. What are the expected genotypes of the F₁ hybrids produced by the described cross? (a) *RRrr* and *YYyy* (b) *RrYy* (c) *RRYY* and *rryy* (d) *RRyy* and *rrYY* (e) *RR* and *YY*

4. What kinds of gametes can the F_1 individuals produce? (a) RR and YY (b) Rr and Yy (c) RR , rr , YY , and yy (d) R , r , Y , and y (e) RY , Ry , rY , and ry
5. What is the expected proportion of F_2 wrinkled, yellow seeds? (a) $9/16$ (b) $1/16$ (c) $3/16$ (d) $1/4$ (e) zero
6. One of the autosomal loci controlling eye color in fruit flies has two alleles, one for brown eyes and the other for red eyes. Fruit flies from a true-breeding line with brown eyes were crossed with flies from a true-breeding line with red eyes. The F_1 flies had red eyes. What conclusion can be drawn from this experiment? (a) these alleles underwent independent assortment (b) these alleles underwent segregation (c) these genes are X-linked (d) the allele for red eyes is dominant to the allele for brown eyes (e) all of the above are true
7. The F_1 flies described in question 6 were mated with red-eyed flies from a true-breeding line. What phenotypes would you expect the offspring to have? (a) all red eyes (b) all brown eyes (c) half red eyes and half brown eyes (d) red-eyed females and brown-eyed males (e) brown-eyed females and red-eyed males
8. The type of cross described in question 7 is a(n) (a) F_2 cross (b) dihybrid cross (c) test cross (d) two-point test cross (e) none of the above
9. Individuals of genotype $AaBb$ were crossed with $aabb$ individuals. Approximately equal numbers of the following classes of offspring were produced: $AaBb$, $Aabb$, $aABb$, and $aabb$. These results illustrate Mendel's principle(s) of (a) linkage (b) independent assortment (c) segregation (d) a and c (e) b and c
10. Assume that the ratio of females to males is 1:1. A couple already has two daughters and no sons. If they plan to have a total of six children, what is the probability that they will have a family of all girls? (a) $1/4$ (b) $1/8$ (c) $1/16$ (d) $1/32$ (e) $1/64$
11. Red-green colorblindness is an X-linked recessive disorder in humans. Your friend is the daughter of a colorblind father. Her mother had normal color vision, but her maternal grandfather was colorblind. What is the probability that your friend is colorblind? (a) 1 (b) $1/2$ (c) $1/4$ (d) $3/4$ (e) zero
12. When homozygous, a particular allele of a locus in rats causes abnormalities of the cartilage throughout the body, an enlarged heart, slow development, and death. This is an example of (a) pleiotropy (b) polygenic inheritance (c) epistasis (d) codominance (e) dosage compensation

REVIEW QUESTIONS

1. In peas, yellow seed color is dominant to green. Predict the phenotypes (and their proportions) of the offspring of the following crosses: (a) homozygous yellow \times green; (b) heterozygous yellow \times green; (c) heterozygous yellow \times homozygous yellow; (d) heterozygous yellow \times heterozygous yellow.
 2. If two animals heterozygous for a single pair of alleles are mated and have 200 offspring, about how many would be expected to have the phenotype of the dominant allele (i.e., to look like the parents)?
 3. When two long-winged flies were mated, the offspring included 77 with long wings and 24 with short wings. Is the short-winged condition dominant or recessive? What are the genotypes of the parents?
 4. A blue-eyed man, both of whose parents were brown-eyed, married a brown-eyed woman whose father was blue-eyed and whose mother was brown-eyed. If brown is dominant to blue, what are the genotypes of the individuals involved?
 5. Outline a breeding procedure whereby a true-breeding strain of red cattle could be established from a roan bull and a white cow.
 6. What is the probability of rolling a seven with a pair of dice? Which is a more likely outcome, rolling a six with a pair of dice or rolling an eight?
 7. In rabbits, spotted coat (S) is dominant to solid color (s), and black (B) is dominant to brown (b). These loci are unlinked. A brown, spotted rabbit from a pure line is mated to a solid black one, also from a pure line. What are the genotypes of the parents? What would be the genotype and phenotype of an F_1 rabbit? What would be the expected genotypes and phenotypes of the F_2 generation?
 8. The long hair of Persian cats is recessive to the short hair of Siamese cats, but the black coat color of Persians is dominant to the brown-and-tan coat color of Siamese. Make up appropriate symbols for the alleles of these two unlinked loci. If a pure black, long-haired Persian is mated to a pure brown-and-tan, short-haired Siamese, what will be the appearance of the F_1 offspring? If two of these F_1 cats are mated, what is the chance that a long-haired, brown-and-tan cat will be produced in the F_2 generation? (Use the shortcut probability method to obtain your answer; then check it with a Punnett square.)
 9. The expression of an allele called *frizzle* in fowl causes abnormalities of the feathers. As a consequence, the animal's body temperature is lowered, adversely affecting the functions of many internal organs. When one gene affects many characteristics of the organism in this way, we say that gene is _____.
 10. A walnut-combed rooster is mated to three hens. Hen A, which is walnut-combed, has offspring in the ratio of 3 walnut:1 rose. Hen B, which is pea-combed, has offspring in the ratio of 3 walnut:3 pea:1 rose:1 single. Hen C, which is walnut-combed, has only walnut-combed offspring. What are the genotypes of the rooster and the three hens?
 11. What kinds of matings result in the following phenotypic ratios? (a) 3:1 (b) 1:1 (c) 9:3:3:1 (d) 1:1:1:1
 12. The weight of the fruit in a certain variety of squash is determined by two pairs of genes: $AABB$ produces fruits weighing 4 pounds each, and $aabb$ produces fruits weighing 2 pounds each. Each allele represented by a capital letter adds 0.5 pound to the weight. When a plant that produces 4-pound fruits is crossed with a plant that produces 2-pound fruits, all of the offspring produce fruits that weigh 3 pounds each. What would be the weights of the fruits produced by the F_2 plants if two of these F_1 plants were crossed?
 13. The X-linked *barred* locus in chickens controls the pattern of the feathers, with the alleles B for barred pattern and b for no bars. If a barred female ($X^B Y$) is mated to a nonbarred male ($X^b X^b$), what will be the appearance of the male and female progeny? (Recall that in birds males are homogametic and females are heterogametic.) Do you see any commercial usefulness for this result? (*Hint*: It is notoriously difficult to determine the sex of newly hatched chicks.)
 14. Individuals of genotype $AaBb$ were mated to individuals of genotype $aabb$. One thousand offspring were counted, with the following results: 474 $Aabb$; 480 $aABb$; 20 $AaBb$; 26 $aabb$. What is this type of cross known as? Are these loci linked? What are the two parental classes and the two recombinant classes of offspring? What is the percentage of recombination between these two loci? How many map units apart are they?
 15. Genes A and B are 6 map units apart, and A and C are 4 map units apart. Which gene is in the middle if B and C are 10 map units apart? Which is in the middle if B and C are 2 map units apart?
- Answers to these Review Questions are included in Appendix A with the Post-Test answers.

YOU MAKE THE CONNECTION

1. Would the development of the science of genetics in the 20th century have been any different if Gregor Mendel had never lived?
2. Sketch a series of diagrams showing each of the following, making sure to end each series with haploid gametes: (a) how a pair of alleles for a single locus segregates in meiosis, (b) how the alleles of two unlinked loci assort independently in meiosis, (c) how the alleles of two linked loci undergo genetic recombination.
3. Can you always ascertain an organism's genotype for a particular locus if you know its phenotype? Conversely, if you are given an organism's genotype for a locus, can you always reliably predict its phenotype? Explain.

CHAPTER 11

DNA: The Carrier of Genetic Information

Following the rediscovery of Mendel's principles, geneticists conducted elegant experiments to learn how genes are arranged in chromosomes and how they are transmitted from generation to generation. However, two very basic questions remained unanswered: What are genes made of? How do genes work? Although studies of inheritance patterns did not answer these questions, they provided a foundation that allowed scientists to make predictions about the chemical nature of genes and how they might function.

It was obvious that the chemical of which genes are made should have the ability to store information in a form that could be retrieved and used by the cell. But genes had other properties that had to be accounted for as well. Countless genetic experiments on a wide variety of organisms had demonstrated that genes are usually quite stable, being passed unchanged from generation to generation. However, occasionally a gene was observed to convert to a different form; such genetic changes, called **mutations**, were then transmitted unchanged to future generations.

As the science of genetics was developing, the science of biochemistry was flourishing as well. Not surprisingly, there was an increased effort to correlate the known properties of genes with the nature of the various biological molecules. What kind of molecule could store information? How could that information be retrieved and used to direct cellular functions? What kind of molecule could be relatively stable, but have the capacity to change under some circumstances?

Some scientists thought that the problem could never be solved. They thought the information required by a cell to be so complex that no one type of molecule could function as the genetic material. However, as more was learned about the central role that proteins play in virtually every aspect of cellular structure and metabolism, other scientists considered them the prime candidates for the genetic material. In this chapter we discuss how the nucleic acid shown in the photograph, **deoxyribonucleic acid (DNA)**, not protein, was found to be the molecule responsible for inheritance, and we examine the unique features of DNA that allow it to carry out this role.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Summarize the evidence that accumulated during the 1940s and early 1950s demonstrating that DNA is the genetic material.
2. Relate the chemical and physical features of DNA to the structure proposed by Watson and Crick.
3. Sketch how nucleotide subunits are linked together to form a single DNA strand.
4. Illustrate how the two strands of DNA are oriented with respect to each other.
5. State the base-pairing rules for DNA and describe how complementary bases bind to each other.
6. Cite experimental evidence that allowed scientists to differentiate between semiconservative replication of DNA and alternative models (conservative and dispersive replication).
7. Summarize how DNA replicates and identify some of the unique features of the process.
8. Explain the special constraints on DNA replication that cause it to be (1) bidirectional and (2) discontinuous in one strand and continuous in the other.
9. Compare the organization of DNA in prokaryotic and eukaryotic cells.

MOST GENES CARRY INFORMATION FOR MAKING PROTEINS

The idea that enzymes (which we now know are proteins) and genes are related in some way was first clearly stated by an English physician, Archibald Garrod, who proposed that certain inherited human diseases are caused by a block in a sequence of chemical reactions within the body.

In the first edition of his book, *Inborn Errors of Metabolism* (1908), Garrod discussed a genetic disease called **alkaptonuria**, which has a simple autosomal recessive inheritance pattern. The condition involves the metabolic pathway that breaks down the amino acids phenylalanine and tyrosine, ultimately converting them to carbon dioxide and water. The urine of affected individuals contains an intermediate in this pathway, homogentisic acid, which turns black when exposed to air (Fig. 11–1).

Garrod hypothesized that persons with alkaptonuria lack the enzyme that normally oxidizes homogentisic acid and that this metabolic block causes homogentisic acid to accumulate in their tissues and blood, and to be excreted in their urine. Before the second edition of his book had been published in 1923, it was found that affected persons do indeed lack the enzyme that oxidizes homogentisic acid. Garrod's hypothesis was correct: a mutation in a specific gene could be associated with the absence of a specific enzyme. Shortly thereafter, in 1926, James Sumner purified a different enzyme, urease, and showed it to be a protein; this finding was the first clear evidence that enzymes are proteins.

Despite the implications of these findings, little work was done in this area, primarily because genetically transmitted errors in metabolism appeared to be rare. The lack of experimental subjects made genetic testing and statistical analysis very difficult.

A major advance in understanding the relationship between genes and enzymes came in the early 1940s, when George Beadle and Edward Tatum developed a new approach to the problem. Most efforts until that time had centered on

Figure 11–1 An “inborn error of metabolism.” Garrod proposed that the alkaptonuria allele causes the absence of a specific enzyme, one that is part of the pathway by which the amino acid tyrosine is catabolized. That enzyme normally converts homogentisic acid to maleylacetoacetate. Homogentisic acid thus accumulates in the blood and is excreted through the urine. When the homogentisic acid in the urine comes in contact with air, it oxidizes and turns black.

studying known loci and attempting to determine what biochemical reactions they affected. Experimenters examined previously identified loci, such as those controlling eye color in *Drosophila* or pigments in plants. They found that specific phenotypes are controlled by a series of biosynthetic reactions, but it was not clear to the investigators whether the genes themselves were acting as enzymes or if they determined the workings of the enzymes in more complex ways.

Beadle and Tatum decided to take the opposite approach. Rather than try to identify the enzymes affected by single genes, they decided to look for mutations interfering with the known metabolic reactions that produce essential molecules such as amino acids and vitamins. They studied the bread mold *Neurospora* (a fungus) for several reasons. First, wild-type¹ *Neurospora* is easy to grow in culture. It can make all of its essential biological molecules when it is grown on a simple minimal medium containing only sugar, salts, and the vitamin biotin. A mutant that cannot make a substance such as an amino acid can still grow if it is simply added to the growth medium.

Second, *Neurospora* grows primarily as a haploid organism. Thus, a recessive mutant allele can be immediately identified because there is no homologous chromosome that could carry a dominant allele that would mask its expression.

Third, the life cycle of *Neurospora* facilitates certain types of manipulations and genetic analysis. *Neurospora* produces large numbers of asexual haploid spores; these can grow and divide mitotically to produce more haploid cells. Two haploid cells can fuse to produce a zygote, which undergoes meiosis to form haploid sexual spores. Thus, researchers can use sexual crosses to perform genetic analyses of isolated mutants. (For an illustration of the generalized life cycles of simple organisms, see Figure 9–12; a more detailed life cycle of organisms similar to *Neurospora* is given in Figure 25–6.)

Beadle and Tatum began by exposing large numbers of wild-type *Neurospora* asexual spores to x rays or ultraviolet radiation to induce mutations. Because each spore contains multiple haploid nuclei, the irradiated cells were mated with another strain, forming zygotes that underwent meiosis to produce haploid sexual spores, each with a single haploid nucleus. (Why did the experimenters not simply irradiate uninucleate sexual spores? The answer is that it is easy to obtain large numbers of asexual spores and they are far more sensitive to the effects of radiation than are sexual spores.) The isolated sexual spores were allowed to grow on a complete medium containing all the amino acids and vitamins normally made by *Neurospora*. Each strain was also tested on a minimal medium. If an isolated strain grew on the complete medium, but failed to grow after transfer to the minimal medium, Beadle and Tatum reasoned that it carried a mutation that made it unable to produce one of the compounds essential for growth. Fur-

ther testing of the mutant on media containing different combinations of amino acids, purines, vitamins, and so on enabled the investigators to determine the exact compound that was required (Fig. 11–2).

Their findings can be illustrated with a class of mutants that require the amino acid arginine. Beadle and Tatum found that some of the arginine-requiring mutants could grow on ornithine or citrulline, as well as arginine; others could grow on citrulline or arginine; and still others could grow only on arginine (Fig. 11–3*a*). This information was then used to deduce the order of these intermediates in the biochemical pathway leading to arginine (Fig. 11–3*b*).

Using this approach, Beadle and Tatum analyzed large numbers of mutants affecting several metabolic pathways. Each mutant strain was verified by special genetic crossing experiments to have a mutation in only one gene locus. They found that for each individual gene locus identified, only one enzyme was affected. This one-to-one correspondence between genes and enzymes was succinctly stated as the *one gene, one enzyme hypothesis*.

Through the discoveries of Beadle and Tatum and others, the sciences of genetics and biochemistry became ever more closely allied, leading to an evolution of the definition of the gene and additional predictions regarding its chemical nature. The idea that a gene encodes the information required to produce a single enzyme held for almost a decade, until additional findings required a modification of this definition.

It became evident that genes control not only enzymes, but other proteins as well. Linus Pauling and his coworkers were able to demonstrate that the structure of hemoglobin can be altered by a mutation of a single locus. This particular mutant form of hemoglobin is associated with the genetic disease sickle cell anemia (Chapter 15). In addition, various studies showed that many proteins are constructed from two or more polypeptide chains, each of which may be controlled by a different locus. For example, hemoglobin was shown to contain two types of polypeptide chains, the α and β subunits (see Chapter 3). Sickle cell anemia results from a mutation affecting the β subunits.

The definition of a gene was therefore extended to state that one gene is responsible for one polypeptide chain. Even this definition has proved to be only partially correct, although we still define a gene in terms of its product (Chapter 12).

EVIDENCE THAT DNA IS THE HEREDITARY MATERIAL WAS FIRST FOUND IN MICROORGANISMS

During the 1940s most geneticists and biochemists were convinced that the genetic material must be protein. Proteins were known to contain more than 20 different kinds of amino acids in many different combinations, allowing each type of protein

¹ *Wild type* refers to the genotypes and phenotypes most commonly found in natural populations of a particular species. Wild-type alleles are generally thought of as “normal” or nonmutant alleles.

Figure 11–2 Mutations affecting biochemical pathways. Beadle and Tatum irradiated multinucleate haploid asexual spores of *Neurospora* to produce random mutations; cultures derived from these spores were then mated with another strain to produce uninucleate haploid sexual spores. Cultures were first established on complete media; subsequent failure to grow on a minimal media indicated a blocked step in a biochemical pathway. The specific nutritional requirement was determined by testing for growth on minimal media supplemented with individual vitamins or amino acids. In this example, the medium containing the amino acid arginine supports growth, indicating that the mutation affects some part of the arginine biosynthetic pathway.

Figure 11-3 Genes and enzymes. (a) In this example, Beadle and Tatum tested a number of different mutant strains that require the amino acid arginine. These were grouped (I, II or III) by their response to various intermediates in the metabolic pathway leading to arginine, which were provided as supplements to the minimal growth medium. (b) Analysis of the experimental results led to this model for a portion of the arginine biosynthetic pathway (which is actually a cycle). Because Group I strains grew on minimal medium supplemented with ornithine, citrulline, or arginine, they were thought to be missing enzyme A, required for formation of all three compounds. Group II strains were thought to be missing enzyme B because they were unable to grow on minimal medium supplemented with ornithine but allowed the conversion of citrulline to arginine. Group III strains were thought to be missing enzyme C because they grew on minimal medium to which only arginine had been added. A one-to-one correspondence between each specific enzyme and a specific gene locus was verified by special genetic crosses (not shown).

to have unique properties. It had been shown that genes control the production of proteins. Given their obvious complexity and diversity compared with other molecules, proteins seemed to be the stuff of which genes are made.

In contrast, DNA and other nucleic acids were known to be made of only four nucleotides, and what was known about their arrangement made them seem relatively uninteresting to most scientists. For this reason, several early clues to the role of DNA were not widely recognized.

In 1928 Frederick Griffith made a curious observation concerning two strains of pneumococcus bacteria. A smooth (S) strain, named for its formation of smooth colonies on a solid growth medium, was known to be **virulent**, or lethal. When it was injected into mice, the animals contracted pneumonia and died. A related rough (R) strain, which forms colonies with a rough surface, was known to be **avirulent**, or nonlethal. Griffith found that when a mixture of *heat-killed*, virulent S-strain cells and live avirulent R-strain cells was in-

Figure 11–4 Griffith’s transformation experiments. Although neither the rough (R) strain nor the heat-killed smooth (S) strain could kill a mouse, a combination of the two did. Autopsy of the dead mouse showed the presence of living, S strain pneumococci. These results indicated that some substance in the heat-killed S strain was responsible for the transformation of the living R strain to a virulent form. Avery and his colleagues later showed that purified DNA isolated from the S-strain confers virulence on the R-strain bacteria, establishing that the DNA carries the necessary information for bacterial transformation.

jected into mice, a high proportion of the mice died. Griffith was then able to isolate living S-strain cells from the dead mice.

Because neither the heat-killed S strain nor the living R strain could be converted to the living virulent form when injected by itself, something in the heat-killed cells appeared to convert the avirulent cells to the lethal form. This phenomenon, called **transformation**, was thought to be caused by some chemical substance (called the “transforming principle”) in the dead bacteria that “transformed” a related strain to a genetically stable new form (Fig. 11–4).

In 1944, O. T. Avery, C. M. MacLeod, and M. McCarty of the Rockefeller Institute chemically identified Griffith’s transforming principle as DNA. Although today we consider their findings to be the first demonstration that DNA is the genetic material, not all scientists of the time were convinced. One argument given was that the DNA preparations used might have been contaminated with a tiny amount of protein, which might have been responsible for the results. This was not a trivial objection, because it was well known that a very small amount of an enzyme could have significant biological effects.

During the next few years, new evidence accumulated that the haploid nuclei of pollen grains and gametes such as sperm contain only half the amount of DNA found in diploid somatic cells of the same species. Because the idea that genes are on chromosomes was generally accepted, these findings correlating DNA content with chromosome number provided strong circumstantial evidence of DNA’s importance in inheritance.

In 1952 Alfred Hershey and Martha Chase performed a series of elegant experiments on the reproduction of **bacte-**

riophages (viruses that infect bacteria; see Chapter 23) (Fig. 11–5). Their demonstration that bacteriophages inject their DNA into bacterial cells, leaving most of their protein on the outside, emphasized the significance of DNA in viral reproduction and was seen by many as another important indication of the role of DNA as the hereditary material.

THE STRUCTURE OF DNA ALLOWS IT TO CARRY INFORMATION AND TO BE FAITHFULLY DUPLICATED

DNA was not widely accepted as the genetic material until James Watson and Francis Crick proposed a model for its structure that had extraordinary explanatory power. The story of how the structure of DNA came to be determined is one of the most remarkable chapters in the history of modern biology.

A great deal was known about the physical and chemical properties of DNA when Watson and Crick became interested in the problem. Their all-important contribution was to integrate all this information into a model that demonstrated how the molecule can both carry information and serve as its own template (pattern) for duplication.

Nucleotides can be covalently linked in any order to form long polymers

As discussed in Chapter 3, each DNA building block is a **nucleotide** consisting of a pentose sugar (**deoxyribose**), a phosphate, and one of four nitrogenous bases (Fig. 11–6a). The

Figure 11–5 The Hershey-Chase experiments. Although bacteriophage protein coats labeled with the radioactive isotope ^{35}S (left) could be separated from infected bacterial cells without interfering with viral reproduction, viral DNA labeled with the radioactive isotope ^{32}P (right) could not, thus demonstrating that the DNA enters the cells and is required for synthesis of new protein coats and DNA.

nitrogenous base is attached to the 1' carbon of the sugar, and the phosphate is attached to the 5' carbon.² The bases include two **purines**—**adenine (A)** and **guanine (G)**—and two **pyrimidines**—**thymine (T)** and **cytosine (C)**.

The nucleotides are linked by covalent bonds to form an alternating sugar-phosphate backbone. The 3' carbon of one sugar is bonded to the 5' phosphate of the adjacent sugar to form a 3', 5' **phosphodiester linkage** (Fig. 11–6b). It is therefore possible to form a polymer of indefinite length, with the nucleotides linked in any order. We now know that most DNA molecules found in cells are millions of bases long. Figure 11–6a also illustrates that a single polynucleotide chain is directional. No matter how long the chain may be, one end (the **5' end**) has a 5' carbon and the other (the **3' end**) has a 3' carbon that is not linked to another nucleotide.

DNA is made of two polynucleotide chains intertwined to form a double helix

Important information about the structure of DNA came from **x-ray diffraction** studies on crystals of purified DNA, carried out by Rosalind Franklin in the laboratory of M. H. F. Wilkins. X-ray diffraction is a powerful method for determining distances between atoms of molecules arranged in a regular, repeating crystalline structure (Fig. 11–7). X rays have such extremely short wavelengths that they can be scattered by the electrons surrounding the atoms in a molecule. Atoms with dense electron clouds (e.g., phosphorus, oxygen) tend to deflect electrons more strongly than do atoms with lower atomic numbers.

When a crystal is exposed to an intense beam of x rays, the regular arrangement of the atoms in the crystal causes the x rays to be diffracted, or bent, in specific ways. The pattern of diffracted x rays is seen on film as dark spots. Mathematical analysis of the arrangement and distances between the spots can then be used to determine precise distances between atoms and their orientation within the molecules.

Franklin had already produced x-ray crystallographic films of DNA patterns when Watson and Crick began to pursue the problem of DNA structure. The pictures clearly showed that DNA has a type of helical structure, and three major types of regular, repeating patterns in the molecule with the dimensions 0.34 nanometer, 3.4 nanometers, and 2.0 nanometers were evident. Franklin and Wilkins had inferred from these patterns that the nucleotide bases (which are flat molecules) are stacked like rungs of a ladder. Using this information, Watson and Crick began to build scale models of the DNA components and then fit them together to agree with the experimental data.

After a number of trials, the two worked out a model that fit the existing data (Fig. 11–8). The nucleotide chains conformed to the dimensions of the x-ray data only if each DNA molecule consisted of *two* polynucleotide chains arranged in a

²It is conventional to number the atoms in a molecule, using a system devised by organic chemists. In nucleic acid chemistry the "prime" designations, such as 2', designate individual carbon atoms in the sugar ring, to distinguish them from carbon atoms in the base.

Figure 11-7 X-ray diffraction image of DNA. Important clues about DNA structure are provided by detailed mathematical analysis of measurements of x-ray diffraction images of the lithium salt of DNA. The diagonal pattern of spots stretching from 11 o'clock to 5 o'clock and from 1 o'clock to 7 o'clock provides evidence for the helical structure of DNA. The elongated horizontal patterns at the top and bottom indicate that the purine and pyrimidine bases are stacked 0.34 nanometers apart and are perpendicular to the axis of the DNA molecule. (Dr. S.D. Dover, Division of Biomolecular Sciences, Kings College, London)

Figure 11-8 Structure of the DNA molecule. On the left is a space-filling model of the DNA double helix. The measurements on the diagrammatic model on the right match those derived from x-ray diffraction images. The ribbons represent the sugar-phosphate backbone of each strand; the thick arrows indicate that the two strands extend in opposite directions.

coiled **double helix**. In their model, the sugar-phosphate backbones of the two chains form the outside of the helix. The bases belonging to the two chains associate as pairs in the center. The reasons for the repeating patterns of 0.34-nanometer and 3.4-nanometer measurements are readily apparent from the model: each pair of bases is exactly 0.34 nanometer from the adjacent pairs above and below. Because exactly ten base pairs are present in each full turn of the helix, each turn is 3.4 nanometers high. To fit the data, the two chains must run in opposite directions; therefore, each end of the double helix must have an exposed 5' phosphate on one strand and an exposed 3' hydroxyl group on the other. Because the two strands run in opposite directions, they are said to be **antiparallel** to each other.

In double-stranded DNA, hydrogen bonds form between adenine and thymine and between guanine and cytosine

Other features of the model integrated important information about the chemical composition of DNA with the x-ray dif-

fraction data. By 1950, the base composition of DNA from a number of organisms and tissues had been determined by Erwin Chargaff and his coworkers at Columbia University. They found a simple relationship among the bases that turned out to be an important clue to the structure of DNA. Regardless of the source of the DNA, in Chargaff's words, the "ratios of purines to pyrimidines and also of adenine to thymine and of guanine to cytosine were not far from 1." In other words, in DNA molecules, A=T and G=C.

The x-ray diffraction studies indicated that the double helix has a precise and constant width, as shown by the 2.0-nanometer reflections. This finding is actually connected to Chargaff's rules. Notice in Figure 11-6 that the pyrimidines (cytosine and thymine) contain only one ring of atoms, whereas the larger purines (guanine and adenine), contain two rings. Study of the models made it clear to Watson and Crick that if each cross-rung of the ladder were to contain one purine and one pyrimidine, the width of the helix at that point would be exactly 2.0 nanometers; the combination of two purines (each of which is 1.2 nanometers wide) would be wider and that of two pyrimidines would be narrower.

Further examination of the model showed that adenine can pair with thymine (and guanine with cytosine) in such a way that hydrogen bonds form between them; the opposite combinations, cytosine with adenine and guanine with thymine, do not lead to favorable hydrogen bonding.

The nature of the hydrogen bonding between adenine and thymine and between guanine and cytosine is shown in Figure 11–9. Two hydrogen bonds can form between adenine and thymine, and three between guanine and cytosine. This concept of *specific base-pairing* neatly explains Chargaff's rules. The amount of cytosine has to equal the amount of guanine, be-

cause every cytosine in one chain must have a paired guanine in the other chain. Similarly, every adenine in the first chain must have a thymine in the second chain. Thus, the sequences of bases in the two chains are **complementary**, but not identical, to each other. In other words, the sequence of nucleotides in one chain dictates the complementary sequence of nucleotides in the other. For example, if one strand has the sequence:

3'—AGCTAC—5'

(a)

Figure 11–9 Hydrogen bonding between bases. The two strands of a DNA double helix are associated by hydrogen bonding between the bases. (a) The two sugar-phosphate chains run in opposite directions. This orientation permits the complementary bases to pair. (b) Diagram of the hydrogen bonding between base pairs adenine (A) and thymine (T) (*top*) and guanine (G) and cytosine (C) (*bottom*). The AT pair has two hydrogen bonds; the GC pair has three.

(b)

then the other strand has the complementary sequence:

5'—TCGATG—3'

The double-helix model strongly suggested that the sequence of bases in DNA can provide for the storage of genetic information. Although there are restrictions on how the bases pair with each other, the number of possible sequences of bases in a strand is virtually unlimited. Because a DNA molecule in a cell can be millions of nucleotides long, it can store enormous amounts of information, usually comprising a large number of genes.

DNA REPLICATION IS SEMICONSERVATIVE

Two immediately apparent and distinctive features of the Watson-Crick model made it seem more plausible that DNA is the genetic material. We have already mentioned that DNA can carry coded information in its sequence of bases. The model also suggested a way in which information in DNA could be precisely copied, a process known as **DNA replication**. The importance of the replication mechanism was known

to Watson and Crick, who noted in a classic and now famous understatement at the end of their first brief paper, “It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material.”

The model suggested that, because the nucleotides pair with each other in a complementary fashion, each strand of the DNA molecule could serve as a template, or pattern, for the synthesis of the opposite strand. It would simply be necessary for the hydrogen bonds between the two strands to break and the two chains to separate. Each half-helix could then pair with complementary nucleotides to replace its missing partner. The result would be two DNA double helices, each identical to the original one and consisting of one original strand from the parent molecule and one newly synthesized complementary strand. This type of information copying is known as a **semiconservative replication** mechanism. The recognition that DNA could be copied in this way suggested how DNA could provide a third essential characteristic of genetic material—the ability to mutate (see *Making the Connection: Mutations and the Structure of DNA*).

Although the semiconservative replication mechanism suggested by Watson and Crick was (and is) a simple and compelling model, experimental proof was needed to establish that DNA in fact duplicates in that manner. First it was necessary

MAKING THE CONNECTION

MUTATIONS AND THE STRUCTURE OF DNA

How do new genetic variants arise? This question was of great interest to geneticists, who had long known that mutations, or genetic changes, could arise in genes and then be transmitted faithfully to succeeding generations. When the double-helix model was proposed, it seemed plausible that mutations could represent a change in the sequence of bases in the DNA. One could predict that if DNA is copied by a mechanism involving complementary base pairing, any change in the sequence of bases on one strand would result in a new sequence of complementary bases during the next replication cycle. The new base sequence would then be passed on to daughter molecules by the same mechanism used to copy the original genetic material, as if no change had occurred.

In the example shown in the figure, an adenine base in one of the DNA strands has been changed to guanine. This could occur by a rare error in DNA replication or by one of several other known mechanisms. (There are systems of enzymes that repair errors when they occur, but not all mutations are corrected properly.) When the DNA molecule is replicated again, one of the strands gives rise to a molecule exactly like the parent strand; the other (mutated) strand gives rise to a molecule with a new combination of bases that will be stably transmitted generation after generation.

Perpetuation of a mutation. The process of DNA replication can stabilize a mutation so that it will be passed to future generations.

to rule out several other possibilities. For example, with a *conservative replication* mechanism, both parent (or old) strands would remain together, and the two newly synthesized strands would form a second double helix. As a third alternative, the parental and newly synthesized strands might become randomly mixed during the replication process; this possibility was known as *dispersive replication*. To discriminate among the semiconservative replication mechanism and the other possibilities, it was necessary to distinguish between old and newly synthesized strands of DNA.

One way to accomplish this is to use a heavy-nitrogen isotope, nitrogen-15 (ordinary nitrogen is nitrogen-14), to label DNA strands by making them more dense. Large molecules such as DNA can be separated on the basis of differences in their density, using a technique known as **density gradient centrifugation**. When DNA is mixed with a solution containing cesium chloride (CsCl) and centrifuged at high speed, the solution forms a density gradient in the centrifuge tube, ranging from a low density region at the top to a region of highest density at the bottom. During centrifugation the DNA molecules migrate to the region of the gradient identical to their own density.

In 1957, Matthew Meselson and Franklin Stahl grew cells of the bacterium *Escherichia coli* on a medium that contained nitrogen-15 in the form of ammonium chloride (NH₄Cl). The cells used the nitrogen-15 to synthesize bases, which then became incorporated into DNA (Fig. 11–10). The resulting heavy nitrogen-containing DNA molecules were extracted from some of the cells. When they were subjected to density gradient centrifugation, they accumulated in the high-density region of the gradient. The rest of the bacteria (which also contained nitrogen-15-labeled DNA) were transferred to a different growth medium in which the NH₄Cl contained the naturally abundant, lighter nitrogen-14 isotope; they were then allowed to undergo additional cell divisions.

The newly synthesized DNA strands were expected to be less dense because they incorporated bases containing the lighter nitrogen-14 isotope. Indeed, double-stranded DNA from cells isolated after one generation had an intermediate density, indicating that they contained half as many nitrogen-15 atoms as the “parent” DNA. This finding supported the semiconservative model, which predicted that each double helix should contain a previously synthesized strand (heavy in this case) and a newly synthesized strand (light in this case). It was inconsistent with the conservative model, which predicted that there should be two classes of double stranded molecules, those with two heavy strands and those with two light strands.

After another cycle of cell division in the medium with the lighter nitrogen-14 isotope, two types of DNA appeared in the density gradient. One consisted of “hybrid” DNA helices (with one nitrogen-15 strand and one nitrogen-14 strand), whereas the other contained only DNA with the naturally occurring light isotope. This finding refuted the dispersive model,

which predicted that all strands should have intermediate density. Instead, each strand of the parental double-helix molecule was conserved, but in a *different* daughter molecule, exactly as predicted by the semiconservative replication model.

DNA replication is complex and has a number of unique features

Although the general principles of DNA replication are simple and straightforward predictions from the Watson-Crick model, the process actually requires a complex “replication machine” containing a large number of proteins and enzymes. Many of the essential features of DNA replication are universal, although some differences exist between prokaryotes and eukaryotes because their DNA is organized differently. In bacterial cells such as *E. coli*, most or all of the DNA is in the form of a single, *circular*, double-stranded molecule. Each unreplicated eukaryotic chromosome contains a single, *linear*, double-stranded molecule associated with a great deal of protein.

DNA strands must be unwound during replication

Watson and Crick recognized that in their double-helix model the two DNA strands are wrapped around one another like the strands of a rope. If we try to pull the strands apart, the rope must either rotate or twist into tighter coils. We would expect similar things to happen when complementary DNA strands are separated for replication. Separating the two strands of DNA is accomplished by **DNA helicase enzymes** that travel along the helix, opening the double helix as they move. Once the strands are separated, **helix-destabilizing proteins** bind to single DNA strands, preventing re-formation of the double helix until the strands are copied. Enzymes called **topoisomerases** produce breaks in the DNA molecules and then re-join the strands, relieving strain and effectively preventing the formation of knots during replication.

DNA synthesis always proceeds in a 5' → 3' direction

The enzymes that catalyze the linking together of the nucleotide subunits are called **DNA polymerases**. They have several limitations that contribute to the complexity of the replication process. They are able to add nucleotides only to the 3' end of a growing polynucleotide strand, and this strand must be paired with the strand being copied (Fig. 11–11). Nucleotides with three phosphate groups are used as substrates for the polymerization reaction. As the nucleotides are linked together, two of the phosphates are removed. Like the hydrolysis of ATP, these reactions are strongly exergonic (see Chapter 6) and do not require additional energy. Because the new polynucleotide chain is elongated by the linkage of the 5'

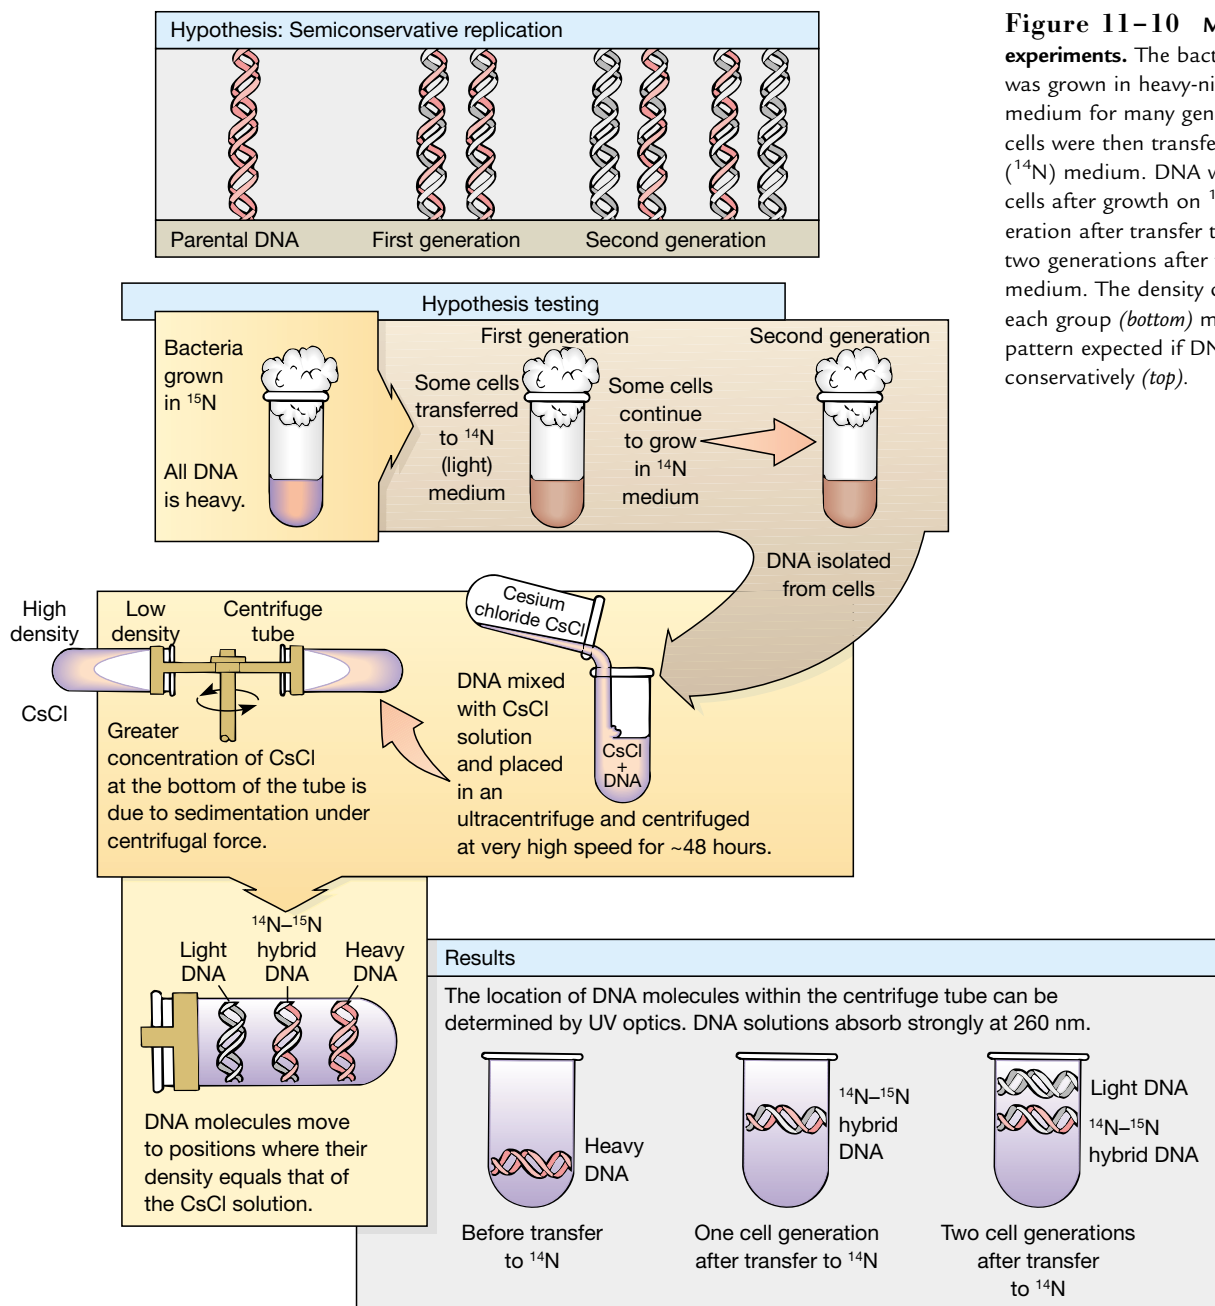

Figure 11–10 Meselson and Stahl’s experiments. The bacterium *Escherichia coli* was grown in heavy-nitrogen (^{15}N) growth medium for many generations. Some of the cells were then transferred to light-nitrogen (^{14}N) medium. DNA was isolated from cells after growth on ^{15}N medium one generation after transfer to ^{14}N medium, and two generations after transfer to ^{14}N medium. The density of the molecules in each group (*bottom*) matches the labeling pattern expected if DNA is replicated semi-conservatively (*top*).

phosphate group of the next nucleotide subunit to the 3′ hydroxyl group of the sugar at the end of the preexisting strand, the new strand of DNA always grows in the 5′ → 3′ direction.

DNA synthesis requires an RNA primer

A second limitation of the DNA polymerases is that they can add nucleotides only to the 3′ end of an *existing* polynucleotide strand. So how can DNA synthesis be initiated once the two

strands are separated? The answer is that a short piece (usually about five nucleotides) of an **RNA primer** is first synthesized at the point of initiation of replication (Fig. 11–12).

RNA, or **ribonucleic acid** (see Chapters 3 and 12), is a nucleic acid polymer consisting of nucleotide subunits that can associate by complementary base-pairing with the single-stranded DNA template. The RNA primer is synthesized by a protein complex known as a **primosome**, which includes an enzyme that is able to start a new strand of RNA opposite a

DNA synthesis begins at a specific base sequence, termed the *origin of replication*.

Strands are separated at the origin of replication and unwound by DNA helicase, which “walks” along the DNA molecule preceding the DNA-synthesizing enzymes. Single-stranded regions are prevented from re-forming into double strands by helix-destabilizing proteins, which bind to single-stranded DNA. The region of active DNA synthesis is associated with the “replication fork,” formed at the junction of the single strands and the double-stranded region. Both strands are synthesized in the vicinity of the fork (each in a 5'→3' direction).

As the new strands continue to grow in the first direction, unwinding and replication initiate on the other side of the origin of replication, forming a second replication fork. Thus replication proceeds in opposite directions.

Completion of replication results in the formation of two daughter molecules, each containing one old and one newly synthesized strand. Each double helix is a chromatid of a duplicated eukaryotic chromosome.

Figure 11-12 Overview of DNA replication. This process requires a number of steps involving several enzymes and RNA primers.

both directions from the origin of replication. Prokaryotic cells usually have only one origin of replication on each circular DNA molecule (Fig. 11-14*a*), so the two replication forks proceed around the circle and eventually meet at the other side to complete the formation of two new DNA molecules.

A eukaryotic chromosome is composed of one, extremely long, linear DNA molecule, so the process is speeded up by having multiple origins of replication (Fig. 11-14*b-d*). Synthesis continues at each replication fork until it meets one coming from the opposite direction, resulting in the formation of a chromosome containing two DNA double helices (each of which corresponds to a chromatid). The ends of eukaryotic chromosomes; known as **telomeres**, present special problems in replication (see *On the Cutting Edge: Telomeres, Cellular Aging, and Cancer on page 263*).

DNA IN CHROMOSOMES IS PACKAGED IN A HIGHLY ORGANIZED WAY

Prokaryotic and eukaryotic cells differ markedly in their DNA content as well as in the organization of DNA molecules. An *E. coli* cell normally contains about 4×10^6 base pairs (almost 1.35 millimeters) of DNA in its single circular DNA molecule. In fact, the total length of the DNA is about 1000 times greater than the length of the cell itself. Therefore the DNA molecule must, with the help of special proteins, be twisted and folded compactly to fit inside the bacterial cell.

A typical eukaryotic cell contains much more DNA than a bacterium does, and it is organized in the nucleus as multi-

The *leading strand* is synthesized continuously in a direction toward the replication fork, whereas the *lagging strand* is synthesized in short pieces called *Okazaki fragments*, in a direction apparently away from the replication fork. Both strands require an *RNA primer* for the initiation of synthesis because DNA can be elongated only by addition to the 3' end of an existing polynucleotide strand.

The synthesis of each Okazaki fragment begins with synthesis of an RNA primer. After the fragment has been elongated by DNA polymerase, the RNA primer is degraded, the gaps are filled in with DNA, and the adjoining fragments are linked together by DNA ligase.

Figure 11–13 Leading and lagging DNA strands. Because elongation can proceed only in a 5' → 3' direction, the two strands at the replication fork are copied in different ways, each by a separate DNA polymerase molecule.

ple chromosomes; these vary widely in size and number among different species. Although a human cell nucleus is about the size of a large bacterial cell, it contains almost 1000 times the amount of DNA found in *E. coli*. The haploid DNA content of a human cell is about 3×10^9 base pairs; if stretched end to end, it would be almost 1 meter long.

In eukaryotes, DNA, which is negatively charged, is associated with positively charged basic proteins known as **histones**³ to form structures called **nucleosomes**. The fundamental unit of the nucleosome complex consists of a beadlike structure with 146 base pairs of DNA wrapped around a disc-shaped core of eight histone molecules (two each of four different histone types) (Fig. 11–15). Although the nucleosome was originally defined as a bead plus a DNA segment that links it to an adjacent bead, today the term more commonly refers

only to the bead itself (i.e., the eight histones and the DNA wrapped around them).

The nucleosomes are part of the **chromatin**, the complex of nucleic acids and protein that makes up the chromosomes. The higher order structures of chromatin are illustrated in Figure 11–16. For example, a fifth type of histone, known as histone H1, is associated with the linker DNA and is responsible for packing adjacent nucleosomes (each of which is 11 nm in diameter) together to form a 30-nm-diameter thread. These 30-nm-diameter threads form large coiled loops held together by a set of nonhistone **scaffolding proteins**. The loops then interact in complex ways to form the chromatin found in a condensed metaphase chromosome.

Nucleosomes function like tiny spools, thereby preventing DNA strands from becoming tangled. The importance of this role is underscored by Figure 11–17, which illustrates the dense packing of the DNA fibers of a mouse chromosome after the histones have been removed. However, their role is more than structural, for their arrangement also affects the activity of the DNA with which they are associated (Chapter 13).

³A few types of eukaryotic cells lack histones. Conversely, histones do occur in one group of prokaryotes, the Archaeobacteria (Chapter 23).

Figure 11–14 Bidirectional DNA replication. The leading strands and lagging strands are not represented in the illustrations. (a) The circular DNA in *E. coli* has only one origin of replication. DNA synthesis proceeds from that point in both directions until the two replication forks meet. (b) This TEM shows two replication forks (arrows) in a segment of a eukaryotic chromosome that has been partly replicated. (c) Eukaryotic chromosomal DNA contains multiple origins of replication. DNA synthesis proceeds in both directions from each origin until adjacent “replication bubbles” eventually merge (d). (b, Courtesy of D.S. Hogness and H.J. Kriegstein)

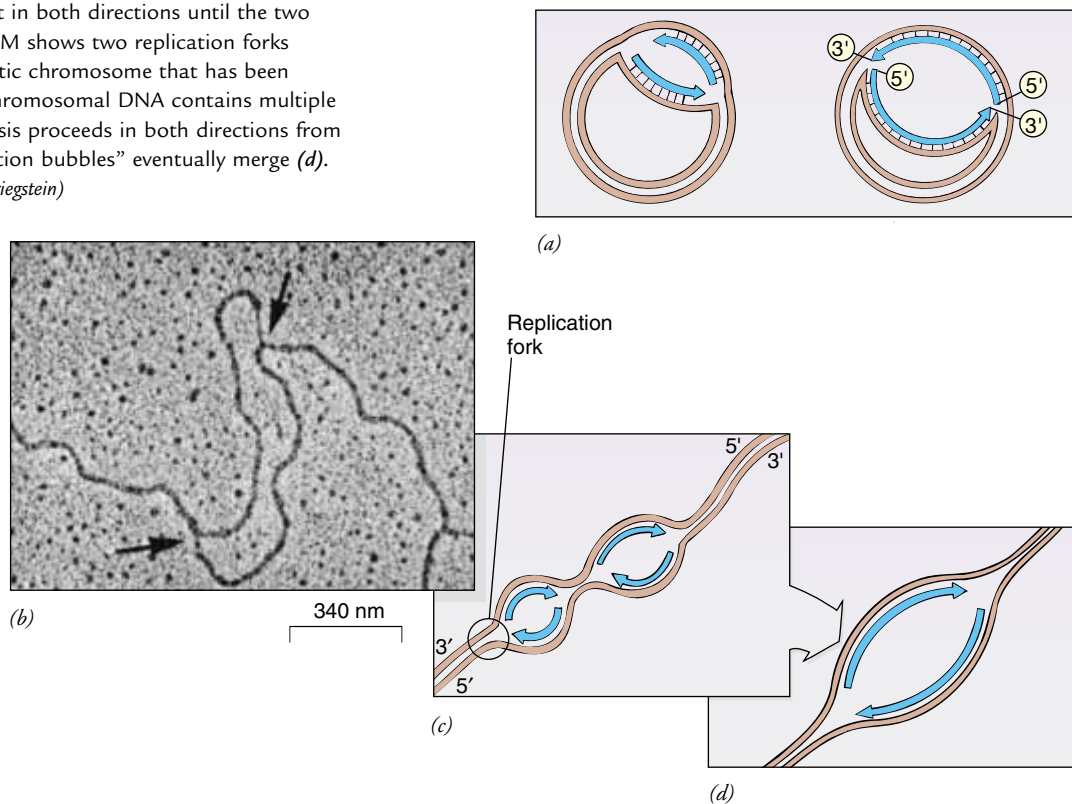

Figure 11–15 Nucleosomes. (a) A model for the structure of a nucleosome. Each nucleosome bead contains a set of eight histone molecules; these form a protein core around which the double-stranded DNA is wound. The DNA surrounding the histone consists of 146 nucleotide pairs; another segment of DNA, about 60 nucleotide pairs long, links nucleosome beads. (b) TEM of nucleosomes from the nucleus of a chicken red blood cell. Normally nucleosomes are packed more closely together, but the preparation procedure has spread them apart, revealing the DNA linkers. (b, courtesy of D.E. Olins and A.L. Olins)

(Visuals Unlimited/K.G. Murti)

Figure 11–17 A chromosome depleted of histones. Note how densely packed the DNA fibrils are in this TEM of a mouse chromosome, even though they have been released from the histone proteins that organize them into tightly coiled structures. The dark structure extending from left to right across the bottom of the photograph is composed of scaffolding proteins. (Courtesy of U. Laemmli, from *Cell* 12:817, 1988. Copyright by Cell Press)

Telomerase, Cellular Aging, and Cancer

- HYPOTHESIS:** The number of cell divisions that normal human somatic cells can undergo when grown in culture is limited by the length of their telomeric DNA.
- METHOD:** To test the prediction that cells will be able to undergo more divisions if their telomeric DNA is lengthened, researchers used a virus to introduce the gene coding for the catalytic subunit of telomerase into cultured normal human cells, which normally lack telomerase activity.
- RESULTS:** The cells produced active telomerase, which elongated the telomeres. The cells continued to actively proliferate for many cell cycles beyond the point at which cell division would normally cease.
- CONCLUSION:** The life spans of cells can be extended by lengthening the telomeric DNA of their chromosomes.

Unlike prokaryotic DNA, which is circular, eukaryotic chromosomes have free ends. This simple fact has far-reaching consequences. Because of the discontinuous way in which DNA polymerases work, they are unable to complete replication neatly when they reach the end of the DNA, and must therefore leave a small portion unreplicated. This situation is less dangerous than it sounds because chromosomes have end caps (telomeres) that do not contain protein-coding genes, but instead consist of short, simple, noncoding DNA sequences that are repeated many times. Therefore, although a small amount of telomeric DNA fails to replicate each time the cell divides, no essential genetic information is lost.

Telomeric DNA can be lengthened by a special DNA replication enzyme known as **telomerase**. This enzyme, which was discovered in 1984 by Carol W. Greider and Elizabeth H. Blackburn, is typically present in cells that can divide an unlimited number of times, including unicellular organisms and many types of cancer cells.

In animals such as humans, active telomerase is usually present in germ line cells (the cells that give rise to eggs and sperm) but not in the normal cells of the body, known as somatic cells. There has been much speculation that this lack of telomerase activity could contribute to the phenomenon known as **cellular aging**. Cellular aging has been analyzed since the 1960s, following the pioneering studies of Leonard Hayflick, who showed that normal human somatic cells grown in culture lose their ability to divide after

a limited number of cell divisions. Furthermore, the number of cell divisions is determined by the age of the individual from whom the cells were taken. Cells from a 70 year old can divide only 20 to 30 times, as compared with those from an infant, which can divide 80 to 90 times.

Although correlations between the ability of cells to undergo unlimited divisions and the presence of telomerase activity have been repeatedly noted, this connection remained controversial. Proof of a causal relationship was lacking until Andrea G. Bodnar and her colleagues at the Geron Corporation teamed up with researchers from the University of Texas Southwestern Medical Center to conduct a direct test.* Using the techniques of recombinant DNA technology (see Chapter 14), they infected cultured normal human cells with a virus that carried the genetic information coding for the catalytic subunit of telomerase. Not only did the cells produce active telomerase, which elongated the telomeres significantly, but the cells continued to divide long past the point at which cell divisions would normally cease. These findings have revived interest in telomeres, particularly with respect to their apparent dual roles in aging and cancer, and are leading to more hypotheses that can be experimentally tested.

SUMMARY WITH KEY TERMS

- I. Many early geneticists thought that genes were made of proteins. Proteins were known to be complex and variable, whereas nucleic acids were thought of as rather simple molecules with a limited ability to store information.
 - A. Garrod's work on inborn errors of metabolism and that of Beadle and Tatum with *Neurospora* mutants suggested that each protein is specified by a single gene.
 - B. Several lines of evidence supported the idea that DNA is the genetic material.
 1. In **transformation** experiments, the DNA of one strain of bacteria can endow related bacteria with new genetic characteristics.
 2. When a bacterial cell becomes infected with a virus, only the DNA from the virus enters the cell; this DNA is sufficient for the virus to reproduce and form new virus particles.
 - C. Watson and Crick's studies on the structure of DNA demonstrated how information can be stored in the molecule's structure and how DNA molecules can serve as templates for their own duplication.
- II. DNA is a very regular polymer of **nucleotides**.
 - A. Each nucleotide subunit contains a nitrogenous base, which may be one of the **purines** (**adenine** or **guanine**) or one of the **pyrimidines** (**thymine** or **cytosine**). Each base is covalently linked to a five-carbon sugar, **deoxyribose**, which is covalently bonded to a phosphate group.

- B. The backbone of each single DNA chain is formed by alternating sugar and phosphate groups, joined by covalent **phosphodiester linkages**. Each phosphate group is attached to the 5' carbon of one deoxyribose and to the 3' carbon of the neighboring deoxyribose.
 - C. Each DNA molecule is composed of two polynucleotide chains that associate as a **double helix**. The two chains are **antiparallel** (meaning they run in opposite directions); at each end of the DNA molecule one chain has an exposed 5' deoxyribose carbon (the **5' end**) and the other has an exposed 3' deoxyribose carbon (the **3' end**).
 - D. The two chains of the helix are held together by hydrogen bonding between specific base pairs. Adenine (A) forms two hydrogen bonds with thymine (T); guanine (G) forms three hydrogen bonds with cytosine (C).
 1. **Complementary base-pairing** between A and T and between G and C is the basis of Chargaff's rules, which state that A=T and G=C.
 2. Because the two strands of DNA are held together by complementary base-pairing, it is possible to predict the base sequence of one strand if one knows the base sequence of the other strand.
- III. During **DNA replication**, the two strands of the double helix unwind. Each strand serves as a template for the formation of a new complementary strand.
- A. DNA replication is **semiconservative**; that is, each daughter double helix contains one strand from the parent molecule and one newly synthesized strand.
 - B. DNA replication is a complex process requiring a number of different enzymes.
 1. The enzyme that adds new deoxyribonucleotides to a growing DNA strand is a **DNA polymerase**.
 2. Additional enzymes and other proteins are required to unwind and stabilize the separated DNA helix and to form **RNA primers**. **Topoisomerases** prevent tangling and knotting, and **DNA ligase** links together fragments of newly synthesized DNA.
 - C. DNA synthesis always proceeds in a 5' → 3' direction. This requires that one DNA strand (the **lagging strand**) be synthesized discontinuously, as short **Okazaki fragments**. The opposite strand (the **leading strand**) is synthesized continuously.
 - D. DNA replication is bidirectional, starting at the **origin of replication** and proceeding in both directions from that point. A eukaryotic chromosome may have multiple origins of replication and may be replicating at many points along its length at any one time.
 - E. Eukaryotic chromosome ends, known as **telomeres**, shorten slightly with each cell cycle, but can be extended by the **telomerase** enzyme. The absence of telomerase activity in certain cells may be a cause of **cellular aging**.
- IV. DNA is organized in a cell.
- A. Prokaryotic cells usually have circular DNA molecules.
 - B. Eukaryotic chromosomes have several levels of organization.
 1. The DNA is associated with **histones** (basic proteins) to form **nucleosomes**, each of which consists of a histone bead with DNA wrapped around it.
 2. The nucleosomes are organized into large coiled loops held together by nonhistone **scaffolding proteins**.
 3. DNA molecules are much longer than the nuclei or the cells that contain them. The organization of DNA into chromosomes allows the DNA to be accurately replicated and segregated into daughter cells without tangling.

POST-TEST

1. Which of the following inspired Avery and his coworkers to do the experiments that demonstrated that the transforming principle in bacteria is DNA? (a) the fact that A=T and G=C (b) Beadle and Tatum's work on biochemical pathways in *Neurospora* (c) Meselson and Stahl's studies on DNA replication in *E. coli* (d) Griffith's experiments on smooth and rough strains of pneumococcus (e) Hershey and Chase's experiments on the reproduction of bacteriophages
2. Which of the following was commonly thought to be true (by scientists) at the time that Beadle and Tatum began their work on *Neurospora*? (a) enzymes are proteins (b) DNA specifies the structure of proteins (c) DNA replication is semiconservative (d) DNA is a double helix (e) the number of purines in DNA is equal to the number of pyrimidines
3. The statement "DNA replicates by a semiconservative mechanism" means that (a) only one DNA strand is copied (b) first one DNA strand is copied, and then the other strand is copied (c) the two strands of a double helix have identical base sequences (d) some portions of a single DNA strand are old, and other portions are newly synthesized (e) each double helix consists of one old and one newly synthesized strand
4. Multiple origins of replication (a) speed up replication of eukaryotic chromosomes (b) allow the lagging strands and leading strands to be synthesized at different replication forks (c) help to relieve strain as the double helix is unwound (d) prevent mutations (e) are necessary for the replication of a circular DNA molecule in bacteria
5. Topoisomerases (a) synthesize DNA (b) synthesize RNA primers (c) join Okazaki fragments (d) break and rejoin DNA to resolve knots that have formed (e) prevent single DNA strands from joining to form a double helix
6. A phosphate in DNA is (a) hydrogen bonded to a base (b) covalently linked to two bases (c) covalently linked to two deoxyriboses (d) hydrogen-bonded to two additional phosphates (e) covalently linked to a base, a deoxyribose, and another phosphate
7. Which of the following depicts the relative arrangement of the complementary strands of a DNA double helix?

(a) 5'—5' (b) 3'—5' (c) 3'—3' (d) 5'—5' (e) 3'—5'
 3'—3' 3'—5' 3'—3' 5'—5' 5'—3'
8. A lagging strand is formed by (a) joining primers (b) joining Okazaki fragments (c) joining leading strands (d) breaking up a leading strand (e) joining primers, Okazaki fragments, and leading strands
9. The immediate source of energy for DNA replication is (a) the hydrolysis of nucleoside triphosphates (b) the oxidation of NADPH (c) the hydrolysis of ATP (d) electron transport (e) the breaking of hydrogen bonds
10. A nucleosome consists of (a) DNA and scaffolding proteins (b) scaffolding proteins and histones (c) DNA and histones (d) DNA, histones, and scaffolding proteins (e) histones only

REVIEW QUESTIONS

1. How did the experiments of Avery and coworkers point to DNA as the essential genetic material? Did the Hershey-Chase experiment establish that DNA is the genetic material in all organisms? Did either of these experiments demonstrate how DNA could function as the chemical basis of genes?
2. Sketch the structure of a single strand of DNA. What types of subunits make up the chain? How are they linked?
3. Describe the structure of double-stranded DNA as determined by Watson and Crick.
4. Does a single strand of DNA obey Chargaff's rules? How do Chargaff's rules relate to the structure of DNA?
5. What are some of the mechanical problems encountered in DNA replication? How are they dealt with by the cell?
6. Why is DNA replication continuous for one strand but discontinuous for the other?
7. Compare the structures of a bacterial DNA molecule and a eukaryotic chromosome. What effects do these differences have on replication?
8. Describe how both prokaryotic and eukaryotic cells cope with the large discrepancy between the length of their DNA molecules and the size of the cell or nucleus.

YOU MAKE THE CONNECTION

1. What characteristics must a molecule have if it is to serve as genetic material? What important features of the structure of DNA are consistent with its role as the chemical basis of heredity?
2. In Chapter 10 we discussed the fact that heritable variation is essential for the study of inheritance. What role did mutant strains play in Beadle and Tatum's development of the one gene, one enzyme hypothesis?

CHAPTER 12

RNA and Protein Synthesis: The Expression of Genetic Information

In Chapter 11 we saw that a base sequence in DNA is replicated by a cell so that it can be passed accurately to its descendents. The basic features of the DNA double helix originally described by Watson and Crick are now known to be the same in all cells studied to date, from bacteria to humans.

By the mid-1950s it became evident that the genetic information in DNA contains the code for all the proteins needed by the cell. However, more than a decade of intense investigation by many scientists was required before a fundamental understanding of how cells are able to convert DNA information into amino acid sequences of proteins could be developed. Much of that understanding came from studying the functions of bacterial genes. After the discovery of the structure of DNA, prokaryotic cells quickly became the organisms of choice for these investigations because they could be grown quickly and easily and because they seemed to contain only the minimal amount of DNA needed for growth and reproduction. The validity, as well as the utility, of this approach has been repeatedly confirmed, as researchers have learned that all organisms share fundamental genetic similarities, which include sharing the same genetic code.

In this chapter we examine at the molecular level how DNA is able to affect the phenotype of the organism through a process known as **gene expression**. Gene expression is a complex series of events by which the information contained in the sequence of bases in DNA is decoded and used to specify the makeup of the proteins in the cell. The proteins produced then affect the phenotype in some way; these effects can range from obvious visible physical traits to subtle changes observable only at the biochemical level. The TEM illustrates **transcription**, the first major step of gene expression. In transcription, RNA molecules (*lateral strands*) are synthesized as complementary copies of a DNA template (*central axis*). A second major step of gene expression is **translation**, or protein synthesis. In Chapter 13 we consider some of the ways the entire process is controlled.

We first focus our attention on gene expression in prokaryotic cells because these cells are best understood. We then extend our discussion to include eukaryotic cells. Our understanding of these cells is improving rapidly as a result of groundwork laid by study of the simpler bacterial systems.

(Professor Oscar Miller/Science Photo Library/Photo Researchers, Inc.)

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Outline the flow of genetic information in cells, from DNA to protein.
2. Compare the structures of DNA and RNA and explain how the structure of each is related to its role in the cell.
3. Compare the processes of transcription and replication, identifying both similarities and differences.
4. Identify the features of tRNA that are important in decoding genetic information and converting it into “protein language.”
5. Explain how the ribosome functions in protein synthesis.
6. Diagram the processes of initiation, chain elongation, and chain termination in protein synthesis.
7. Compare eukaryotic and prokaryotic mRNAs and explain the functional significance of their structural differences.
8. Analyze the differences in translation in prokaryotic and eukaryotic cells.
9. Explain why the genetic code is said to be redundant and virtually universal. Discuss how these features may reflect the evolutionary history of the code.
10. Give examples of the different classes of mutations that affect the base sequence of DNA and demonstrate the effects that each has on the protein produced.

DNA IS TRANSCRIBED TO FORM RNA; RNA IS TRANSLATED TO FORM PROTEIN

Although the sequence of bases in DNA determines the sequence of amino acids in proteins, the information in DNA is not used directly. Instead, a related nucleic acid, **RNA**, or **ribonucleic acid**, serves as an intermediary between DNA and protein (Fig. 12–1). Like DNA, RNA is a polymer of nucleotides, but it has some important differences.

RNA is usually single-stranded, although internal regions of some RNAs may have complementary sequences that allow the strand to fold back and pair to form short, double-stranded segments. As shown in Figure 12–1, the sugar in RNA is **ribose**, which is similar to deoxyribose of DNA, but with an extra hydroxyl group. The base **uracil** substitutes for thymine and, like thymine, is a pyrimidine that can form two hydrogen bonds with adenine. Hence, uracil and adenine are a complementary pair.

When a protein-coding gene is expressed, an RNA copy is made of the information in the DNA (Fig. 12–2). This process resembles DNA replication in that the sequence of bases in the RNA strand is determined by complementary base-pairing with one of the DNA strands. Because RNA synthesis involves making a copy of information in one kind of nucleic acid (DNA) in the form of another nucleic acid (RNA), we refer to this process as **transcription** (“copying”). The RNA that carries the specific information for making a protein is called **messenger RNA**, or **mRNA**.

In the second stage of gene expression, the transcribed information in the mRNA is used to specify the amino acid sequence of a protein. This process is called **translation** because

it involves conversion of the “nucleic acid language” in the mRNA molecule into the “amino acid language” of the protein.

The protein-coding information in mRNA is contained in its sequence of bases. A sequence of three consecutive bases,

Figure 12–1 Nucleotide structure of RNA. The nucleotide subunits of RNA are joined by 5' → 3' phosphodiester linkages, like those found in DNA. Adenine, guanine, and cytosine are present, as in DNA, but the base uracil replaces thymine. All four nucleotide types contain the five-carbon sugar ribose, which has a hydroxyl group on its 2' carbon atom. (Compare with the deoxyribose of DNA, which has only a hydrogen at the 2' position.)

Figure 12–2 Overview of transcription and translation. In transcription, messenger RNA is synthesized as a complementary copy of one of the DNA strands. Messenger RNA carries genetic information in the form of sets of three bases called codons, each of which specifies one amino acid. Messenger RNA codons are translated consecutively, thus specifying the linear sequence of amino acids in the polypeptide chain.

called a **codon**, specifies one amino acid. For example, one codon that corresponds to the amino acid threonine is 5′–ACG–3′ (Table 12–1). Because each codon requires three nucleotides, the code is referred to as a **triplet code**.

Translation requires cellular machinery that can recognize and decode the mRNA codons. **Transfer RNAs (tRNAs)** are critical parts of the decoding machinery because they act as “adapters” that provide a connection between amino acids and nucleic acids. This is possible because each tRNA can (1) link with a specific amino acid and (2) recognize the appropriate mRNA codon for that particular amino acid. A particular tRNA can recognize a specific codon because it has a sequence of three bases, called the **anticodon**, that associates with the mRNA codon by complementary base-pairing. The exact anticodon that is complementary to the codon for threonine in our example is 3′–UGC–5′.

Translation requires that (1) tRNA anticodons be bonded

to the mRNA and (2) the amino acids carried by the tRNAs be linked together in the order specified by the mRNA. This is accomplished by **ribosomes** (see Chapter 4), complex organelles composed of two different subunits, each containing a number of proteins and **ribosomal RNA (rRNA)**. Ribosomes attach to one end of the mRNA and travel along it, thereby allowing the tRNAs to attach sequentially to the mRNA. In this way the amino acids become properly positioned to be joined by peptide bonds in the correct sequence to form a polypeptide.

The Watson and Crick model of DNA showed it to be a linear sequence of four nucleotides. If each nucleotide were to code for a single amino acid, it would be possible to specify only 4 amino acids, not the 20 found in the vast variety of cellular proteins. Scientists saw that the DNA bases could serve as a four-letter “alphabet” and hypothesized that three-letter combinations of the four bases (4^3) would make it possible to

TABLE 12-1 The Genetic Code: Codons of mRNA that Specify a Given Amino Acid

form a total of 64 “words,” more than sufficient to specify all the naturally occurring amino acids. By 1967 the “cracking” of the genetic code was completed, verifying the existence of the three-base triplet code that is common to all organisms.

TRANSCRIPTION IS THE SYNTHESIS OF RNA FROM A DNA TEMPLATE

Three main kinds of RNA are transcribed from DNA: ribosomal RNA (rRNA) and transfer RNA (tRNA), as well as messenger RNA (mRNA). Most RNA is synthesized by **DNA-**

dependent RNA polymerases, enzymes that are present in all cells. These enzymes require DNA as a template and have many similarities to the DNA polymerases. Like DNA polymerases, they synthesize nucleic acids in a 5' to 3' direction. They use nucleotides with three phosphate groups as substrates, removing two of the phosphates as the subunits are covalently linked to the 3' end of the RNA (Fig. 12–3). Like DNA replication and the hydrolysis of ATP, these reactions are strongly exergonic (see Chapter 6).

Whenever nucleic acid molecules associate by complementary base-pairing, the two strands are antiparallel. Just as the two paired strands of DNA are antiparallel (see Chapter 11), the transcribed strand of the DNA and the complementary RNA strand are also antiparallel.

Messenger RNA contains base sequences that code for protein

An RNA polymerase begins transcription after it binds to a DNA sequence known as a **promoter**; the promoter is not transcribed. Unlike DNA synthesis, RNA synthesis does not require a primer. However, transcription requires a number of proteins in addition to RNA polymerase; these are discussed in Chapter 13. As illustrated in Figure 12–3, the first nucleotide at the 5' end of a new mRNA chain retains its triphosphate group, but as each additional nucleotide is incorporated at the 3' end of the growing RNA molecule, two of its phosphates are removed in an exergonic reaction that leaves the remaining phosphate to become part of the sugar-phosphate backbone (as in DNA). The last nucleotide to be incorporated has an exposed 3' hydroxyl group. The termination of transcription, like its initiation, is controlled by a set of specific base sequences. These sequences at the end of the gene act as “stop” signals for the RNA polymerase.

It is conventional to refer to a sequence of bases in a gene or the mRNA sequence transcribed from it as *upstream* or *downstream* of some reference point. **Upstream** means toward the 5' end of the mRNA sequence or the 3' end of the transcribed DNA strand. **Downstream** means toward the 3' end of the RNA or the 5' end of the transcribed DNA strand.

In the bacterium *Escherichia coli*, transcription of a gene is initiated when RNA polymerase (with the help of another protein) recognizes a specific promoter sequence of bases upstream from the protein-coding sequence. Different genes may have slightly different promoter sequences, so the cell can direct which genes are transcribed at any one time (Chapter 13).

Figure 12-3 Transcription. The unwinding of the DNA double helix allows bases of incoming nucleotides with three phosphates to pair with complementary bases on the DNA template strand (*right*). RNA polymerase cleaves two phosphates from each nucleotide (*not shown*) and covalently links the remaining phosphate to the 3' end of the growing RNA chain. Thus, RNA, like DNA, is synthesized in a 5' → 3' direction.

Bacterial promoters are usually about 40 bases long and are positioned in the DNA just upstream of the point at which transcription will begin. Once the polymerase has recognized the correct promoter, it unwinds the helix and begins transcription.

Usually only one of the strands in a protein-coding region of DNA is transcribed. This strand, referred to as the *transcribed strand* or the *template strand*, is complementary to the mRNA (Fig. 12-4a). For example, consider a segment of DNA that contains the following DNA base sequence in the template strand:

3'—TAACGGTCT—5'

If the complementary DNA strand

5'—ATTGCCAGA—3'

were to be transcribed, a message specifying an entirely different (and generally nonfunctional) protein would be produced. However, the fact that only one strand is transcribed does not mean that the same strand is always the template throughout the length of a chromosome-sized DNA molecule. Instead, a particular strand may serve as the transcribed strand for some genes and the nontranscribed strand for others (Fig. 12-4b).

Figure 12–4 Synthesis of mRNA. (a) The mRNA is synthesized in a 5′ → 3′ direction from the template strand of the DNA molecule. Transcription starts downstream from a DNA promoter sequence, to which the RNA polymerase initially binds. Termination sequences, found downstream from the protein-coding sequences, signal the RNA polymerase to stop transcription and be released from the DNA. (b) Usually only one of the two strands is transcribed for a given gene, but the opposite strand may be transcribed for a neighboring gene. Each transcript starts at its own promoter.

Messenger RNA contains additional base sequences that do not directly code for protein

A completed bacterial RNA contains more than the nucleotide sequence that codes for a protein. RNA polymerase starts transcription of a gene well upstream of the protein-coding sequences. As a result, the mRNA has a noncoding **leader sequence** at its 5′ end. The leader contains recognition signals for ribosome binding, which allow the ribosomes to be properly positioned to translate the message. The leader sequence is followed by the **coding sequence**, which contains the actual messages for the proteins. In bacterial cells, one or more proteins may be encoded by a single mRNA molecule (see Chapter 13). At the end of each coding sequence is a special **termination**, or **stop, codon**. The stop codons—UAA, UGA, or UAG (see Table 12–1)—do not code for amino acids, but

instead specify the end of the protein. These are followed by noncoding 3′ trailing sequences, which can vary in length (Fig. 12–5).

DURING TRANSLATION, THE NUCLEIC ACID MESSAGE IS DECODED

Translation, or protein synthesis, adds another level of complexity to the process of information transfer because it involves the conversion of the four-base nucleic acid code to the 20-amino acid alphabet of proteins. The structural differences between a polynucleotide chain and a polypeptide chain are so great that no simple way exists for amino acids to interact directly with an mRNA molecule to make a protein. Translation therefore requires the coordinated functioning of more

Figure 12–5 Bacterial mRNA. This figure compares a bacterial mRNA with the region of DNA from which it was transcribed. RNA polymerase recognizes, but does not transcribe, promoter sequences in the DNA. Initiation of RNA synthesis occurs five to eight bases downstream from the promoter. Ribosome-recognition sites are located in the 5′ mRNA leader sequences. Protein-coding sequences begin at a start codon, which follows the leader sequences, and end at a downstream termination codon near the 3′ end of the molecule. Noncoding trailing sequences, which can vary in length, follow the protein-coding sequences.

than 100 kinds of macromolecules, including the protein and RNA components of the ribosomes, mRNA, and amino acids linked to tRNAs.

An amino acid is attached to transfer RNA before becoming incorporated into a polypeptide

Amino acids are joined together by peptide bonds to form proteins (see Chapter 3). This joining involves linking the amino and carboxyl groups of adjacent amino acids. Peptide bond formation is only one aspect of the translation process, however, because the amino acids must be linked in the correct sequence specified by the codons in the mRNA.

Francis Crick recognized this problem and proposed that a molecule was needed to serve as an “adapter” in protein synthesis and bridge the gap between mRNA and proteins. Crick’s adapters turned out to be transfer RNA (tRNA) molecules. DNA contains special tRNA genes that are transcribed to form the tRNAs. Amino acids are covalently linked to their respective tRNA molecules by specific enzymes called **aminoacyl-tRNA synthetases**, which use ATP as an energy source (Fig. 12–6). The resulting complexes, called **aminoacyl-tRNAs**, are able to bind to the mRNA coding sequence so as to align the amino acids in the correct order to form the polypeptide chain.

Transfer RNA molecules have specialized regions with specific functions

Although tRNA molecules are considerably smaller than mRNA or rRNA molecules, they have a complex structure. A

tRNA molecule must have several properties:

1. It must be recognized by a specific aminoacyl-tRNA synthetase that adds the correct amino acid.
2. It must have a region that serves as the attachment site for the amino acid.
3. It must be recognized by ribosomes.
4. It must have an **anticodon**, a specific complementary binding sequence for the correct mRNA codon.

The tRNAs are polynucleotide chains about 70 nucleotides long, each with a number of unique base sequences, as well as some sequences that are common to all (Fig. 12–7). Complementary base-pairing within each tRNA molecule causes it to be doubled back and folded. Three or more loops of unpaired nucleotides are formed, one of which contains the anticodon triplet. The amino acid binding site is at the 3′ end of the molecule. The carboxyl group of the amino acid is bound to the exposed 3′ hydroxyl group of the terminal nucleotide, leaving the amino group free to participate in peptide bond formation. The pattern of folding results in a constant distance between the anticodon and amino acid in all tRNAs examined, allowing for precise positioning of the amino acids during translation.

The components of the translational machinery come together at the ribosomes

The importance of ribosomes and of protein synthesis in cellular metabolism is exemplified by a rapidly growing *E. coli* cell, which contains some 15,000 ribosomes—nearly one-third of the total mass of the cell. Although prokaryotic and eu-

◀ **Figure 12-6 Formation of aminoacyl-tRNA.** (a) Aminoacyl-tRNA synthetase catalyzes an ATP-requiring reaction (b) in which the carboxyl group of the amino acid becomes attached to the 3' end of the tRNA, (c), and the resulting aminoacyl-tRNA complex is released (d).

▼ **Figure 12-7 Three representations of a tRNA molecule.** The genetic code is “read” by tRNA molecules, which have characteristic structures. (a) The three-dimensional shape of a tRNA molecule is determined by hydrogen bonds that form between complementary bases. (b) One loop contains the triplet anticodon; these unpaired bases can pair with a complementary mRNA triplet codon. The amino acid is attached to the terminal ribose at the 3' OH end. (c) This schematic diagram of an aminoacyl tRNA shows an amino acid attached to its tRNA by its carboxyl group, leaving its amino group exposed for peptide bond formation.

Figure 12-8 Ribosomal structure. A ribosome (a) consists of two subunits, one larger and one smaller, and (b) contains two binding sites for aminoacyl tRNA molecules.

karyotic ribosomes are not identical, ribosomes from all organisms are composed of two subunits made up of protein and ribosomal RNA, which is transcribed from DNA. Ribosomal RNA does not transfer specific information, but instead has structural and catalytic functions.

Each ribosomal subunit can be isolated intact in the laboratory and then separated into each of its RNA and protein constituents. For example, it has been found that in bacteria the smaller of these subunits contains 21 proteins and one ribosomal RNA molecule, and the larger contains 35 proteins and two ribosomal RNA molecules. Under certain conditions it is possible to reassemble each subunit into a functional form by adding each component in its correct order. Through this approach, together with sophisticated electron microscopic studies, it has been possible to determine the three-dimensional structure of the ribosome (Fig. 12-8a), as well as how it is assembled in the living cell. The large subunit contains a depression on one surface into which the small subunit fits. The mRNA fits in a groove formed between the contact surfaces of the two subunits.

Within each ribosome are two depressions, the **A** and **P** binding sites for tRNA molecules (Fig. 12-8b). The tRNA holding the polypeptide chain occupies the P site. The A site is so named because the aminoacyl-tRNA delivering the next amino acid in the sequence binds at this location. Following peptide bond formation between the amino acid at the A site

and the end of the growing polypeptide chain, the tRNA (now with the entire polypeptide chain attached) moves to the P site of the ribosome, leaving the A site available for the next aminoacyl-tRNA molecule.

One of the roles of the ribosome is to hold the mRNA template, the aminoacyl-tRNA, and the growing peptide chain in the correct orientation so that the genetic code can be read and the peptide bond formed.

Translation includes initiation, elongation, and termination

For purposes of discussion, the process of protein synthesis is generally divided into three distinct stages: **initiation**, repeating cycles of **elongation**, and **termination**.

The initiation process consists of several steps and requires a number of proteins, called **initiation factors**. Initiation begins with the loading of a special **initiation tRNA** onto the small ribosomal subunit. In all organisms the codon for the initiation of protein synthesis is AUG, which codes for the amino acid methionine (Fig. 12-9).

Once the initiator tRNA is loaded on the small subunit, the initiation complex binds to the special **ribosome-recognition sequences** near the 5' end of the mRNA; these are upstream of the coding sequences. Binding results in alignment of the anticodon of the initiator tRNA with the AUG initia-

Figure 12–9 Initiation of protein synthesis.
The small ribosomal subunit participates in the formation of an initiation complex, which then associates with the large subunit. The initiation complex shown is found in *E. coli*.

tion codon of the mRNA. The large ribosomal subunit then binds to the complex, forming the completed ribosome.

The addition of other amino acids to the growing polypeptide is called **elongation**. The initiator tRNA is bound to the P site of the ribosome, leaving the A site unoccupied so that it can be filled by the aminoacyl-tRNA specified by the next codon. Figure 12–10 outlines the events involved in elongation. The appropriate aminoacyl-tRNA binds to the A site by specific base-pairing of its anticodon with the complementary mRNA codon. This binding step requires energy, in this case supplied by GTP (guanosine triphosphate, an energy transfer molecule similar to ATP).

The amino group of the amino acid at the A site is now aligned with the carboxyl group of the preceding amino acid at the P site. Peptide bond formation then takes place between the amino group of the new amino acid and the carboxyl group of the preceding amino acid. In this process, the amino acid attached at the P site is released from its tRNA and becomes

attached to the aminoacyl-tRNA at the A site. This reaction is spontaneous (i.e., it does not require additional energy) because energy was transferred from ATP during the formation of the aminoacyl-tRNA. It does, however, require an enzyme (known as *peptidyl transferase*). Remarkably, there is evidence that this enzyme is not a protein, but an rRNA component of the large ribosomal subunit. Such an RNA catalyst is known as a **ribozyme**.

Recall from Chapter 3 that polypeptide chains have direction, or polarity. The amino acid on one end has a free amino group (the amino end), and the amino acid at the other end has a free carboxyl group (the carboxyl end). Protein synthesis always proceeds from the amino end to the carboxyl end of the growing peptide chain.

After the peptide bond is formed, the tRNA molecule in the P site is released. The growing peptide chain, which is now attached to the tRNA in the A site, is then translocated to the P site, leaving the A site open for the next aminoacyl tRNA.

Figure 12–10 Elongation. Each repetition of the elongation process adds one amino acid to the growing polypeptide chain.

This **translocation** process requires energy, which is again supplied by GTP.

The ribosome and the message move in relation to each other so that the mRNA codon specifying the next amino acid in the polypeptide chain becomes positioned in the unoccupied A site. This process involves movement of the ribosome in the 3' direction along the mRNA molecule; thus, translation of the mRNA always proceeds in a 5' to 3' direction. The end of the mRNA molecule that is synthesized first during transcription is also the first to be translated to form a polypeptide. Formation of each peptide bond requires only about 1/20 of a second; by repeating the elongation cycle an average-sized protein of about 360 amino acids can be assembled in about 18 seconds.

The synthesis of the polypeptide chain is terminated by “release factors” that recognize the termination, or stop, codon at the end of the coding sequence. Recognition of a termination codon by the release factors causes the ribosome to dis-

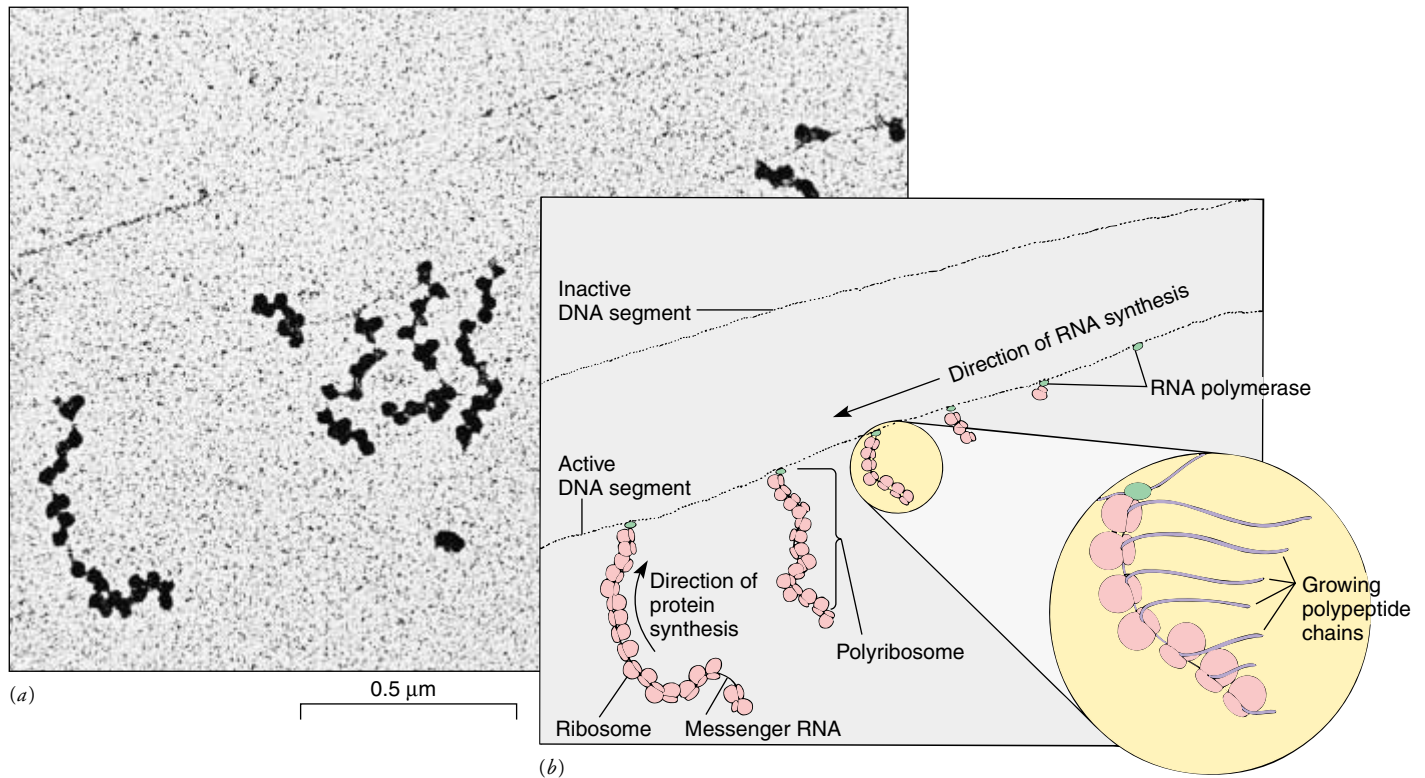

Figure 12-11 Coupled transcription and translation in bacteria. (a) TEM of two strands of *E. coli* DNA, one inactive and the other actively producing mRNA. Protein synthesis begins while the mRNA is being completed, as multiple ribosomes attach to the mRNA to form a polyribosome. sociate into its two subunits, which can then be used to form a new initiation complex with another mRNA molecule.

A polyribosome is a complex of one mRNA and many ribosomes

In *E. coli* and other prokaryotes, transcription and translation are *coupled* (Fig. 12-11). Ribosomes can bind to the 5' end of the growing mRNA and initiate translation long before the message is completed. As many as 15 ribosomes may be bound to a single mRNA molecule. Messenger RNA molecules bound to clusters of ribosomes are referred to as **polyribosomes**, or sometimes **polysomes**. (Polyribosomes also occur in eukaryotic cells.)

Although a number of polypeptide chains can be actively synthesized on a single messenger RNA at any one time, the half-life (the time it takes for half of the molecules to be degraded) of mRNA molecules in bacterial cells is only about 2 minutes. Usually, degradation of the 5' end of the mRNA begins even before the first polypeptide has been synthesized. Once the ribosome recognition sequences are degraded, no more ribosomes can attach to the mRNA and initiate protein synthesis.

TRANSCRIPTION AND TRANSLATION ARE MORE COMPLEX IN EUKARYOTES THAN IN PROKARYOTES

Although the basic mechanisms of transcription and translation are quite similar in all organisms, some significant differences exist between eukaryotes and prokaryotes, particularly with regard to the characteristics of their mRNAs. Whereas bacterial mRNAs are used immediately after transcription without further processing, eukaryotic mRNA molecules undergo specific **posttranscriptional modification and processing**.

Although bacterial mRNA is translated as it is being transcribed from the DNA, eukaryotic RNA is not. Eukaryotic chromosomes are confined to the nucleus of the cell, and protein synthesis takes place in the cytoplasm. The mRNA must be transported through the nuclear envelope and into the cytoplasm before it can be translated. In addition, the original transcript must be modified in several ways (while it is still in the nucleus) before it becomes competent for transport and translation.

Modification of the eukaryotic message begins when the

MAKING THE CONNECTION

“SPLIT GENES” AND EVOLUTION

Why do introns occur in most eukaryotic nuclear genes but not in the genes of most prokaryotes (or of mitochondria and chloroplasts)? How did this remarkable genetic system involving interrupted coding sequences (“split genes”) evolve and why has it survived? It seems incredible that as much as 75% of the original transcript of a eukaryotic nuclear gene has to be removed to make a working message.

Scientific debate has centered around two major questions: How did “split genes” first originate? What role have they played in the evolution of organisms that have them? One idea that is central to both questions has been advanced. This is the proposal that, although proteins are synthesized as continuous linear amino acid sequences, they actually are *modular* in that they are made up of various functional regions called **domains**. For example, the active site of an enzyme might comprise one domain. A different domain might enable that enzyme to bind to a particular cellular structure, and yet another might be a site involved in allosteric regulation (see Chapter 6).

In the early 1980s, Walter Gilbert of Harvard University proposed that exons are nucleotide sequences that code for different structural and functional protein domains. This has turned out to be only partially true. Analyses of the DNA and amino acid sequences of a number of eukaryotic genes have shown that most exons are too small to code for an entire protein domain. However, a block of several exons can code for a domain.

Gilbert further postulated that new proteins with new functions can emerge rapidly when novel combinations of exons are produced by genetic recombination within intron regions of genes that code for different proteins. This hypothesis has become known as *evolution by “exon shuffling.”* For example, the low-density lipoprotein (LDL) receptor protein (a protein found on the surface of human cells that binds to cholesterol transport molecules; see

Chapter 5) has a number of domains that are related to parts of several other proteins with totally different functions.

Evidence supporting evolution by exon shuffling has led some scientists, including Gilbert, to speculate that the number of basic “exon families” (and their corresponding protein domains) is actually relatively small, and that all of the diverse array of proteins found today evolved from just a few thousand domain prototypes. They argue that these were coded for by “mini-genes” (corresponding to exons) separated by “spacers” (corresponding to introns) in organisms that were ancestral to both prokaryotes and eukaryotes. According to their view, known as the *exon theory of genes*, prokaryotes subsequently lost their introns and retained only their exons.

Many scientists disagree; they contend that while exon shuffling probably has been important in the evolution of recently evolved proteins, such as the LDL receptor, these findings do not necessarily support the exon theory of genes. They consider studies of proteins thought to be of “ancient” origin (that is, present in the common ancestor of modern prokaryotes and eukaryotes) to be a better test. Sophisticated biochemical and statistical analyses of such ancient genes have so far failed to reveal any correspondence between exons and protein structure. Thus the exon theory of genes has become less attractive.

Another view is that introns first evolved in the nucleus of an early eukaryote and were propagated as mobile genetic elements, known as *transposons* (discussed later in the chapter). Regardless of how split genes originated, intron excision provides one of the many ways in which present-day eukaryotes regulate the expression of their genes (see Chapter 13). This opportunity for control, together with the fact that eukaryotic RNAs are far more stable than those of prokaryotes, may balance the energy cost of maintaining a large load of noncoding DNA.

growing RNA transcript is about 20 to 30 nucleotides long. At that point enzymes add a **cap** to the 5' end of the mRNA chain. The cap is in the form of an unusual nucleotide, 7-methylguanylate, which is guanosine monophosphate with a methyl group added to one of the nitrogens in the base. Eukaryotic ribosomes cannot bind to an uncapped message.

Capping may also protect the RNA from certain types of degradation and may therefore be partially responsible for the fact that eukaryotic mRNAs are much more stable than prokaryotic mRNAs. Eukaryotic mRNAs have half-lives ranging from 30 minutes to as long as 24 hours; the average half-life of an mRNA molecule in a mammalian cell is about 10 hours (compared with 2 minutes in a bacterial cell).

A second modification of eukaryotic mRNA occurs at the 3' end of the molecule. Near the 3' end of a completed message there is usually a sequence of bases that serves as a signal for the addition of a “tail” with many adenines, known as a **polyadenylated** (or **poly-A**) **tail**. Within about one minute of

completion of the transcript, enzymes in the nucleus recognize this **polyadenylation signal** and cut the mRNA molecule at that site. This is followed by the enzymatic addition of a string of 100 to 250 adenine nucleotides to the 3' end. The function of polyadenylation is not completely understood, although there is evidence that it helps in the export of the mRNA from the nucleus and may stabilize some mRNAs against degradation in the cytoplasm.

Both noncoding and coding sequences are transcribed from eukaryotic genes

One of the greatest surprises in the history of molecular biology was the finding that most eukaryotic genes have **interrupted coding sequences**; that is, there are long sequences of bases within the protein-coding sequences of the gene that do not code for amino acids in the final protein product! The noncoding regions within the gene are called **introns** (inter-

vening sequences), as opposed to **exons** (expressed sequences) which are parts of the protein-coding sequence. The reason for this complex structure of eukaryotic genes is a matter of ongoing debate among molecular biologists (see *Making the Connection: "Split Genes" and Evolution*).

A typical eukaryotic gene may have multiple exons and introns, although the number is quite variable. For example, the β -globin gene, which produces one component of hemoglobin, contains 2 introns; the ovalbumin gene of egg white contains 7; and the gene specifying another egg-white protein, conalbumin, contains 16. In many cases the combined lengths of the introns are much greater than those of the exon se-

quences. For instance, the ovalbumin gene contains about 7700 base pairs, whereas the total of all the exon sequences is only 1859 base pairs.

When a gene that contains introns is transcribed, the entire gene is copied as a large RNA transcript called **precursor mRNA**, or **pre-mRNA**. This molecule contains both exon and intron sequences. (Note that the terms *intron* and *exon* refer to corresponding nucleotide sequences in both DNA and RNA.) For the pre-mRNA to be made into a functional message, not only must it be capped and have a poly-A tail added, but the introns must be removed and the exons spliced together to form a continuous protein-coding message (Fig. 12–12). The

Figure 12–12 Posttranscriptional modification of eukaryotic RNA. (a) A DNA sequence containing both exons and introns is transcribed by RNA polymerase to make the primary transcript, or mRNA precursor. As it is synthesized, the pre-mRNA is “capped” by the addition of a modified base to its 5′ end; (b) A poly-A tail (50 to 200 nucleotides long) is added to the 3′ end; introns are removed, and the exons are spliced together. (c) The mature mRNA is transported through the nuclear envelope and into the cytosol (d) to be translated.

MAKING THE CONNECTION

THE GENETIC CODE AND EVOLUTION

Why does this chapter have only one table to represent the genetic code? This is because of the single most remarkable feature of the code: *it is essentially universal!* Over the years the genetic code has been examined in a diverse array of species and found to be the same in organisms as different as *E. coli*, roses, and humans. These findings strongly suggest that the code is an ancient legacy, derived by the evolution of all living organisms from a common ancestor.

It is thought that the code evolved very early in the history of life (see Chapter 20) and that it has been retained as a kind of “frozen accident” because all but the most minimal changes would

be lethal. Recently some very minor exceptions to the universality of the genetic code have been discovered. In several single-celled protozoa, two of the stop codons, UAA and UGA, code for the amino acid glutamine. The other exceptions are found in mitochondria, which contain their own DNA and protein-synthesis machinery for a small number of genes (see Chapters 4 and 20). These slight coding differences vary with the organism, but it is important to keep in mind that in each case all of the other coding assignments are identical to the standard genetic code.

splicing reactions are mediated by special base sequences within and to either side of the introns. Splicing itself can occur by several different mechanisms. In many instances it involves the association of **small nuclear ribonucleoprotein complexes (snRNPs)** which bind to the introns and catalyze the excision and splicing reactions. In some cases the RNA within the intron acts as a ribozyme, splicing itself without the use of protein enzymes.

THE GENETIC CODE IS READ AS A SERIES OF CODONS

Before the genetic code was deciphered, a number of scientists had become interested in how a genetic code might work. In 1961, Francis Crick and his coworkers concluded from a mathematical analysis that the code was based on nonoverlapping triplets of bases. They predicted that the code is read, one triplet at a time, from a fixed starting point that establishes the **reading frame**. Because there are no “commas” separating the triplets, an alteration in the reading frame would result in the incorporation of incorrect amino acids.

Experimental evidence allowing the assignment of specific triplets to specific amino acids was first obtained by Marshall Nirenberg and Heinrich Matthaei. By constructing artificial mRNA molecules with known base sequences, they were able to determine which amino acids would be incorporated into protein in purified in vitro protein synthetic systems. For example, when the synthetic mRNA polyuridylic acid (UUUU-UUUUU . . .) was added to a mixture of purified ribosomes, aminoacyl tRNAs, and essential cofactors needed to synthesize protein, only phenylalanine was incorporated into the resulting polypeptide chain. The inference that UUU is the triplet that codes for phenylalanine was inescapable. Similar experiments showed that polyadenylic acid (AAAAAAAAA . . .) codes for a polypeptide of lysine, and polycytidylic acid (CCCCC-CCCC . . .) codes for a polypeptide of proline.

By using mixed nucleotide polymers (such as a random polymer of A and C) as artificial messengers, it became possible to assign the other nucleotide triplet codons to specific amino acids. However, three of the codons, UAA, UGA, and UAG, were not found to specify any amino acid. These codons (the stop, or termination, codons mentioned earlier) are now known to be the signals that specify the end of the coding sequence for a polypeptide chain.

Taken together, these experiments led to the coding assignments of all 64 possible codons, listed in Table 12–1, which are essentially universal in living organisms (see *Making the Connection: The Genetic Code and Evolution*). Investigators were also able to demonstrate conclusively that the code is a nonoverlapping triplet code.

Remember that the genetic code we define and use is an mRNA code. The tRNA anticodon sequences as well as the DNA sequence from which the message is transcribed are complementary to the sequences shown in Table 12–1. For example, the mRNA codon for the amino acid methionine is 5′–AUG–3′. It is transcribed from the DNA base sequence 3′–TAC–5′, and the corresponding tRNA anticodon is 3′–UAC–5′.

The genetic code is redundant

Given the fact that there are 64 possible codons, it is not surprising that certain amino acids are specified by more than one codon. This redundancy in the code has certain characteristic patterns. The codons CCU, CCC, CCA, and CCG are synonymous in that they all code for the amino acid proline. The only difference among the four codons involves the nucleotide at the 3′ end of the triplet. Although the code may be read three nucleotides at a time, only the first two nucleotides appear to contain specific information for proline. A similar pattern can be seen for many other amino acids. Only methionine and tryptophan have single-triplet codes. All other amino acids are specified by two to six different codons.

There are 61 codons that specify amino acids. Although most cells contain only about 40 different tRNA molecules, some of these tRNAs can pair with more than one codon, so all the codons can still be used. This apparent breach of the base-pairing rules was first proposed by Francis Crick as the **wobble hypothesis**. Crick reasoned that the third nucleotide of a tRNA anticodon (which is the 5' base of that sequence) may sometimes be capable of forming hydrogen bonds with more than one kind of third nucleotide (the 3' base) of an mRNA codon. Investigators later established this experimentally by determining the anticodon sequences of tRNA molecules and testing their specificities in artificial systems. Some tRNA molecules can recognize as many as three separate codons specifying the same amino acid.

A GENE IS DEFINED AS A FUNCTIONAL UNIT

In Chapter 11 we traced the development of ideas regarding the nature of the gene. For a time it was useful to define a gene as a sequence of nucleotides that codes for one polypeptide chain. As we have continued to learn more about how genes work, we have revised our definition. We now know that some genes are transcribed to produce RNA molecules such as rRNA and tRNA, whereas others specify the RNA component of the small nuclear ribonucleoprotein complexes used to modify complex mRNA molecules. Studies have also shown that in eukaryotic cells a single gene may be capable of producing more than one polypeptide chain by modifications in the way the mRNA is processed (see Chapter 13).

It is perhaps most useful to define a gene in terms of its product. A **gene** can therefore be thought of as a nucleotide sequence that carries the information needed to produce a specific RNA or protein product. Thus a gene includes noncoding regulatory sequences, as well as coding sequences.

MUTATIONS ARE CHANGES IN DNA

One of the first major discoveries about genes was that they can undergo changes, called **mutations**. We now know that mutations are caused by changes in the nucleotide sequence of the DNA. However, the overall observed mutation rate is much lower than the frequency of damage to DNA, because all organisms have special systems of enzymes that can repair certain kinds of alterations in the DNA.

As explained in Chapter 11, once the DNA sequence has been changed, DNA replication copies the altered sequence just as it would copy a normal sequence, making the mutation stable over an indefinite number of generations. In most cases the mutant gene has no greater tendency than the original gene to mutate again. Mutations provide the diversity of genetic material that makes it possible to study inheritance and

the molecular nature of genes. As we will see in later chapters, mutations also provide the variation necessary for evolution to occur within a given species.

Genes can be altered by mutation in a number of ways (Fig. 12–13 on p. 284). The simplest type of mutation, called a **base substitution mutation**, involves a change in only one pair of nucleotides. It is now possible to determine where a specific mutation occurs in a gene by using recombinant DNA methods to isolate the gene and determine its sequence of bases (see Chapter 14). Often these mutations result from errors in base pairing that occurred during the replication process. For example, an AT base pair might be replaced by a GC, CG, or TA pair. Such a mutation may cause the altered DNA to be transcribed as an altered mRNA. The altered mRNA may then be translated into a peptide chain with only one amino acid different from the normal sequence.

Base substitutions that result in the replacement of one amino acid by another are sometimes referred to as **missense mutations**. Missense mutations can have a wide range of effects. If the amino acid substitution occurs at or near the active site of an enzyme, the activity of the altered protein may be decreased or even destroyed. Some missense mutations involve a change in an amino acid that is not part of the active site. Others may result in the substitution of a closely related amino acid (one with very similar chemical characteristics). Such mutations may be *silent* (undetectable), at least if one simply examines its effects on the whole organism. Because silent mutations occur relatively frequently, the true number of mutations in an organism or a species is much greater than what is actually observed.

Nonsense mutations are base substitutions that convert an amino acid-specifying codon to a termination codon. A nonsense mutation usually destroys the function of the gene product; in the case of a protein-specifying gene, the part of the polypeptide chain that follows the termination codon is missing.

In **frameshift mutations**, one or two nucleotide pairs are inserted into or deleted from the molecule, causing an alteration of the *reading frame*. As a result of this shift, codons downstream of the insertion site specify an entirely new sequence of amino acids. Depending on where the insertion or deletion occurs in the gene, a number of different effects can be generated. In addition to producing an entirely new polypeptide sequence immediately after the change, frameshift mutations usually produce a stop or termination codon within a short distance of the mutation. This codon terminates the already altered polypeptide chain. A frame shift in a gene specifying an enzyme usually results in a loss of enzyme activity. If the enzyme is an essential one, the effect on the organism can be disastrous.

Other types of mutations may be due to a change in chromosome structure (see Chapters 13, 15, and 16). These changes usually have a wide range of effects because they involve large numbers of genes.

One type of mutation is caused by DNA sequences that “jump” into the middle of a gene. These movable sequences

REVERSE TRANSCRIPTION, JUMPING GENES, AND PSEUDOGENES

For several decades, one of the central premises of molecular biology was that genetic information always flows from DNA to RNA to protein. An important exception to this rule was discovered by Howard Temin in 1964 through his studies of certain viruses. Although viruses are noncellular, they contain a single type of nucleic acid and are capable of reproducing in a host cell. Temin was studying certain unusual, cancer-causing tumor viruses that have RNA, rather than DNA, as their genetic material. He found that infection of a host cell by one of these particular viruses is blocked by inhibitors of DNA synthesis and also by inhibitors of transcription. These findings suggested that DNA synthesis and transcription are required for the multiplication of RNA tumor viruses and that there must be a way for information to flow in the “reverse” direction (that is, from RNA to DNA).

Temin proposed that a **DNA provirus** is formed as an intermediary in the replication of RNA tumor viruses. This hypothesis required a new kind of enzyme that would synthesize DNA using RNA as a template. In 1970 Temin and David Baltimore dis-

covered just such an enzyme, and in 1975 they shared the Nobel Prize for their discovery. This RNA-directed DNA polymerase, also known as **reverse transcriptase**, was found in all RNA tumor viruses. (Some RNA viruses that do not produce tumors, however, are replicated directly without using a DNA intermediate.)

After an RNA tumor virus enters the host cell, the viral reverse transcriptase synthesizes a DNA strand that is complementary to the viral RNA. Next, a complementary DNA strand is synthesized, thus completing the double-stranded DNA provirus, which is then integrated into the host cell's DNA. The provirus DNA is transcribed, and the resulting viral mRNA is translated to form specific viral proteins. Additional viral RNA molecules are produced and then incorporated into mature virus particles enclosed by protein coats. Because of their reversal of the usual direction of information flow, such viruses have become known as **retroviruses** (Fig. A). The AIDS virus (HIV-1) is the most widely known retrovirus.

Until a few years ago, reverse transcription was thought to be associated only

with retroviruses. Evidence now suggests that reverse transcription may be quite common, which may partially explain such curious phenomena as “jumping” genes and pseudogenes. Jumping genes, now known as **mobile genetic elements**, **transposable elements**, or **transposons**, were discovered in maize (corn) by Barbara McClintock in the 1950s. She observed that certain genes appeared to be “turned off” and “turned on” spontaneously. She deduced that the mechanism involved a gene that moved from one region of a chromosome to another, where it would either activate or inactivate genes in that vicinity. It was not until the development of recombinant DNA methods (see Chapter 14) and the discovery of jumping genes in a wide variety of organisms that this phenomenon began to be understood. In recognition of her insightful findings, McClintock was awarded a Nobel Prize in 1983.

Transposons are segments of DNA that range from a few hundred to several thousand bases. The elements themselves seem to require a special **transposase** enzyme in order to be incorporated into a new location within the chromosome. The longer elements may contain other genes that “go along for the ride.”

Many transposable elements have been found to have similarities to retroviruses. Their DNA has unusual base sequences at each end, and their genes are remarkably similar, especially those that code for the proteins required for reverse transcription and integration into the chromosome.

Experiments in Gerald Fink's laboratory have provided evidence that reverse transcriptase is involved in the mechanism by which some transposons move. In these cases the DNA sequence itself does not jump from one location to another; instead, the *information moves through an RNA intermediate* (Fig. B). Fink and his colleagues used recombinant DNA methods (see Chapter 14) to insert an intron into the

Figure A Infection cycle of an RNA tumor virus.

of DNA, called **transposons**, not only disrupt the functions of some genes but under some conditions also activate previously inactive genes (see *Focus On: Reverse Transcription, Jumping Genes, and Pseudogenes*).

All the mutations discussed so far can occur infrequently

but spontaneously, as a consequence either of mistakes in DNA replication or defects in the mitotic or meiotic separation of chromosomes. Some regions of DNA, known as mutational **hot spots**, are much more likely than others to undergo mutation. An example would be a short stretch of repeated nu-

DNA sequence of a yeast transposon as a way of identifying it. They then set up conditions that allowed them to recover and analyze the transposed sequence once it had “jumped.” When the transposed sequence appeared at a new location, the intron had been removed, just as introns are removed during the processing of normal mRNA molecules.

Because RNA processing enzymes are known only to splice RNA, it appeared that the transposed DNA sequence had been produced from a processed RNA copy of the original DNA, rather than from the DNA itself. This would have required the RNA sequence to be converted back to DNA by reverse transcriptase activity within the yeast cells.

Other evidence of nonviral reverse transcriptase activities in cells comes from analyses of **pseudogenes**, which closely resemble certain types of normal genes in mammalian cells. Pseudogenes are DNA sequences that are almost identical to those of normal genes, except that they are riddled with mutations that prevent them from functioning in normal protein synthesis. Many pseudogenes resemble DNA copies of mRNA, for where a normal gene would contain one or more introns, these pseudogenes do not. In addition, many pseudogene DNA sequences end with long poly-A tails. One hypothesis concerning the origin of pseudogenes is that some of them may be derived from the processed mRNAs of normal genes. Reverse transcriptase may have synthesized DNA copies, which were reinserted into the chromosome. Because they lack promoter sequences, they are not expressed and simply act as excess baggage, silently accumulating mutations. It is estimated that there may be hundreds or thousands of such sequences in normal human DNA.

Figure B Transposon movement through an RNA intermediate.

cleotides, which can cause DNA polymerase to “slip.”

Mutations in certain genes can increase the overall mutation rate. For example, a mutation in a gene coding for DNA polymerase might make DNA replication less precise, or a mutation in a gene coding for a repair enzyme might cause more

mutations to persist rather than to be repaired.

Not all mutations occur spontaneously; many of the types of mutations discussed above can also be caused by agents known as **mutagens**. Among these are various types of radiation, including x rays, gamma rays, cosmic rays, and ultraviolet

Figure 12-13 Mutations. Missense and nonsense mutations are types of base-substitutions. A missense mutation results in a protein of normal length, but with an amino acid substitution. A nonsense mutation, caused by conversion of an amino acid-specifying codon to a termination codon, results in the production of a truncated protein, which is usually not functional. A frameshift mutation, which results from the insertion or deletion of one or two bases, causes the base sequence following the mutation to shift to a new reading frame. A frame shift may produce a termination codon downstream from the mutation (which would have the same effect as a nonsense mutation caused by base substitution), or it may produce an entirely new amino acid sequence.

let rays. Some chemical mutagens react with and modify specific bases in the DNA, leading to mistakes in complementary base pairing when the DNA molecule is replicated. Other mutagens are inserted into the DNA molecule and change the normal reading frame during replication.

Nevertheless, some new mutations do persist. In fact, each of us is very likely to have some mutant gene that was not present in either of our parents. Although some of these muta-

tions can produce an altered phenotype, most are not noticeable because they are recessive.

Mutations that occur in the cells of the body (somatic cells) are not passed on to the offspring. However, these mutations are of concern because there is a close relationship between somatic mutations and cancer. Many mutagens are also **carcinogens**, agents that produce cancer.

S U M M A R Y W I T H K E Y T E R M S

- I. The mechanism by which information encoded in DNA is used to specify the sequences of amino acids in proteins involves two processes: transcription and translation.
 - A. During **transcription**, an RNA molecule that is complementary to the transcribed or template DNA strand is synthesized. **Messenger RNA (mRNA)** molecules contain information that specifies the amino acid sequences of polypeptide chains.
 - B. During **translation**, a polypeptide chain specified by the mRNA is synthesized.
 1. Each triplet (three-base sequence) in the mRNA constitutes a **codon**, which specifies one amino acid in the polypeptide chain.
 2. Translation requires tRNAs and complex machinery, including ribosomes.
- II. Messenger RNA is synthesized by **DNA-dependent RNA polymerase** enzymes.
 - A. RNA is formed from nucleotide subunits, each of which contains the sugar ribose, a base (uracil, adenine, guanine, or cytosine), and three phosphates.
 - B. RNA polymerase initially binds to a special DNA sequence called the **promoter** region.
 - C. Like DNA, RNA subunits are covalently joined by a 5'—3' linkage to form an alternating sugar-phosphate backbone. The same base-pairing rules are followed as in DNA replication, except that uracil is substituted for thymine.
 - D. RNA synthesis proceeds in a 5' → 3' direction, which means that the template DNA strand is “read” in a 3' → 5' direction.
- III. **Transfer RNAs (tRNAs)** are the “decoding” molecules in the translation process.
 - A. Each tRNA molecule is specific for only one amino acid.
 1. One part of the molecule contains a three-base **anticodon**, which is complementary to a codon of the mRNA.
 2. Attached to one end of the tRNA molecule is the amino acid specified by the complementary mRNA codon.
 - B. Amino acids are covalently bound to tRNA by **aminoacyl-tRNA synthetase** enzymes.
- IV. **Ribosomes** bring together all of the mechanical machinery necessary for translation. They couple the tRNAs to their proper codons on the mRNA, facilitate the formation of peptide bonds between amino acids, and translocate the mRNA so that the next codon can be read.
 - A. Each ribosome is made of a large and a small subunit; each subunit contains **ribosomal RNA (rRNA)** and a large number of proteins.
 - B. **Initiation**, the first stage of translation, includes the binding of the small ribosomal subunit protein, plus initiation factors and the initiation tRNA, to the 5' region of the mRNA, followed by binding of the large ribosomal subunit.
 - C. **Elongation** is a cyclic process in which amino acids are added one by one to the growing polypeptide chain.
 1. Elongation proceeds in a 5' → 3' direction along the mRNA.
 2. The polypeptide chain grows from its amino end to its carboxyl end.
 - D. **Termination**, the final stage of translation, occurs when the ribosome reaches one of three special **termination**, or **stop, codons**, which triggers release of the completed polypeptide chain.
- V. In bacterial cells, transcription and translation are coupled. Translation of the mRNA molecule usually begins before the 3' end of the transcript is completed. A single mRNA molecule can be translated by groups of ribosomes called **polyribosomes**.
- VI. The basic features of transcription and translation are the same in prokaryotic and eukaryotic cells, but eukaryotic genes and their mRNA molecules are more complex than those of bacteria.
 - A. After transcription, eukaryotic mRNA molecules are **capped** at the 5' end with a modified guanosine triphosphate. Many also have a **tail** of poly-A nucleotides added at the 3' end. These modifications appear to protect the molecules from degradation, giving them longer lifetimes than bacterial mRNA.
 - B. In many eukaryotic genes the coding regions, called **exons**, are interrupted by noncoding regions, called **introns**. Both introns and exons are transcribed, but the introns are later removed from the mRNA precursor, and the exons are spliced together to produce a continuous protein-coding sequence.
- VII. The genetic code is defined at the mRNA level. There are 61 codons that code for amino acids, plus three codons that serve as stop signals.
 - A. The start signal for all proteins is the codon AUG, which also specifies the amino acid methionine.
 - B. The genetic code is virtually universal, strongly suggesting that all organisms are descended from a common ancestor. The only exceptions to the standard code are a few minor variations.
 - C. The code is said to be redundant because some amino acids are specified by more than one codon.
 - D. The genetic code is read from mRNA as a series of nonoverlapping triplets that specify a single sequence of amino acids.
- VIII. A **gene** can be defined as a sequence of nucleotides (plus closely associated regulatory sequences) that can be transcribed to yield a specific protein or RNA product.
- IX. Types of **mutations** range from disruption of the structure of a chromosome to a change in only a single pair of nucleotide bases.
 - A. A **base substitution** can destroy the function of a protein if a codon is altered such that it specifies a different amino acid (**missense mutation**) or becomes a termination codon (**nonsense mutation**). A base substitution has minimal effects if the amino acid is not altered or if the codon is changed to specify a similar amino acid.
 - B. Insertion or deletion of one or two base pairs in a gene invariably destroys the function of that protein because it results in a **frameshift mutation** that changes the codon sequences downstream from the mutation.
 - C. Mutations can be produced by errors in DNA replication, by physical agents such as x rays or ultraviolet rays, or by chemical **mutagens**. Mutations can also occur through **transposons** or **mobile genetic elements**, also known as “jumping genes,” which move from one part of a chromosome to another, disrupting the function of a part of the DNA. Some damage to DNA can be repaired by special systems of enzymes.

POST - TEST

1. The genetic code is defined as a series of _____ in _____.
(a) anticodons; tRNA (b) codons; DNA (c) anticodons; mRNA
(d) codons; mRNA (e) codons and anticodons; rRNA
2. Transcription is the process by which _____ is/are synthesized.
(a) mRNA (b) mRNA and tRNA (c) mRNA, tRNA, and rRNA (d) protein
(e) mRNA, tRNA, rRNA, and protein
3. RNA differs from DNA in that the base _____ is substituted for _____.
(a) adenine; uracil (b) uracil; thymine (c) guanine; uracil (d) cytosine; guanine (e) guanine; adenine
4. RNA grows in the _____ direction, as DNA-dependent RNA polymerase moves along the template DNA strand in the _____ direction.
(a) $5' \rightarrow 3'$; $3' \rightarrow 5'$ (b) $3' \rightarrow 5'$; $3' \rightarrow 5'$ (c) $5' \rightarrow 3'$; $5' \rightarrow 3'$ (d) $3' \rightarrow 3'$; $5' \rightarrow 5'$ (e) $5' \rightarrow 5'$; $3' \rightarrow 3'$
5. Which of the following is/are NOT found in a prokaryotic mRNA molecule?
(a) protein termination codon (b) upstream leader sequences (c) downstream trailing sequences (d) start codon (e) promoter sequences
6. Which of the following is/are typically removed from pre-mRNA during nuclear processing in eukaryotes?
(a) upstream leader sequences (b) poly-A tail (c) introns (d) exons (e) all of the above are removed
7. Which of the following is a spontaneous process, with no direct requirement for ATP or GTP?
(a) formation of a peptide bond (b) translocation of the ribosome (c) formation of aminoacyl-tRNA (d) a and b (e) all of the above are spontaneous processes
8. Select the events of the elongation cycle of protein synthesis from the following list and place them in the proper sequence.
 1. peptide bond formation
 2. binding of the small ribosomal subunit to the 5' end of the mRNA
 3. binding of aminoacyl-tRNA to the A site
 4. translocation of the ribosome(a) $1 \rightarrow 3 \rightarrow 2 \rightarrow 4$ (b) $3 \rightarrow 1 \rightarrow 4$ (c) $3 \rightarrow 1 \rightarrow 3 \rightarrow 2$
(d) $1 \rightarrow 3 \rightarrow 4$ (e) $4 \rightarrow 2 \rightarrow 1 \rightarrow 3$
9. The statement "the genetic code is redundant" means that (a) some codons specify punctuation (stop and start signals) rather than an amino acid (b) some codons specify more than one amino acid (c) certain amino acids can be specified by more than one codon (d) in some cases, the third nucleotide of an anticodon may be able to pair with more than one kind of base in a codon (e) all organisms have essentially the same genetic code
10. A nonsense mutation (a) causes one amino acid to be substituted for another in a polypeptide chain (b) results from the deletion of one or more bases, leading to a shift in the reading frame (c) results from the insertion of one or more bases, leading to a shift in the reading frame (d) results from the insertion of a transposon (e) usually results in the formation of an abnormally short polypeptide chain

REVIEW QUESTIONS

1. A certain transcribed DNA strand has the following nucleotide sequence:

3'—TACTGCATAATGATT—5'

What would be the sequence of codons in the mRNA transcribed from this strand? What would be the nucleotide sequence of the complementary nontranscribed DNA strand? What would be the exact anticodon for each codon? Use Table 12–1 to determine the amino acid sequence of the polypeptide. Be sure to label the 5' and 3' ends of the nucleic acids, and the carboxyl and amino ends of the polypeptide.

2. What are ribosomes made of? Do ribosomes themselves carry information to specify the amino acid sequence of proteins?
3. In what ways are DNA polymerase and RNA polymerase similar? How do they differ?
4. Describe initiation, elongation, and termination of protein synthesis.
5. Explain how the genetic code was deciphered. What experimental procedures needed to be developed before this could be accomplished?
6. What are the main types of mutations? What effects does each have on the protein product produced?
7. Why can't amino acids become incorporated into polypeptides without the aid of tRNA?

YOU MAKE THE CONNECTION

1. How many amino acids could be specified if two bases coded for one amino acid? Why is redundancy important to the idea of wobble? If you could "reinvent" the genetic code, would you make any changes? Why or why not?
2. Compare and contrast the formation of mRNA in prokaryotic and eu-

karyotic cells. How do the differences affect the way in which each type of mRNA is translated? Does one system have any obvious advantage in terms of energy cost? Which system offers greater opportunities for control of gene expression?

CHAPTER 13

Gene Regulation: The Control of Gene Expression

Each type of cell in a multicellular organism has a characteristic shape, carries out very specific activities, and makes a distinct set of proteins. Yet, with few exceptions, they all contain the same genetic information. Why, then, are they not identical in structure and molecular composition? This is because genes are regulated, and only certain subsets of the total genetic information are expressed in any given cell. For example, the chromosomes in the LM are from a cell in the salivary gland of the larva of the fruit fly, *Drosophila*. The expanded, “puffed” chromosomal regions (arrows) contain genes that are actively transcribed in that cell, while the more compact banded regions include genes that are transcribed at very low rates, or not at all.

What are the mechanisms controlling the expression of a gene? Let us consider a gene that codes for a protein that is an enzyme. Expression of that gene involves not only transcription to form mRNA; the mRNA must be translated into protein, and the protein must actively catalyze a specific reaction. Gene expression, then, is the result of a series of processes, each of which can be controlled in many different ways. The control mechanisms require information in the form of various signals (some originating within the cell and others coming from the environment) that interact with DNA, RNA, or protein.

Some of the main strategies used to regulate gene expression include controlling (1) the amount of mRNA that is available, (2) the rate of translation of the mRNA, and (3) the activity of the protein product.

In bacterial cells, energy efficiency and economical use of resources are usually of primary importance. As a result, most gene regulation in prokaryotes involves transcriptional level

(Peter J. Bryant/Biological Photo Service)

control of genes whose products are involved in resource utilization. In eukaryotes there is a much greater emphasis on fine-tuning the control systems, which is consistent with the greater complexity of these cells and the need to control development in multicellular organisms (see Chapter 16). Consequently, eukaryotic gene regulation occurs at many levels.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Explain why the organization of genes into operons is advantageous to bacteria. Explain why some genes, such as those of the lactose operon, are inducible, while others, such as those of the tryptophan operon, are repressible.
 2. Sketch the main elements of an inducible operon, such as the lactose operon, and explain the functions of the operator and promoter regions.
 3. Diagram the major components of an mRNA molecule produced by the lactose operon and relate that structure to the organization of the operon.
 4. Differentiate between positive and negative control and show how both types of control operate in the regulation of the lactose operon.
 5. Sketch the structure of a typical eukaryotic gene and the DNA sequences involved in the regulation of that gene.
 6. Give examples of some of the ways eukaryotic DNA-binding proteins bind to DNA.
 7. Illustrate how a change in chromosome structure might affect the activity of a gene.
 8. List two ways that a gene in a multicellular organism might be able to produce different products in different types of cells.
 9. Identify some of the types of regulatory controls that can be exerted in eukaryotes after mature mRNA is formed.
-

GENE REGULATION IN PROKARYOTES IS ECONOMICAL

A cell of *Escherichia coli*, a bacterium that is a common inhabitant of the intestine, has 4288 genes that code for proteins, approximately 62% of which have known functions. Some of these genes encode proteins that are always needed (e.g., enzymes involved in glycolysis). These genes, which are constantly transcribed, are called **constitutive genes**. Other proteins are needed only when the bacterium is growing under special conditions.

For instance, the bacteria living in the colon of an adult cow are not normally exposed to the milk sugar lactose. If those cells were to end up in the colon of a calf, however, they would have lactose available as a source of energy. This poses a dilemma. Should a bacterial cell invest energy and materials to produce lactose-metabolizing enzymes just in case it ends up in the digestive system of a calf? Given that the average lifetime of an actively growing *E. coli* cell is about 30 minutes, such a strategy appears wasteful. Yet if *E. coli* cells do not have the capacity to produce those enzymes, they might starve in the midst of an abundant food supply. *E. coli* handles this problem by regulating many of its enzymes in order to efficiently use available organic molecules.

Cells have two basic ways of controlling their metabolic activity. They can regulate the *activity* of certain enzymes (how effectively an enzyme molecule works), and/or they can control the *number* of enzyme molecules present in each cell. Some enzymes may be regulated in both ways in the same type of cell. An *E. coli* cell growing on glucose is estimated to need about 800 different enzymes. Some of these must be present in large numbers, whereas only a few molecules of others are required. In order for the cell to function properly, each enzyme must be efficiently controlled.

Operons in prokaryotes permit coordinated control of functionally related genes

The French researchers François Jacob and Jacques Monod are credited with the first demonstration, in 1961, of how some genes are regulated at the biochemical level. They studied the genes that code for the enzymes that metabolize the disaccharide lactose (see Chapter 3). For *E. coli* to use lactose as an energy source, the sugar must be cleaved into the monosaccharides glucose and galactose by the enzyme β -galactosidase. (β -galactosidase also converts some lactose molecules to a structural isomer, *allolactose*.) Galactose is then converted to glucose by another enzyme, and the resulting two glucose molecules are further broken down by the glycolysis pathway (see Chapter 7).

E. coli cells growing on glucose contain very little of the β -galactosidase enzyme, perhaps no more than one to three molecules per cell. However, cells grown on lactose have as many as 3000 β -galactosidase molecules per cell, accounting for about 3% of the total cellular protein. Levels of two other enzymes, galactose permease and galactoside transacetylase, also increase when the cells are grown on lactose. The permease is needed to transport lactose efficiently across the bacterial plasma membrane; without it, only small amounts of lactose can enter the cell. The transacetylase may be involved in a minor aspect of lactose metabolism, although its function is not clear.

Jacob and Monod were able to identify mutant strains of *E. coli* in which a single genetic defect resulted in the loss of all three enzymes. This finding, along with other information, led them to the conclusion that the coding DNA sequences for all three enzymes are linked together as a unit on the bacterial DNA and are subject to a common control mechanism. Each protein coding sequence is known as a **structural gene**. Jacob and Monod coined the term **operon** to refer to a gene

Figure 13–1 The lactose operon. The structural genes coding for the three enzymes used by *E. coli* to metabolize the disaccharide lactose are transcribed as part of a single mRNA molecule. **(a)** In the absence of lactose, a repressor protein, encoded by an adjacent gene, binds a region known as the operator. By preventing RNA polymerase from binding to the promoter, the bound repressor protein blocks transcription of the structural genes. **(b)** When lactose is present, it is converted to allolactose, which binds to the repressor at an allosteric site, altering the structure of the protein so that it can no longer bind to the operator. This allows RNA polymerase to bind to the promoter and transcribe the structural genes.

complex consisting of a group of structural genes with related functions, plus the closely linked DNA sequences responsible for controlling them. The structural genes of the lactose operon—*lacZ*, *lacY*, and *lacA*—code for β -galactosidase, galactose permease, and galactoside transacetylase, respectively. (Fig. 13–1).

Transcription of the lactose operon begins as RNA polymerase binds to a single promoter site upstream from the coding sequences. It then proceeds to transcribe the DNA, forming a single mRNA molecule that contains the coding information for all three enzymes. This mRNA contains translation termination and initiation codons between the enzyme-coding sequences; hence it is translated to form three separate protein molecules. Because all three enzymes are translated from the same mRNA molecule, their synthesis can be coordinated by turning a single molecular “switch” off or on.

The switch that controls mRNA synthesis is called the **operator**; it is a sequence of bases that overlaps part of the promoter region and is upstream from the first structural gene in the operon. When lactose is absent, a **repressor protein** called the **lactose repressor** binds tightly to the operator region. Because the repressor protein is large enough to cover part of the promoter sequence, RNA polymerase is unable to bind to the

lactose promoter site, and transcription of the lactose operon is effectively blocked.

The lactose repressor protein is encoded by a regulatory gene, which in this case is an adjacent structural gene located upstream from the promoter site. Unlike the lactose operon genes, the repressor gene is constitutive; that is, it is always “on,” so small amounts of the repressor protein are produced continuously. This protein binds specifically to the lactose operator sequence. When cells are grown in the absence of lactose, the operator site is nearly always occupied by a repressor molecule. Only on rare occasions, when the operator site is briefly free of the repressor, can RNA polymerase bind and initiate transcription of the structural genes. Because *E. coli* mRNA is rapidly degraded (having a half-life of about 2 to 4 minutes), very few proteins are translated from that mRNA.

Lactose is able to “turn on,” or *induce*, the transcription of the lactose operon because the lactose repressor protein contains a second functional region separate from its DNA binding site; this is an allosteric binding site for allolactose. (Recall from Chapter 6 that an allosteric regulator, such as allolactose in this case, binds to a site in a protein other than its active site, changing its conformation and thereby altering its function.) If lactose is present in the growth medium, a few mol-

ecules are able to enter the cell and are converted to allolactose by the few β -galactosidase molecules present. When a molecule of allolactose binds to the repressor at the allosteric site, it alters the conformation of the protein so that its DNA binding site can no longer recognize the operator. When all the repressor molecules have allolactose bound to them and are therefore inactivated, RNA polymerase binds to the unblocked promoter, and the operon is actively transcribed.

E. coli cell continues to produce β -galactosidase and the other lactose operon proteins until virtually all of the lactose is used up. When intracellular levels of lactose drop, the repressor proteins no longer have the allolactose sugar bound to them. They then assume a conformation that allows them to bind to the operator region and shut down transcription of the operon.

How were Jacob and Monod able to dissect the lactose operon? Their approach centered around the use of mutant strains, which even today play an essential role in allowing researchers to unravel the components of a regulatory system. Mutant strains permit investigators to map the positions of the genes on the DNA and to infer normal gene functions by studying what happens when they are missing or altered. This information is usually combined with results of direct biochemical studies.

For example, Jacob and Monod studied various constitutive mutants; these transcribed the structural genes of the lactose operon at a significant rate even in the absence of lactose. One group of constitutive mutants had abnormal genes with map positions just outside the lactose operon itself. Using special genetic strains, it was possible to show that these particular mutations always caused constitutive expression, regardless of their location in the genome.

On the basis of these findings, Jacob and Monod hypothesized the existence of a repressor gene that is responsible for producing a repressor molecule (later found to be a protein). Although the specific defect may vary, the members of this group of constitutive mutants do not produce active repressor proteins; hence no binding to the lactose operator and promoter takes place, and the lactose operon is transcribed constitutively.

The genes responsible for the behavior of a second group of constitutive mutants had map positions within the lactose operon but did not directly involve any of the three structural genes. The members of this group were found to produce normal repressor molecules but to have abnormal operator sequences incapable of binding the repressor.

In contrast to the constitutive mutants, other mutants failed to transcribe the lactose operon even when lactose was present. Some of these abnormal genes had the same map position as the hypothesized regulatory gene. They were eventually found to have an altered binding site on the repressor protein that prevented allolactose from binding, although the ability of the repressor to bind to the operator was unaffected. Once bound to the operator, such a mutant repressor remains bound, keeping the operon “turned off.”

An inducible gene is not transcribed unless a specific inducer inactivates its repressor

The lactose operon is called an **inducible system**. An inducible gene or operon is usually controlled by a repressor that keeps it in the “off” state. The presence of an **inducer molecule** (in this case allolactose) renders the repressor inactive so that the gene or operon is turned “on.” Inducible genes or operons usually code for enzymes that are part of catabolic pathways; these break down molecules to provide both energy and components for anabolic reactions. This type of regulatory system enables the cell to save the energy costs of making enzymes when no substrates are available for them to act on.

A repressible gene is transcribed unless a specific repressor/corepressor complex is bound to the DNA

Another type of gene regulation system in bacteria is associated mainly with anabolic pathways in which amino acids, nucleotides, and other essential molecules are synthesized from simpler precursors. Regulation of these pathways normally involves **repressible** enzymes, which are coded for by repressible genes.

Repressible genes and operons are usually “on”; they are turned off only under special conditions. In most cases the molecular signal used to regulate these genes is the end product of the metabolic pathway. When the supply of the end product (e.g., an amino acid) is low, all enzymes in the pathway are actively synthesized. When intracellular levels of the end product are high, enzyme synthesis is repressed. Because compounds such as amino acids are continuously needed by the growing cell, the most effective strategy is to keep the genes that control their production “on” except when a large supply of the amino acid is available. The ability to turn the genes off allows cells to avoid overproduction of amino acids and other molecules that are essential but energetically expensive to make.

The tryptophan operon is an example of a repressible system. In both *E. coli* and a related bacterium, *Salmonella*, the operon consists of five structural genes that code for the enzymes required for synthesis of the amino acid tryptophan; these are clustered together as a transcriptional unit with a single promoter and a single operator (Fig. 13–2). A distant repressor gene codes for a diffusible repressor protein, which differs from the lactose repressor in that it is synthesized in an inactive form that is unable to bind to the operator region of the tryptophan operon.

The DNA-binding site of the repressor becomes effective only when tryptophan, its **corepressor**, binds to an allosteric site on the repressor. When intracellular tryptophan levels are low, the repressor protein is inactive and unable to bind to the operator region of the DNA. As the concentration of intracellular tryptophan rises, some tryptophan binds to the allosteric site of the repressor, altering its conformation so that it binds tightly to the operator. This has the effect of switching the operon off, thereby blocking transcription.

Figure 13–2 The tryptophan operon. Genes coding for enzymes that synthesize the amino acid tryptophan are organized in a repressible operon. (a) A regulatory gene encodes a repressor protein that is initially inactive; it is unable to prevent transcription because it cannot bind to the operator. (b) When intracellular tryptophan levels are high, the amino acid binds to an allosteric site on the repressor protein, changing its conformation. The resulting active form of the repressor binds to the operator region, blocking transcription of the operon until tryptophan is again required by the cell.

Negative regulators repress transcription; positive regulators activate transcription

The features of the lactose and tryptophan operons described so far are examples of **negative control**. Systems under negative control are those in which the DNA-binding regulatory protein is a repressor that turns off transcription of the gene. Some regulatory systems involve **positive control**, that is, regulation by **activator proteins** that bind to DNA and thereby stimulate transcription of a gene. The lactose operon contains both negative and positive controlling elements (Fig. 13–3).

Positive control of the lactose operon requires that the cell be able to sense the absence of the sugar glucose, which is the initial substrate in the glycolysis pathway (see Chapter 7). Lactose, like glucose, is a catabolite and can undergo stepwise breakdown to yield energy. However, because lactose must first be converted to glucose, it is most efficient for *E. coli* cells to use the available supply of glucose first. By using glucose as the preferred substrate, the cell is spared the considerable energy cost of making additional enzymes such as β -galactosidase.

The lactose operon has a very inefficient promoter sequence; that is, it has a low affinity for RNA polymerase even when the repressor protein is inactivated. However, a DNA se-

(a) Lactose high, glucose low, cAMP high

(b) Lactose high, glucose high, cAMP low

Figure 13–3 Positive control of the lactose operon. The lactose promoter by itself is weak and binds RNA polymerase inefficiently even when the lactose repressor is inactive. The CAP is an allosteric regulator that can bind to a sequence of bases in the promoter, allowing RNA polymerase to bind efficiently, thereby stimulating transcription of the operon. The CAP molecule contains two polypeptides. When each has cAMP bound to its allosteric site, the protein can bind to the DNA sequence. The cell's cAMP concentration is inversely proportional to the glucose concentration. (a) When glucose levels are low, cAMP binds to CAP, which then activates transcription of the operon by binding to the DNA. (b) When glucose levels are high, cAMP is low. CAP is in an inactive form and cannot stimulate transcription. Therefore, only low-level transcription occurs.

Figure 13–4 The binding of CAP to DNA. This computer-generated picture illustrates the bend formed in the DNA double helix when it binds to CAP. CAP is a dimer consisting of two identical polypeptide chains, each of which binds one molecule of cAMP. (Courtesy of S.C. Schultz, G.C. Shields, and T.A. Steitz, Yale University)

quence adjacent to the promoter site is a binding site for another protein, called the **catabolite gene activator protein (CAP)**.

CAP increases the affinity of the promoter region for RNA polymerase, allowing the enzyme to recognize the promoter efficiently and to bind tightly to the DNA. In its active form CAP has **cyclic AMP**, or **cAMP**, an alternative form of adenosine monophosphate (see Fig. 3–25), bound to an allosteric

site.¹ As the cells become depleted of glucose, cAMP levels increase. The cAMP molecules bind to CAP, and the resulting complex then binds to the CAP-binding site near the lactose operon promoter and stimulates the transcription of the operon in the presence of lactose (Fig. 13–4). Thus, the operon is fully active only if lactose is present and intracellular glucose levels are low. The properties of negative and positive control systems are summarized in Table 13–1.

A regulon is a group of functionally related operons controlled by a common regulator

CAP differs from the lactose and tryptophan repressors in that it can control transcription of operons involved in the metabolism of a number of other catabolites, such as the sugars galactose, arabinose, and maltose, as well as of lactose. A group of operons controlled by one regulator of this type is generally referred to as a **regulon** (Fig. 13–5).

Other multigene systems in bacteria are also controlled in this manner. For example, genes involved in nitrogen and phosphate metabolism are organized into regulons that consist of multiple sets of operons controlled by one or more combinations of regulatory genes. Other complex multigene systems respond to changes in environmental conditions, such as rapid shifts in temperature, exposure to radiation, changes in osmotic pressure, and changes in oxygen levels. Specific mutants often provide clues to the existence of a regulon system. A single

¹For this reason, CAP is also known as CRP, which stands for **cAMP receptor protein**.

TABLE 13–1 Types of Transcriptional Control in Prokaryotes*

NEGATIVE CONTROL

Inducible genes

Repressor protein alone	→	Active repressor “turns off” regulated gene(s)
Lactose repressor alone	→	Lactose operon not transcribed
Repressor protein + inducer	→	Inactive repressor/inducer complex fails to “turn off” regulated gene(s)
Lactose repressor + allolactose	→	Lactose operon transcribed

Repressible genes

Repressor protein alone	→	Inactive repressor fails to “turn off” regulated gene(s)
Tryptophan repressor alone	→	Tryptophan operon transcribed
Repressor protein + corepressor	→	Active repressor-corepressor complex “turns off” regulated gene(s)
Tryptophan repressor + tryptophan	→	Tryptophan operon not transcribed

POSITIVE CONTROL

Activator protein alone	→	Activator alone cannot stimulate transcription of regulated gene(s)
CAP alone	→	Transcription of lactose operon not stimulated
Activator protein + coactivator	→	Functional activator-coactivator complex stimulates transcription of regulated gene(s)
CAP + cAMP	→	Transcription of lactose operon stimulated

*A general description of each type is followed by a specific example. A negative regulator is a repressor that “turns off” transcription of the regulated gene(s). Conversely, a positive regulator is an activator that stimulates transcription.

Figure 13–5 A regulon. Operons that convert several different sugars to glucose in *E. coli* make up a regulon that is under positive control by CAP.

mutation that destroys the activity of CAP, for example, prevents the cell from efficiently metabolizing not only lactose but many other sugars also regulated by CAP.

Not all constitutive genes are transcribed at the same rate

Many of the gene products encoded by the *E. coli* DNA are needed only under certain environmental or nutritional conditions. As we have seen, these genes are generally regulated at the level of transcription. They can be turned on and off as metabolic and environmental conditions change. By contrast, constitutive genes are continuously transcribed, but they are not necessarily transcribed (or their mRNAs translated) at the same rate. Some enzymes work more effectively or are more stable than others and consequently need to be present in smaller amounts. Constitutive genes that encode proteins required in large amounts are generally transcribed more rapidly than genes coding for proteins required at lower levels. The transcription rate of these genes is controlled by their promoter sequences. Constitutive genes with efficient (“strong”) promoters bind RNA polymerase more frequently and consequently transcribe more mRNA molecules than those with inefficient (“weak”) promoters.

Genes coding for repressor or activator proteins that regulate metabolic enzymes are usually constitutive and produce their protein products constantly. Because each cell usually needs relatively few molecules of any specific repressor or activator protein, promoters for those genes tend to be relatively weak.

Some posttranscriptional regulation occurs in prokaryotes

As we have seen, much of the variability in protein levels in *E. coli* is determined by **transcriptional level control**. However, regulatory mechanisms that operate after transcription, known as **posttranscriptional controls**, also occur, operating at various levels of gene expression.

Translational controls are posttranscriptional controls that regulate the rate at which a particular mRNA molecule is translated. Because the lifetime of an mRNA molecule in a bacterial cell is very short, a molecule that is translated rapidly can produce more proteins than one that is translated slowly. Some mRNA molecules in *E. coli* are translated as much as 1000 times faster than others. Most of the differences appear to be due to the rate at which ribosomes can attach to the mRNA and begin translation.

Posttranslational controls generally act as switches that activate or inactivate one or more existing enzymes. These systems allow the cell to respond to changes in the intracellular concentrations of essential molecules, such as amino acids, by rapidly adjusting the activities of its enzymes. A common post-translational control adjusts the rate of synthesis in a metabolic pathway through **feedback inhibition** (see Chapter 6). The end product binds to the first enzyme in the pathway at an allosteric site, temporarily inactivating the enzyme. When the first enzyme in the pathway does not function, all of the succeeding enzymes are deprived of substrates. Notice that this differs from the end-product repression of the tryptophan operon discussed previously. In that case, the end product of

MAKING THE CONNECTION

REGULATION IN PROKARYOTES AND EUKARYOTES

Why do prokaryotic and eukaryotic cells have distinctly different strategies for regulating the activity of their genes? In large part these differences reflect the ways in which the organisms make their living. Bacterial cells exist independently, and each cell must be able to perform all of its own essential functions. Because they grow rapidly and have relatively short lifetimes, bacterial cells carry little excess baggage.

The dominant theme of prokaryotic gene regulation is *economy*, and controlling transcription is usually the most cost-effective way to regulate gene expression. The organization of related genes into operons and regulons that can be rapidly turned on and off as units allows these cells to synthesize only the gene products needed at any particular time. This type of regulation requires rapid turnover of mRNA molecules to prevent messages from accumulating and continuing to be translated when they are not needed. Bacteria rarely regulate enzyme levels by degrading proteins. Once the synthesis of a protein ends, the previously synthesized protein molecules are diluted so rapidly in subsequent cell divisions that breaking them down is usually not necessary. Only when cells are starved or deprived of essential amino acids are protein-digesting

enzymes used to recycle their amino acids by breaking down proteins no longer needed for survival.

Eukaryotic cells have different regulatory requirements. In multicellular organisms, groups of cells cooperate with each other in a division of labor. Because a single gene may need to be regulated in different ways in different types of cells, eukaryotic gene regulation is complex, occurring not only at the level of transcription but also at other levels of gene expression. Eukaryotic cells also usually have long lifetimes during which they may need to respond repeatedly to many different stimuli. Rather than synthesize new enzymes each time they respond to a stimulus, these cells make extensive use of preformed enzymes and other proteins that can be rapidly converted from an inactive to an active state.

Much of the emphasis of gene regulation in multicellular organisms is on *specificity* in the form and function of the cells in each tissue. Each type of cell has certain genes that are active and others that may never be used. Apparently the adaptive advantages of cellular cooperation in eukaryotes far outweigh the detrimental effects of carrying a load of inactive genes through many cell divisions.

the pathway prevented the formation of new enzymes. Feedback inhibition acts as a fine-tuning mechanism that regulates the activity of the existing enzymes in a metabolic pathway.

GENE REGULATION IN EUKARYOTES IS MULTIFACETED

Like bacteria, eukaryotic cells must respond to changes in their environment by turning appropriate sets of genes on and off. Multicellular eukaryotes require additional modes of regulation that permit individual cells to become committed to specialized roles and groups of cells to organize into tissues and organs (see *Making the Connection: Regulation in Prokaryotes and Eukaryotes*). In previous chapters we observed that all aspects of information transfer, including replication, transcription, and translation, are far more complicated in eukaryotes. Not surprisingly, this complexity provides additional opportunities for control of gene expression.

Unlike many of the prokaryotic genes, most eukaryotic genes are not found in operon-like clusters. However, each eukaryotic gene has specific regulatory sequences that are essential in the control of transcription.

Many of the “housekeeping” enzymes (those needed by all cells) appear to be encoded by constitutive genes, which are expressed in all cells at all times. Some inducible genes have also been found; these respond to environmental threats or stimuli such as heavy metal ingestion, viral infection, and heat

shock. For example, when a cell is exposed to high temperature, many proteins fail to fold properly. A system that appears to be sensitive to these unfolded proteins causes genes known as heat-shock genes to be transcribed, resulting in the production of heat-shock proteins. Although the functions of most of the heat-shock proteins are not known, some are molecular chaperones (see Chapter 3), which are responsible for helping other proteins attain their proper conformation.

Some genes appear to be inducible only during certain periods in the life of the organism; they are thought to be controlled by **temporal regulation** mechanisms. Finally, a number of genes are under the control of **tissue-specific regulation**. For example, a gene involved in the production of a particular enzyme may be regulated by one stimulus (e.g., a hormone) in muscle tissue, by an entirely different stimulus in pancreatic cells, and by a third stimulus in liver cells. These types of regulation are explored in more detail in Chapter 16.

Eukaryotic transcription is controlled at many sites and by many different regulatory molecules

Various DNA segments, including upstream promoter elements, enhancers, and transcription initiation sites, are important in transcriptional control. In addition, the rate of transcription is affected by regulatory proteins known as transcription factors and by the way the DNA is organized in the chromosome.

a) A prokaryotic promoter

A typical prokaryotic promoter contains a “Pribnow box” and a “-35 box,” usually found, respectively, 10 and 35 bases upstream from the transcription initiation site. The base sequences shown are those most commonly found.

b) Eukaryotic promoter elements

A eukaryotic promoter usually contains a “TATA box,” located 30 base pairs upstream from the transcription initiation site. The most commonly found base sequence is shown (either T or A can be present at the positions where they appear together).

c) A weak eukaryotic promoter

A weakly expressed gene contains only one UPE.

d) A strong eukaryotic promoter

A strongly expressed gene is likely to contain several UPEs.

e) A strong eukaryotic promoter plus an enhancer

Transcription of this eukaryotic gene is stimulated by an enhancer, located several thousand bases from the promoter.

Figure 13–6 The control of transcription.

(a) A typical prokaryotic contains a “Pribnow box” and a “-35 box,” usually found, respectively, 10 and 35 base pairs upstream from the transcription initiation site. (b) A eukaryotic promoter usually contains a “TATA box” located 30 base pairs upstream from the transcription initiation site. The most commonly found base sequence is shown (either T or A can be present where they appear together). Eukaryotic transcription is stimulated by upstream promoter elements (UPEs). (c) A weakly expressed gene contains only one UPE. (d) A strongly expressed gene is likely to contain several UPEs. Upstream and downstream enhancers also stimulate transcription. The DNA double helix and other elements are not drawn to scale.

Eukaryotic promoters vary in efficiency, depending on their upstream promoter elements

In eukaryotic as well as prokaryotic cells, the transcription of any gene requires a transcription initiation site, plus a promoter to which RNA polymerase binds. A prokaryotic promoter (Fig. 13–6a) includes certain characteristic base sequences, known as a *Pribnow box* and a *-35 box* (35 base pairs

upstream from the transcription initiation site). In multicellular eukaryotes RNA polymerase binds to a sequence of bases, known as a **TATA box**, about 30 base pairs upstream from the transcription initiation site (Fig. 13–6b). A eukaryotic promoter generally contains one or more sequences of 8 to 12 bases within a short distance upstream of the RNA polymerase-binding site. These have been given various names; we will refer to them as **upstream promoter elements (UPEs)**. The efficiency of the promoter seems to depend on the number and

type of UPEs. Thus, a constitutive gene containing only one UPE is generally weakly expressed, whereas one containing five or six UPEs is usually actively transcribed (Fig. 13–6*c* and *d*).

Enhancers are DNA sequences that increase the rate of transcription

Regulated eukaryotic genes commonly require not only the upstream promoter elements but also DNA sequences called **enhancers**. Whereas the promoter elements are required for accurate and efficient initiation of mRNA synthesis, enhancers increase the *rate* of RNA synthesis after initiation, often by several orders of magnitude (Fig. 13–6*e*).

Enhancer sequences are remarkable in many ways. Although present in all cells, a particular enhancer is functional only in certain types of cells. An enhancer can regulate a gene on the same DNA molecule from very long distances (up to thousands of base pairs away from the promoter) and can be either upstream or downstream of the promoters it controls. Furthermore, if an enhancer sequence is experimentally cut out of the DNA and inverted, it still regulates the gene it normally controls. As we shall see, evidence suggests that at least some enhancers work by interacting with proteins that regulate transcription.

Transcription factors are regulatory proteins that have several functional domains and may work in various combinations

We previously discussed some DNA-binding proteins that regulate transcription in prokaryotes. These **transcription factors** include the lactose repressor, the tryptophan repressor, and the catabolite gene activator protein (CAP). Although transcription factors were first studied in prokaryotes, many have been identified in eukaryotes.

It is useful to compare prokaryotic and eukaryotic transcription factors. Many transcription factors are modular molecules; that is, they have more than one **domain** (region with its own tertiary structure), and each domain has a different function. For example, every prokaryotic regulator has a DNA-binding domain, plus at least one other domain. Examples include domains that can activate RNA polymerase, or bind inducers (such as allolactose) or corepressors (such as tryptophan).

The DNA-binding regions of the lactose repressor and CAP contain two α -helical segments. Each, known as a *recognition helix*, is inserted into a major groove of the DNA without unwinding the double helix (Fig. 13–7*a*). Recall from Chapter 3 that an α -helix of a protein is arranged such that

Figure 13–7 Transcription factors. (a) Generalized view of a recognition α -helix inserted into the major groove of the DNA. The rest of the protein is not shown. Specific amino acid side chains (*not shown*) are thought to form hydrogen bonds with the edges of specific base pairs. (b) Regions of certain transcription factors form projections known as “zinc fingers,” which can insert into the grooves of the DNA and bind to specific base sequences. The colored circles represent amino acids that bind to the zinc atoms and form the loop. (c) Some zinc-finger proteins have multiple projections, each of which is thought to fit into a separate groove in the DNA. (d) This leucine zipper protein is a dimer, held together by hydrophobic interactions involving side chains of leucine and other amino acids.

the peptide bonds are in the interior of the helix and the functional groups of the amino acids are on the surface of the helix. This structure allows certain functional groups of specific amino acids to form hydrogen bonds with specific base pairs in the DNA. These hydrogen bonds differ from those involved in complementary base-pairing because they form between specific amino acids and the *edges* of the base pairs.

Eukaryotic regulators, like those of prokaryotes, may be either activators or repressors; we discuss only eukaryotic activators here because they seem to be more common and have been studied more.

Each activator has several functional domains, including a DNA-binding region. In some cases, the binding region consists of one or more recognition α -helices that can be inserted into specific regions of the DNA in a manner similar to that described previously for some prokaryotic regulators. Some other activators have multiple “zinc fingers,” loops of amino acids held together by zinc ions (Fig. 13–7*b* and *c*). Certain amino acid functional groups exposed in each finger have been shown to recognize specific DNA sequences.

Many activators are functional only as pairs or *dimers*, and these have special domains required for dimer formation. Many of these transcription factors are known as **leucine zipper proteins** because they are held together by the side chains of leucine and other hydrophobic amino acids (Fig. 13–7*d*). In some cases the two polypeptides that make up the dimer may be identical and form a *homodimer*. In other instances they are different, and the resulting *heterodimer* may have very different regulatory properties. For a very simple and speculative example, let us assume that three regulatory proteins—A, B, and C—are involved in controlling a particular set of genes. These

three proteins might associate as dimers in six different ways: three kinds of homodimers (AA, BB, and CC) and three kinds of heterodimers (AB, AC, and BC). Such multiple combinations of regulatory proteins have the potential to greatly increase the number of possible ways that transcription can be controlled.

Transcription factors interact with the general transcription machinery

Transcription in eukaryotes requires multiple regulatory proteins that are bound to different parts of the promoter. The “general transcription machinery” is a protein complex that binds to the TATA region of the promoter near the transcription initiation site. That complex is required for RNA polymerase to bind and initiate transcription. Other combinations of regulatory proteins are bound to the more distant enhancer or UPE regions of the promoter. Those proteins then make contact with the general machinery and control the activity of the RNA polymerase.

Each activator must have at least two functional domains: a DNA recognition site that usually binds to an enhancer or UPE, and a “gene activation site” that contacts the target in the general transcriptional complex. Both enhancers and UPEs apparently become functional when specific regulatory proteins are bound to them. The DNA between the enhancer and promoter sequences is thought to form a loop that allows an activator bound to an enhancer to come in contact with one or more target proteins associated with the general transcriptional complex. When this occurs, transcription is stimulated (Fig. 13–8).

Figure 13–8 Stimulation of transcription by an enhancer. (a) This gene is transcribed at a very low rate or not at all, even though the general transcriptional machinery, including RNA polymerase, is bound to the promoter. (b) A regulatory protein that functions as a transcriptional activator becomes bound to an enhancer. The intervening DNA forms a loop, allowing the activator to contact one or more target proteins in the general transcriptional machinery, thereby increasing the rate of transcription.

Figure 13–9 Transcription initiation at two different sites in the same gene. The yeast invertase gene encodes an mRNA with two start codons (AUG) in its coding region. If transcription is initiated at a downstream site, a short mRNA is made that yields, when translated, an intracellular form of the enzyme. If transcription starts at a point upstream from both AUG codons, a longer message is made. Translation begins at the first start codon, producing an enzyme with a “signal sequence” at the amino-terminal end of the polypeptide chain that targets the protein to the endoplasmic reticulum and then to the Golgi complex for secretion from the cell.

Transcriptional units may overlap in eukaryotes

A given gene may sometimes be transcribed in more than one way, and somewhat different forms of its protein product may be produced as a result. For example, the enzyme invertase, which cleaves the disaccharide sucrose, exists in two forms in yeast: an intracellular form and a form secreted from the cell into the growth medium. Both forms are encoded by the same gene (Fig. 13–9), but their mRNAs are transcribed from two different **transcription initiation sites**. The longer mRNA encodes the extracellular form of the enzyme, which is a longer polypeptide with extra amino acids at its amino-terminal end. Those amino acids serve as a “signal sequence” indicating that the protein is to be processed through the Golgi complex and secreted from the cell. The smaller mRNA encodes a protein that lacks the signal sequence and remains in the cytosol.

Other genes have tissue-specific overlapping transcriptional units. The primary pre-mRNA transcript of the gene for amylase (an enzyme that breaks down starch) in the mouse salivary gland is several thousand bases longer than its counterpart in the mouse liver. This is because in the salivary gland, transcription starts at a site on the DNA that is farther upstream. Although the coding portions of the mRNAs in both cell types are identical after splicing and processing, transcription occurs about 100 times more frequently in the salivary gland than in the liver, resulting in the production of higher levels of the salivary amylase enzyme.

The organization of the chromosome may affect the expression of some genes

A chromosome is not simply a bearer of genes. Various arrangements of its ordered components can result in increased or decreased expression of the genes it contains.

Multiple copies of genes A single gene cannot always provide enough copies of its mRNA to meet the cell’s needs. The requirement for high levels of certain products may be met if multiple copies of the genes that encode them are present in the chromosome. Genes of this type, whose products are essential for all cells, may occur as tandemly repeated gene sequences in all cells. Other genes, which may be required by only a small group of cells, may be selectively replicated in those cells in a process called **gene amplification** (see Chapter 16).

Within an array of repeated genes, each copy is almost identical to the others. Histone genes, which code for the proteins that associate with DNA to form nucleosomes (see Chapter 11), are usually found as multiple copies of 50 to 500 genes in cells of multicellular organisms.

Genes for rRNA and tRNA also occur in multiple copies in all cells. To ensure that the rRNA molecules are made in equal amounts, the RNA genes are arranged as multiple transcription units, each containing one copy of each of the three rRNA genes (Fig. 13–10). Most eukaryotic species contain 150 to 450 such transcription units per cell. The demand for rRNA is so great in actively growing mammalian cells that, although hundreds of copies of the genes are present, each gene is usually copied simultaneously by approximately 100 RNA polymerase enzymes.

Gene inactivation by changes in chromatin structure In multicellular eukaryotes, only a subset of the genes present in a cell are active at any one time. The inactivated genes differ among cell types and in many cases seem to be irreversibly dormant.

Some of the inactive genes appear to be associated with highly compacted chromatin, which can be seen as densely

Figure 13-10 Repeated gene sequences. Multiple copies of genes may be required when large amounts of their products are needed by the cell. (a) Human rRNA genes are organized in transcription units, each of which codes for three different rRNAs. The transcription units are arranged as 200 to 300 tandemly repeated copies (of which only three are shown here), separated by nontranscribed spacer units. (b) As each transcription unit is transcribed, it must be maximally loaded with RNA polymerase in order to meet the great need for rRNA in actively growing cells. Each precursor rRNA will be processed to yield three different rRNA molecules. (Not to scale.)

staining regions of chromosomes during cell division. These regions of chromatin remain tightly coiled throughout the cell cycle, and even during interphase are visible as darkly staining fibers called **heterochromatin**. Evidence suggests that the DNA of heterochromatin is not transcribed. When one of the two X chromosomes is inactivated in female mammals, most of the inactive X chromosome becomes heterochromatic and is seen as the Barr body (see Chapter 10). Active genes are associated with a more loosely packed chromatin structure called **euchromatin** (Fig. 13-11).

Gene inactivation by DNA methylation Inactive genes of vertebrates and some other organisms typically exhibit a pattern of **DNA methylation** in which the DNA has been chemically altered by enzymes that add methyl groups to certain cytosines. (The resulting 5-methylcytosine is still able to base pair with guanine in the usual way.) There is evidence that certain proteins selectively bind to methylated DNA and make it inaccessible to the transcription machinery.

DNA methylation is thought to reinforce gene inactivation, rather than to serve as the initial mechanism. It appears

Figure 13-11 The effect of chromatin structure on transcription.

(a) An inactive region of DNA (heterochromatin) is organized into tightly associated nucleosomes. (b) Active genes are associated with decondensed chromatin (euchromatin). Chromatin decondensation is often a response to specific inducing signals. The loosely packed chromatin increases the accessibility to RNA polymerase required for transcription of the region.

that once a gene has been turned off by some other means, DNA methylation ensures that it will remain inactive. For example, the DNA of the inactive X of a female mammal becomes methylated after the chromosome has become a condensed Barr body. Each time the DNA replicates, the methylation enzymes perpetuate the preexisting methylation pattern; hence the DNA continues to be transcriptionally inactive in both daughter cells.

The long-lived, highly processed mRNAs of eukaryotes provide many opportunities for posttranscriptional control

The half-life of prokaryotic mRNA is usually measured in minutes; eukaryotic mRNA, even when it turns over rapidly, is far more stable. Prokaryotic mRNA is transcribed in a form that can be translated immediately. In contrast, eukaryotic mRNA molecules require further modification and processing before they can be used in protein synthesis (see Chapter 12). The message is capped, polyadenylated, spliced, and then transported from the nucleus to the cytoplasm to initiate translation. These events represent potential control points at which translation of the message and production of its encoded protein can be regulated.

Some pre-mRNAs can be processed in more than one way

Several forms of regulation involving mRNA processing have been discovered. In some instances, the same gene is used to produce one type of protein in one tissue and a related but somewhat different type of protein in another tissue. This is possible because some genes produce pre-mRNA molecules that have multiple splicing patterns; that is, they can be spliced in more than one way depending on the tissue. Typically, such a gene includes at least one segment that can be either an intron or an exon. Through **differential mRNA processing**, the cells in each tissue produce their own version of mRNA corresponding to the particular gene (Fig. 13–12).

Figure 13–12 Differential mRNA processing. In some cases a complex transcriptional unit can be processed in more than one way to yield two or more mRNAs, each of which encodes a related, but different, protein. In this generalized example the gene contains a segment that can be an exon in tissue A (*left*), but an intron in tissue B (*right*).

The stability of mRNA molecules can vary

Controlling the lifetime of a particular kind of mRNA molecule makes it possible to control the number of protein molecules translated from it. In some cases messenger RNA stability is under hormonal control. This is true for mRNA that codes for vitellogenin, a protein synthesized in the livers of certain female animals such as frogs and chickens and then transported to the oviduct, where it is used in the formation of egg yolk proteins.

Vitellogenin synthesis is regulated by the hormone estradiol. When estradiol levels are high, the half-life of vitellogenin mRNA in frog liver is about 500 hours. When cells are deprived of estradiol, the half-life of the mRNA drops rapidly to less than 165 hours. This leads to a rapid decrease in cellular vitellogenin mRNA levels and decreased synthesis of the vitellogenin protein. In addition to affecting the stability of the mRNA, the hormone seems to control the rate at which the mRNA is synthesized.

The activity of eukaryotic proteins may be altered by posttranslational chemical modifications

The ultimate phenotypic expression of a gene may also be controlled by regulation of the activity of the gene product. As in bacteria, many metabolic pathways in eukaryotes contain allosteric enzymes that are regulated through feedback inhibition. In addition, many eukaryotic proteins are extensively modified after they are synthesized.

In *proteolytic processing* the proteins are synthesized as inactive precursors, which are converted to an active form by removal of a portion of the polypeptide chain. Other proteins may be regulated in part by a process of *selective degradation*, which keeps their numbers constant within the cell.

Chemical modification, through the addition or removal of functional groups, can reversibly alter the activity of an enzyme. One very common way of modifying the activity of an enzyme or other protein is the addition or removal of phosphate groups. These alterations allow the cell to respond rapidly to certain hormones (Chapter 47), or to fast-changing environmental or nutritional conditions.

S U M M A R Y W I T H K E Y T E R M S

- I. Most regulated genes in bacteria are organized into **operons**, each of which may encode several proteins.
 - A. Each operon has a single **promoter** region upstream from the protein-coding regions.
 - B. The **operator** is a sequence of bases that overlaps the promoter and serves as the regulatory switch responsible for **transcriptional level control** of the operon.
 1. A **repressor protein** binds specifically to the operator sequence and blocks transcription by preventing RNA polymerase from binding to the promoter.
 2. When the repressor is not bound to the operator, RNA polymerase can bind to the promoter and transcription can proceed.
 - C. An **inducible** operon such as the lactose operon is normally turned off. The repressor protein is synthesized in an active form that binds to the operator. If lactose is present, it is converted to allolactose (the **inducer**), which binds an allosteric site on the repressor protein, causing it to change shape. The altered repressor cannot bind to the operator, and the operon is transcribed.
 - D. A **repressible** operon such as the tryptophan operon is normally turned on. The repressor protein is synthesized in an inactive form that cannot bind to the operator. A metabolite (usually the end product of a metabolic pathway) acts as a **corepressor**. When intracellular corepressor levels are high, one of the molecules binds to an allosteric site on the repressor, changing its shape so that it can bind to the operator and thereby turn off transcription of the operon.
 - E. Repressible and inducible operons are under **negative control**. When the repressor protein binds to the operator, transcription of the operon is turned off.
 - F. Some inducible operons are also under **positive control**. A separate protein can bind to the DNA and stimulate transcription of the gene.
 1. The lactose operon is activated by **CAP (catabolite gene activator protein)**, which binds to the promoter region, stimulating transcription by binding RNA polymerase tightly.
 2. To bind to the lactose operon, CAP requires cAMP (cyclic adenosine monophosphate). Levels of cAMP increase as levels of glucose decrease.
 - G. A group of operons can be organized into a multigene system, known as a **regulon**, which is controlled by a single regulatory protein. CAP activates a regulon associated with the metabolism of carbohydrates.
- II. **Constitutive genes** are neither inducible nor repressible; they are active at all times. Regulatory proteins such as CAP and the repressor proteins are produced constitutively. The activity of these genes is controlled by how efficiently RNA polymerase binds to their promoter regions.
- III. **Transcription factors** are DNA-binding regulatory proteins that work by recognizing and binding to specific base sequences in the DNA.
- IV. Some **posttranscriptional controls** operate in prokaryotes.
 - A. A **translational level control** regulates the rate of translation of a particular mRNA.
 - B. **Posttranslational controls** include **feedback inhibition** of key enzymes in some metabolic pathways.
- V. Eukaryotic genes are generally not organized into operons. Regulation of eukaryotic genes can occur at the levels of transcription, mRNA processing, translation, and the protein product.
 - A. The promoter of a regulated eukaryotic gene consists of an RNA polymerase-binding site and short DNA sequences known as **upstream promoter elements (UPEs)**. The efficiency of the promoter is determined by the number and types of UPEs within the promoter region.
 - B. Inducible eukaryotic genes are controlled by **enhancer** elements, which can operate thousands of bases away from the promoter. Proteins that bind to enhancers appear to facilitate the binding of RNA polymerase to the promoter.
 - C. As in prokaryotes, eukaryotic genes are controlled by transcription factors. Many of these are transcriptional activators; others are transcriptional repressors.
 - D. The activity of eukaryotic genes is affected by chromosome structure.
 1. Some genes whose products are required in large amounts exist as multiple copies in the chromosome. Other genes may be selectively amplified by DNA replication in some cells.
 2. Genes can be inactivated by changes in chromosome structure. Densely packed regions of chromosomes called **heterochromatin** contain inactive genes. Active genes are associated with a loosely packed chromatin structure called **euchromatin**.
 3. **DNA methylation** is a mechanism that perpetuates gene inactivation.
 - E. Many eukaryotic genes are regulated after the RNA transcript is made.
 1. Gene regulation can occur as a consequence of mRNA processing. In some cases a single gene can produce different forms of a protein, depending on how the pre-mRNA is polyadenylated or spliced.
 2. Certain regulatory mechanisms increase the stability of mRNA, allowing more proteins to be formed per mRNA molecule prior to degradation.
 3. Posttranslational control of eukaryotic genes can occur by feedback inhibition or by modification of the protein structure.

P O S T - T E S T

1. At a time when the lactose operon is actively transcribed
 - (a) the operator is bound to the inducer
 - (b) the lactose repressor is bound to the promoter
 - (c) the operator is not bound to the promoter
 - (d) the gene coding for the repressor is not expressed constitutively
 - (e) the lactose repressor is bound to the inducer
2. A repressible operon codes for the enzymes of the following pathway. Which component of the pathway is most likely to be the corepressor for that operon?

$$A \xrightarrow{\text{Enzyme 1}} B \xrightarrow{\text{Enzyme 2}} C \xrightarrow{\text{Enzyme 3}} D$$

 - (a) substance A
 - (b) substance B or C
 - (c) substance D
 - (d) enzyme 1
 - (e) enzyme 3
3. An mRNA molecule transcribed from the lactose operon contains nucleotide sequences complementary to
 - (a) structural genes coding for enzymes
 - (b) the operator region
 - (c) the promoter region
 - (d) the repressor gene
 - (e) introns
4. Feedback inhibition is an example of control at the _____ level.
 - (a) transcriptional
 - (b) translational
 - (c) posttranslational
 - (d) replicational
 - (e) all of the above
5. Which of the following control mechanisms is generally the most economical in terms of conserving energy and resources?

- (a) control by means of operons and regulons
 - (b) feedback inhibition
 - (c) selective degradation of mRNA
 - (d) selective degradation of enzymes
 - (e) gene amplification
6. A repressible operon, such as the tryptophan operon, is “off” when
 - (a) the gene that codes for the repressor is expressed constitutively
 - (b) the repressor-corepressor complex binds to the operator
 - (c) the repressor binds to the structural genes
 - (d) the corepressor binds to RNA polymerase
 - (e) CAP binds to the promoter
 7. Which of the following is an example of positive control?
 - (a) transcription can occur when a repressor binds to an inducer
 - (b) transcription cannot occur when a repressor binds to a corepressor
 - (c) transcription is stimulated when a transcription activator binds to DNA
 - (d) a and b
 - (e) a and c
 8. Which of the following are typically absent in prokaryotes?
 - (a) enhancers
 - (b) transcription factors
 - (c) repressors
 - (d) promoters
 - (e) operators
 9. The “zipper” of a leucine zipper protein attaches
 - (a) specific amino acids to specific DNA base pairs
 - (b) two polypeptide chains to each other
 - (c) one DNA region to another DNA region
 - (d) amino acids to zinc atoms
 - (e) RNA polymerase to the operator
 10. Inactive genes tend to be associated with
 - (a) highly condensed chromatin, known as euchromatin
 - (b) decondensed chromatin, known as euchromatin
 - (c) highly condensed chromatin, known as heterochromatin
 - (d) decondensed chromatin, known as heterochromatin
 - (e) chromatin that is not organized as nucleosomes

REVIEW QUESTIONS

1. Make a sketch of the lactose operon and briefly describe its function. Be sure to include the following elements: (a) structural genes, (b) promoter, (c) operator, (d) CAP-binding site.
2. What structural features does the tryptophan operon have in common with the lactose operon? What features are different?
3. Why do we define the tryptophan operon as repressible and the lactose operon as inducible?
4. How is glucose involved in the positive control of the lactose operon? How is CAP similar to the lactose repressor protein? How is it different?
5. Compare the structure of a prokaryotic promoter region with known eukaryotic promoter regions. How does the regulation of inducible eukaryotic genes differ from the regulation of inducible prokaryotic genes?
6. Explain why it is necessary for certain genes in eukaryotic cells to be present in multiple copies.
7. How can the activity of some eukaryotic genes be affected by the structure of the chromosome?
8. Make a sketch showing how differential mRNA processing can give rise to different forms of a eukaryotic protein.

YOU MAKE THE CONNECTION

1. Develop a simple hypothesis that would explain the behavior of each of the following types of mutants in *E. coli*:
 - (a) *Mutant a*: The map position of this mutation is in the tryptophan operon. The mutant cells are constitutive; that is, they produce all of the enzymes coded for by the tryptophan operon, even if large amounts of tryptophan are present in the growth medium.
 - (b) *Mutant b*: The map position of this mutation is in the tryptophan operon. The mutant cells do not produce any of the enzymes coded for by the tryptophan operon under any conditions.
 - (c) *Mutant c*: The map position of this mutation is some distance from the tryptophan operon. The mutant cells are constitutive; that is, they produce all of the enzymes coded for by the tryptophan operon, even if the growth medium contains large amounts of tryptophan.
 - (d) *Mutant d*: The map position of this mutation is some distance from the tryptophan operon. The mutant cells do not produce any of the enzymes coded for by the tryptophan operon under any conditions.
2. Compare the types of bacterial genes associated with inducible operons, those associated with repressible operons, and those that are constitutive. Predict the category into which each of the following would most likely fit: (a) a gene that codes for RNA polymerase; (b) a gene that codes for an enzyme required to break down maltose; (c) a gene that codes for an enzyme used in the synthesis of adenine.
3. The regulatory gene that codes for the tryptophan repressor is not tightly linked to the tryptophan operon. Would it be advantageous if it were? Explain your answer.

CHAPTER 14

Genetic Engineering

Beginning in the mid-1970s, a revolution in the field of biology occurred as the development of **recombinant DNA technology** led to radically new research approaches. This technology has had a major impact not only in genetic studies but also in areas ranging from cell biology to evolution.

Recombinant DNA techniques were initially developed to permit scientists to obtain a great many copies of any specific DNA segment in order to study it biochemically. This was first done by introducing foreign DNA into the cells of microorganisms. Under the right conditions, this DNA is replicated and transmitted to the daughter cells when a cell divides. In this way a particular DNA sequence can be amplified, or **cloned**, to provide millions of identical copies that can be isolated in pure form. Today methods for cloning DNA in vitro (outside of a living organism) have become increasingly important.

Studies of cloned **DNA sequences** have been of immense value in allowing scientists to understand the organization of genes and the relationship between genes and their products. In fact, most of our knowledge of the complex structure and control of eukaryotic genes (see Chapters 12 and 13) is derived from the application of these methods.

Recombinant DNA technology also has many practical applications. One of the rapidly advancing areas of study today is **genetic engineering**—the modification of the DNA of an organism to produce new genes with new characteristics. Genetic engineering can take many forms, ranging from the production of strains of bacteria that manufacture useful protein products to the development of plants and animals that express foreign genes. Discoveries in molecular genetics have led to technologies that today are applied in such diverse areas as medicine and the pharmaceutical industries, foods and agriculture, and others. For example, the scientists in the photograph are using genetic engineering techniques to introduce desirable characteristics (perhaps disease resistance or increased yield) into tomatoes.

(Robert Holmgren/Peter Arnold, Inc.)

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Draw a sketch that demonstrates how a typical restriction enzyme cuts DNA molecules and give examples of the ways in which these enzymes are used in recombinant DNA technology.
2. Summarize the properties of plasmids that allow them to be used as DNA cloning vectors.
3. Distinguish between a genomic DNA library and a cDNA library.
4. Explain why one would clone the same eukaryotic gene from both a genomic library and a cDNA library.
5. Identify some of the uses of DNA hybridization probes.
6. Describe how specific primers can be used to amplify specific genes from a mixture of genomic DNA or cDNA.
7. Draw a diagram that illustrates the most widely used DNA sequencing technique.
8. List some important proteins and other products that can be produced by genetic engineering techniques.
9. List some of the difficulties encountered in using *Escherichia coli* to produce proteins coded by eukaryotic genes and explain the rationale behind using transgenic plants and animals to solve some of those problems.

RECOMBINANT DNA METHODS GREW OUT OF RESEARCH IN MICROBIAL GENETICS

Recombinant DNA technology was not developed quickly. It actually began with the first genetic studies of bacteria and the viruses that infect them, the **bacteriophages** (literally “bacteria eaters”; see Chapters 11 and 23). Only after decades of basic research and the accumulation of extensive knowledge did the current technology become feasible and available to the many scientists who now use these methods.

Bacteria have provided researchers with special enzymes, known as restriction enzymes, that cut DNA molecules only in specific places. Bacteria, viruses, and other microorganisms also provide a means by which many identical copies of DNA molecules can be made. This is accomplished in vitro through the use of certain bacterial DNA polymerases and in vivo by introducing recombinant DNA molecules into bacteria or other microorganisms, such as yeast. Recombinant DNA technology also depends on a fundamental property of nucleic acid molecules: the ability of complementary nucleotide sequences to pair by means of specific hydrogen bonding. Because new methods of genetic engineering are continually emerging, we will not attempt to explore them all. (Several Internet sites, such as “Access Excellence” and the “National Center for Biotechnology Information,” are good sources of updated information.) Instead, we will discuss some of the major approaches that have provided a foundation for these developments.

Restriction enzymes are “molecular scissors”

A major breakthrough in the development of recombinant DNA technology was the discovery of bacterial enzymes called **restriction enzymes**, which are able to cut DNA molecules only at specific base sequences. For example, a restriction enzyme known as Hind III recognizes and cuts a DNA molecule at the base sequence 5'—AAGCTT—3', whereas the sequence

5'—GAATTC—3' is cut by another, known as EcoRI.¹ Recall from Chapter 11 that during infection a bacteriophage injects its DNA into a bacterial cell. Such a cell can defend itself if it possesses restriction enzymes capable of attacking the bacteriophage DNA. The bacteria protect their own DNA from breakdown by modifying it after replication. An enzyme adds a methyl group to one or more bases in each restriction site so that the restriction enzyme is unable to recognize and cut the DNA. Purification of restriction enzymes has enabled scientists to cut DNA from chromosomes into shorter fragments in a controlled way.

Many of the restriction enzymes used for recombinant DNA studies cut **palindromic** sequences, which means that the base sequence of one strand reads the same as its complement, but in the opposite direction. (Thus, the complement of our example, 5'—AAGCTT—3', reads 3'—TTCGAA—5'.) By cutting both strands of the DNA, but in a staggered fashion, these enzymes produce fragments with identical, complementary, single-stranded ends. These ends are called “sticky ends” because they can pair (by hydrogen bonding) with the complementary, single-stranded ends of other DNA molecules that have been cut with the same enzyme (Fig. 14–1). Once two molecules have been joined together in this way, they can be treated with **DNA ligase** (see Chapter 11), an enzyme that covalently links the two DNA fragments to form a stable recombinant DNA molecule.

Restriction enzymes vary widely in the number of DNA bases that they recognize, ranging from as few as 4 to as many as 23 bases. If the restriction sites are randomly distributed in the DNA, we expect the restriction sequence of a “four-base cutter” to occur on the average of every 4⁴, or 256, bases. A four-base cutter would therefore produce fragments with an average length of 256 bases, whereas a six-base cutter would produce fragments averaging 4⁶, or 4096, bases.

¹ The names of restriction enzymes are generally derived from the names of the bacteria from which they originally isolated. Hence Hind III and EcoRI are derived from *Hemophilus influenzae* and *Escherichia coli* respectively.

Figure 14–1 Cutting DNA with a restriction enzyme. Many restriction enzymes, like Hind III, cut DNA at sequences that are palindromic, thereby producing complementary sticky ends.

Recombinant DNA is formed when DNA is spliced into a vector

Most recombinant DNA molecules are isolated and amplified by introducing them into cells of the bacterium *E. coli*. To isolate a specific piece of DNA after it has been cut by a restriction enzyme, that fragment must first be incorporated into a suitable carrier, or **vector molecule**.

Bacteriophages or special DNA molecules called plasmids are commonly used as vectors (Fig. 14–2). Recall that bacterial DNA is in the form of a circle; a **plasmid** is a separate, much smaller, circular DNA molecule that may be present and able to replicate inside a bacterial cell. These plasmids can be isolated from bacterial cells in pure form and then be introduced into other cells by a method called **transformation** (see Chapter 11), which involves altering the bacterial cell wall to make it permeable to the plasmid DNA molecules. Once a plasmid enters a cell, it is replicated and distributed to the daughter cells during cell division. Plasmids do not carry genes that are essential to the *E. coli* cells under normal conditions, but they often carry genes that are useful under some environmental conditions, such as those that confer resistance to particular antibiotics.

The plasmids now used in recombinant DNA work have been extensively “engineered” to include a number of features helpful in the isolation and analysis of cloned DNA. Among these are: (1) an origin of replication, (2) one or more sites that can be cut by restriction enzymes, and (3) genes that allow researchers to select cells that have been transformed by recombinant plasmids. These are genes that permit transformed cells to grow under specified conditions that do not allow growth of untransformed cells. Genes that confer resistance to certain antibiotics, and genes that allow the cells to use a particular nutrient are examples (Fig. 14–3).

A limiting property of any vector, however, is the size of the DNA fragment that it can effectively carry. The size of a DNA segment is often given in kilobases, with 1 **kilobase (kb)**

being equal to 1000 bases. Fragments smaller than 10 kb can usually be inserted into plasmids for use in *E. coli*. However, larger fragments require the use of bacteriophage vectors, which can handle up to 15 kb of DNA.

Recombinant DNA can also be introduced into cells of more complex organisms. For example, engineered viruses are used as vectors in mammalian cells. These viruses have been disabled in such a way that they do not kill the cells they infect; instead their DNA, and any foreign DNA they carry, becomes incorporated into the chromosomes of the cell following infection. As discussed later, other methods have been developed that do not require a biological vector.

DNA can be cloned inside cells

Because a single gene is only a small part of the total DNA in an organism, isolating the piece of DNA containing that particular gene is like finding a needle in a haystack. A powerful detector is needed. Today there are many methods that permit the isolation of a gene from an organism. We will start with methods that begin with cloning inside bacterial cells to construct a library, or gene bank, using human DNA as an example, although the procedure can be applied to any organism.

A genomic library contains fragments of all the DNA in the genome

The total DNA per cell is referred to as a **genome**. For example, if DNA is extracted from human cells, we refer to it as human genomic DNA. A **genomic library** is a collection of DNA fragments that are more or less representative of all the DNA in the genome. Each fragment is spliced into a plasmid, which is usually contained inside a bacterial cell.

The first step in producing a genomic library is to cut the DNA with a restriction enzyme, generating a population of DNA fragments. These fragments vary in size and in the genetic information they carry, but they all have identical sticky

Figure 14–2 Splicing DNA into a vector. In this example, a circular plasmid from a bacterium is the vector. (a) The plasmids and the DNA from another organism are cut by the same restriction enzyme to produce (b) linear molecules with complementary single-stranded ends. (c) The recombinant DNA is constructed by mixing the two types of molecules so that their sticky ends pair. DNA ligase then forms covalent 5' → 3' phosphodiester linkages at the junctions.

ends. Plasmid DNA to be used as a vector is treated with the same restriction enzyme, which converts the circular plasmids into linear molecules with sticky ends complementary to those of the human DNA fragments. Recombinant plasmids are produced by first mixing the two kinds of DNA (human and plasmid) together under conditions that promote hydrogen bonding of complementary bases. Then DNA ligase is used to covalently bond the paired ends of the plasmid and human DNA.

The recombinant plasmids are inserted into antibiotic-sensitive *E. coli* cells by transformation. Because the ratio of plasmids to cells is kept very low, it is rare for a cell to receive more than one plasmid molecule, and not all cells receive a plasmid. The normally antibiotic-sensitive cells are incubated on a nutrient medium that includes antibiotics, so only cells that have incorporated a plasmid (which contains a gene for

antibiotic resistance) are able to grow (Fig. 14–4). In addition, the plasmid has usually been engineered in ways that permit researchers to select cells containing *recombinant* plasmids.

A genomic library contains redundancies; that is, many human DNA sequences have been duplicated many times, purely by chance. However, each individual recombinant plasmid (analogous to a book in the library) contains only a single fragment of the total human genome. Each of these fragments is usually smaller than a gene; therefore several fragments must be isolated to study the complete gene.

To allow identification of a plasmid containing a sequence of interest, each plasmid must be amplified, or cloned, until there are millions of copies to work with. This process occurs as the *E. coli* cells grow and divide. A dilute sample of the bacterial culture is spread on solid growth medium, so that the cells will be widely separated. When each cell reproduces it

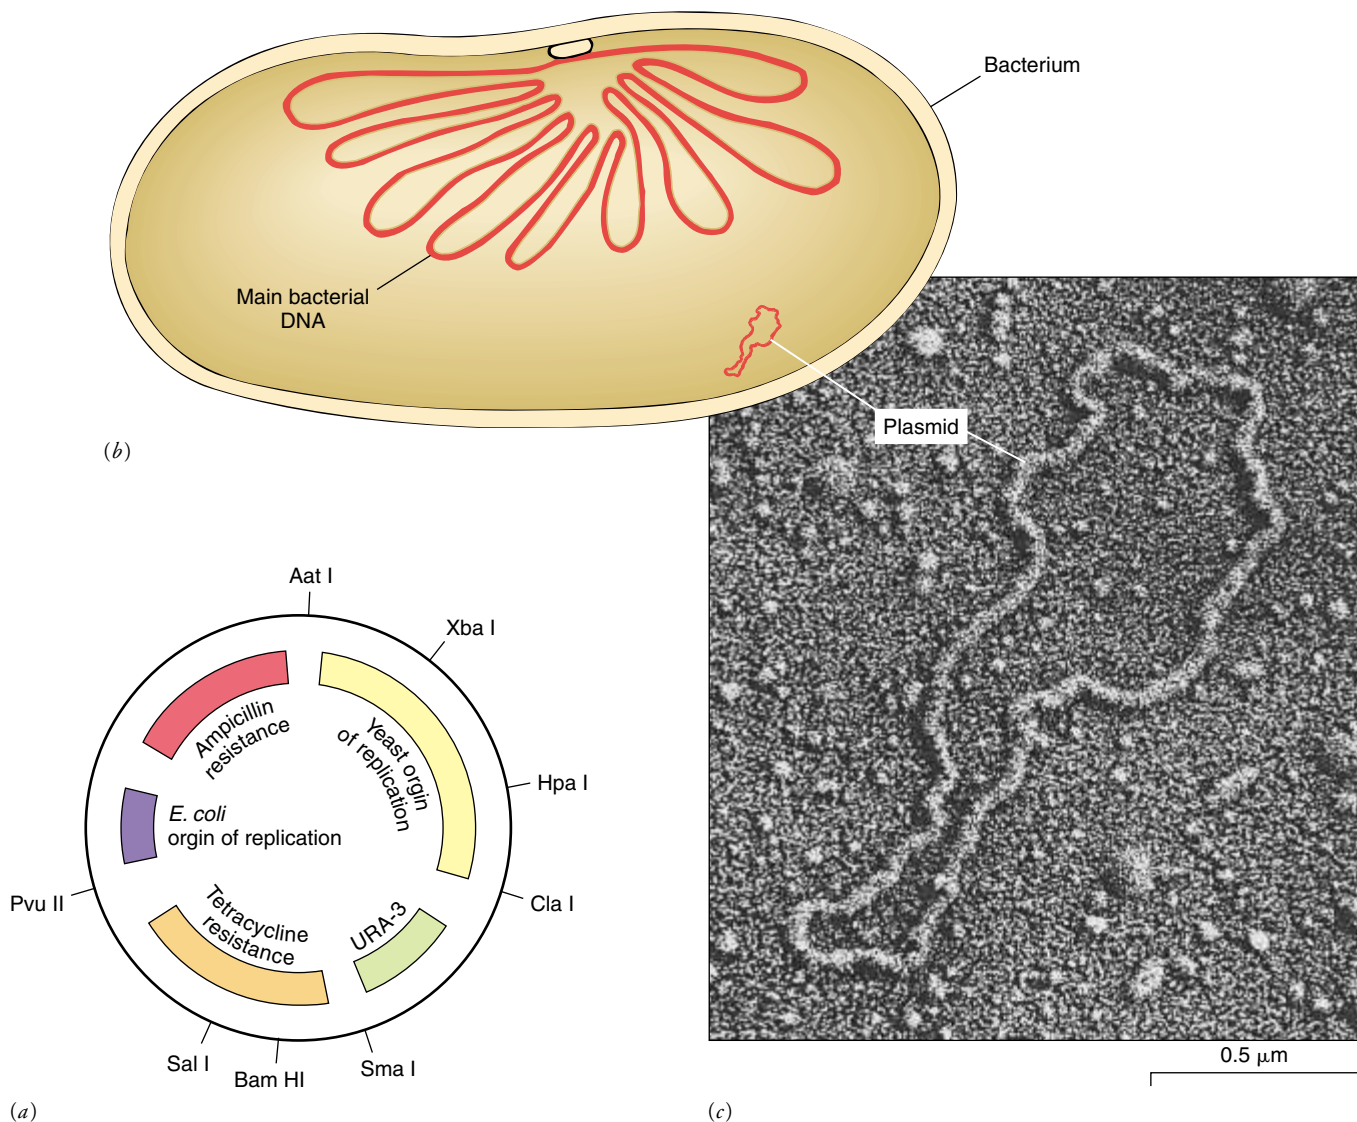

Figure 14-3 Plasmids. (a) This genetically engineered plasmid vector has many useful features. It was constructed from DNA fragments isolated from plasmids, *E. coli* genes, and yeast genes. The two origins of replication, one for *E. coli* and one for yeast, *Saccharomyces cerevisiae*, allow it to replicate independently in either type of cell. Letters on the outer circle designate sites for restriction enzymes that cut the plasmid only at that position. Resistance genes for the antibiotics ampicillin and tetracycline, and the yeast URA-3 gene are also shown. The URA-3 gene is useful when transforming yeast cells lacking an enzyme required for uracil synthesis. Cells that take up the plasmid are able to grow on a uracil-deficient medium. (b) The relative sizes of a plasmid and the main DNA of a bacterium. (c) TEM of a plasmid from *E. coli*. (c, Dr. Stanley Cohen/Science Photo Library/Photo Researchers, Inc.)

gives rise to a **colony**, which is a clone of genetically identical cells. All the cells of a particular colony contain the same recombinant plasmid, so during this process a specific sequence of human DNA has also been cloned. The major task is to determine which colony (out of thousands) contains a cloned fragment of interest. There are a number of ways in which specific DNA sequences can be identified.

A specific DNA sequence can be detected by a complementary genetic probe

A common approach to the problem of detecting the DNA of interest involves the use of a **genetic probe**, which is usually a radioactively labeled segment of RNA or single-stranded DNA that can **hybridize** (become attached by base pairing)

Figure 14-4 Cloning genomic DNA.

to complementary DNA sequences in the target gene. Suppose that a researcher wishes to identify a gene that codes for a specific protein. If at least part of the amino acid sequence of that protein is known, it is possible to synthesize a radioactive, single-stranded DNA fragment that could code for that sequence. This is not as simple as it may sound: because the genetic code is redundant, a specific amino acid sequence could potentially be coded for by a number of different base sequences (see Chapter 12). One approach to this problem has been to synthesize a mixture of probes, each of which could code for the desired amino acid sequence.

Genetic probes can be used in a variety of ways. For example, cells from *E. coli* colonies containing recombinant plasmids can be transferred to a nitrocellulose filter, which then becomes a *replica* of the colonies. The cells on the filter are treated chemically to lyse them and to cause the DNA to become denatured (single-stranded). The filter is then incubated with the radioactive probe mixture to allow the probes to hybridize with any complementary DNA that may be present. Each spot on the filter containing DNA complementary to

that particular probe becomes radioactive and can be detected by autoradiography (see Chapter 2), using a special x-ray film. Each spot on the film therefore identifies a colony containing a plasmid that includes the DNA of interest (Fig. 14-5).

A cDNA library is complementary to mRNA and does not contain introns

For reasons that will be discussed below, researchers frequently wish to avoid cloning introns and other parts of genes that do not directly code for proteins. In such cases they construct libraries consisting of DNA copies of eukaryotic mRNA. The copies, known as **complementary DNA (cDNA)** because they are complementary to RNA, lack introns. **Reverse transcriptase** (see Chapter 12) is used to synthesize single-stranded cDNA, which is then separated from the RNA and made double stranded by DNA polymerase (Fig. 14-6). A **cDNA library** is formed when the double-stranded cDNA molecules are inserted into plasmid or virus vectors, which then multiply in *E. coli* cells.

Figure 14-5 Use of a genetic probe. A radioactive nucleic acid probe (which can be either RNA or single-stranded DNA) reveals the presence of complementary DNA sequences.

Cloning a gene from both a cDNA library and a genomic library has several advantages. Analysis of the genomic DNA clones gives useful information about the structure of the gene in the chromosome and the structure of the primary pre-mRNA transcript, as well as nontranscribed regulatory regions.

Analysis of cDNA clones allows investigators to determine certain characteristics of the protein encoded by the gene, including its exact amino acid sequence. The structure of the processed mRNA can also be studied. Furthermore, because the cDNA copy of the mRNA does not contain intron sequences, comparison of the cDNA and genomic DNA base sequences reveals the locations of intron and exon coding sequences in the gene.

Cloned cDNA sequences are also useful when it is desirable to produce a eukaryotic protein in *E. coli*. When an intron-containing human gene such as the gene for human growth hormone is introduced into *E. coli*, the bacterium is unable to remove the introns from the transcribed RNA to make a functional mRNA for the production of its protein product. If a cDNA clone of the gene is inserted into the bacterium, however, its transcript contains an uninterrupted coding region. A functional protein can be synthesized if the gene is inserted downstream of an appropriate bacterial promoter.

Figure 14-6 Formation of cDNA. Enzymes, including reverse transcriptase, are used to produce a mixture of cDNA molecules similar to the one illustrated.

The polymerase chain reaction is a technique for amplifying DNA in vitro

The methods to amplify a specific DNA sequence described above all involve cloning DNA in cells, usually those of bacteria. These processes are time-consuming and require an adequate DNA sample as starting material. The **polymerase chain reaction (PCR)** technique allows researchers to amplify a tiny sample of DNA millions of times in a few hours (Fig. 14-7).

DNA polymerase uses nucleotides and primers to replicate a DNA sequence in vitro, thereby producing two DNA molecules. The two strands of each molecule are then separated by heating and replicated again, so then there are four, double-stranded molecules. After the next cycle of heating and replication there are eight molecules, and so on, with the number of DNA molecules doubling in each cycle. After only 20 heating and cooling cycles (which are carried out using automated equipment) this exponential process yields 2^{20} , or over 1 million, copies of the target sequence!

Because the reaction can only be carried out efficiently if the DNA polymerase can remain stable through many heating cycles, a special heat-resistant DNA polymerase, known as *Taq* polymerase is used. The name of this enzyme reflects its source, *Thermus aquaticus*, a bacterium that lives in hot springs

Figure 14–7 The polymerase chain reaction. The number of double-stranded DNA molecules doubles each time the cycle of heating and cooling is repeated. The initial reaction mixture (*not shown*) includes a very small amount of double-stranded DNA, DNA precursors (deoxyribonucleotides), specific nucleic acid primers, and *Taq* polymerase.

in Yellowstone Park. (Similar enzymes can be found in bacteria living in deep-sea thermal vents; see *Focus On: Life without the Sun*, Chapter 52.)

The PCR technique is particularly valuable because only specific *target sequences* are replicated. Recall from Chapter 11 that DNA polymerase can add nucleotides only to a preexisting polynucleotide strand. In the cell, DNA synthesis begins with the formation of a short primer, which is then extended by DNA polymerase. In the PCR technique, chemically synthesized primers with a specified nucleotide sequence are included in the reaction mixture. The primers attach to complementary target sequences of the single-stranded DNA, thereby designating the starting point for replication by DNA polymerase. In this way, a specific sequence can be cloned from an unpurified mixture of DNA sequences.

The PCR technique has virtually limitless applications. It allows the amplification and analysis of tiny DNA samples from seemingly unlikely sources, ranging from crime scenes to archaeological remains; for example, in 1997 the first analysis of DNA obtained from the bones of Neandertals was reported (Chapter 21).

If the PCR technique has a flaw, it is the fact that it is almost too sensitive. Even a tiny amount of contaminant DNA in a sample could potentially become amplified and lead to an erroneous conclusion. Researchers are constantly improving their methods to avoid this and other technical pitfalls.

Gel electrophoresis is the most widely used technique to separate macromolecules

Mixtures of certain macromolecules such as polypeptides, DNA fragments, or RNA can be separated by **gel electrophoresis**, a method that exploits the fact that these mole-

cules carry charged groups that cause them to migrate in an electrical field. Figure 14–8 illustrates gel electrophoresis of DNA molecules. Because nucleic acids are negatively charged (see Chapters 11 and 12), both DNA and RNA migrate through the gel toward the positive pole of the electrical field. Because the gel retards the movement of the large molecules more than the small molecules, the rate at which they travel is inversely proportional to their length (molecular weight). Including DNA fragments of known size as standards allows accurate measurement of the molecular weights of the unknown fragments.

It is sometimes easier to work with the DNA fragments separated by gel electrophoresis if they are transferred to a nitrocellulose filter, which picks up the DNA much as a blotter picks up ink. The DNA on the filter is then denatured and incubated with a radioactive genetic probe, which hybridizes with any complementary fragments. When the “blot,” which is essentially a replica of the gel, is used for autoradiography (Chapter 2), the resulting spots on the x-ray film correspond to the locations of the fragments in the gel that are complementary to the probe. This type of **blot hybridization** (called a **Southern blot** after its inventor, E.M. Southern) has widespread applications. It is often used to diagnose certain types of genetic disorders.

Similar blotting techniques are used to study RNA and proteins. When RNA molecules separated by electrophoresis are transferred to a membrane, the result is, rather in jest, called a **Northern blot**. In the same spirit, the term **Western blot** is applied to a blot consisting of polypeptides previously separated by gel electrophoresis. (So far, no one has invented a type of blot that could be called an “Eastern blot.”) In the case of Western blotting, the polypeptides of interest are recognized by radioactive antibody molecules that bind to them specifically.

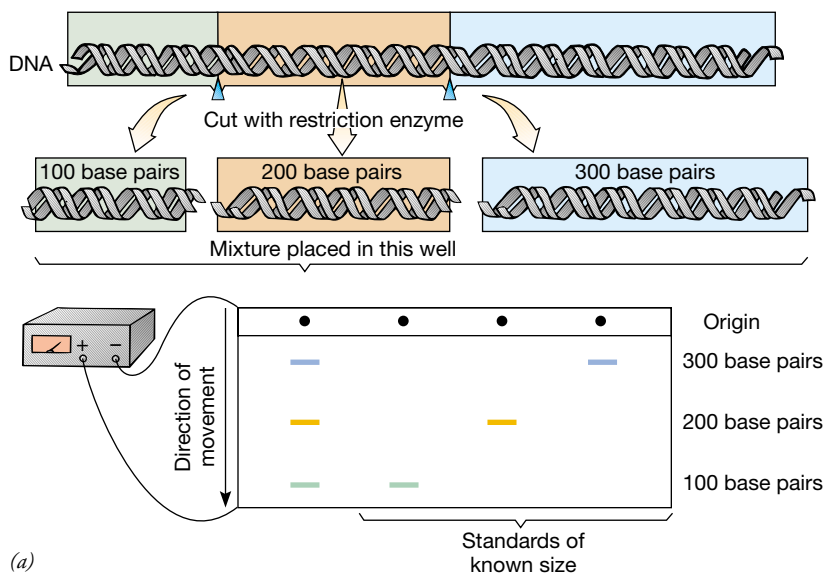

Figure 14–8 Gel electrophoresis. Charged molecules, such as DNA, RNA, or protein, can be separated based on the rate at which they migrate in an electrical field. (a) An electrical field is set up in a gel material, consisting of agarose or polyacrylamide, which is poured as a thin slab on a glass or Plexiglas holder. After the gel has solidified, samples containing a mixture of macromolecules of different sizes are loaded in wells formed at one end of the gel, and then an electrical current is applied. The smallest DNA fragments (*green*) travel the longest distance. (b) A gel containing separated DNA fragments. The gel is stained with ethidium bromide, a dye that binds to DNA and is fluorescent under UV light. (b, Michael Gabridge/Visuals Unlimited)

A great deal of information can be inferred from a DNA nucleotide sequence

A cloned piece of DNA can be used as a research tool for a wide variety of applications. Even if the purpose of cloning the gene is to obtain the encoded protein for some industrial or pharmaceutical process, a great deal must be known about the gene and how it functions before it can be “engineered” for a particular application. The usual first step is to determine the sequence of nucleotides.

The most commonly used method of DNA sequencing is based on the fact that a replicating DNA strand that has incorporated a particular type of modified nucleotide, known as a dideoxynucleotide, cannot elongate beyond that point. Unlike a “normal” deoxynucleotide (which lacks a hydroxyl group on its 5′ carbon), a dideoxynucleotide also lacks a hydroxyl group on its 3′ carbon (Figure 14–9a). (Recall from Chapter 11 that a 3′ hydroxyl group is needed to react each time a phosphodiester linkage is formed.)

Four different reaction mixtures are prepared. Each contains DNA polymerase, appropriately radioactively labeled primers, and all four deoxynucleotides needed to synthesize DNA: dATP, dCTP, dGTP, and dTTP. Each also includes a

small amount of only one of the four dideoxynucleotides: ddATP, ddCTP, ddGTP, or ddTTP (Figure 14–9b).

For example, consider how the reaction proceeds in the mixture that includes ddATP. At each site where adenine is specified, occasionally a growing strand will incorporate a ddATP and will be unable to elongate further. Consequently, a mixture of DNA fragments of varying lengths is formed in the reaction mixture. Each fragment that contains a ddATP marks a specific location where adenine is normally found. Similarly, in the reaction mixture that includes ddCTP, each fragment that contains ddCTP marks the position of a cytosine, and so on (Figure 14–9c).

The radioactive fragments from each reaction are denatured and then separated by gel electrophoresis, with each reaction mixture (corresponding to A, T, G, or C) occupying its own lane in the gel. The positions of the fragments in the gel can then be determined by autoradiography (Fig. 14–9d and e). Because the high resolution of the gel makes it possible to distinguish between fragments that differ in length by only a single nucleotide, one can read off the sequence one base at a time, beginning with the shortest fragment. To follow the example in Figure 14–9d, if the shortest fragment is in the “G” lane, then the first base is G; similarly, if the next shortest frag-

(a) Dideoxynucleotides are modified nucleotides that lack a 3' hydroxyl group and thus block further elongation of a new DNA chain.

Single-stranded DNA fragment to be sequenced
5' A T G C T A T G C T C C 3'

All reaction mixtures contain dATP, dTTP, dGTP, dCTP, DNA polymerase and radioactively labeled primers

(b) Four different reaction mixtures are used to sequence a DNA fragment; each contains a small amount of a single dideoxynucleotide, such as dideoxy ATP (adenine), and larger amounts of the four normal deoxynucleotides.

(c) The random incorporation of dideoxy ATP into the growing chain generates a series of smaller DNA fragments ending at all the possible positions where adenine is found in the original fragment.

(d) The radioactive products of each reaction mixture are separated by gel electrophoresis and located by exposing the gel to x-ray film. The nucleotide sequence of the newly synthesized DNA is read directly from the film (5' → 3').

(e) An exposed x-ray film of a DNA sequencing gel. The four lanes represent A, C, G, and T dideoxy reaction mixes, respectively.

Figure 14–9 DNA sequencing. (e, Courtesy of B. Slatko, New England Biolabs)

ment is also in the “G” lane, then the next base is also G; if the third shortest fragment is in the “A” lane, then the third base is A, and so on.

Knowing the DNA sequence of a cloned gene allows investigators to identify which parts of the DNA molecule contain the actual protein-coding sequences, as well as which parts may be regulatory regions involved in gene expression (see Chapter 13). Signals involved in mRNA processing and modification can be recognized, and the amino acid sequence of the encoded protein can be inferred directly from the base sequence. Prior to the development of DNA-sequencing methods, protein sequences were determined by laborious methods from highly purified protein samples. Although protein microsequencing technology has also advanced rapidly, in most cases cloning and sequencing a gene is easier than purifying and sequencing the encoded protein.

Because many parts of the process can now be automated, DNA sequencing can be done very rapidly. These advances in sequencing technology have made it possible for researchers to study the nucleotide sequences of a wide variety of organisms, both prokaryotic and eukaryotic. Much of this research received its initial impetus in conjunction with the Human Genome Project, to be discussed in Chapter 15. The genomes of a number of prokaryotes, both parasitic and free-living, have been completely sequenced. The complete sequence of the 4.6 million base pairs (4288 genes) of *E. coli* was published in 1997. This was preceded by another major landmark, electronic publication of the complete sequence of the 12 million base pairs (6223 genes) of yeast, a unicellular eukaryote with an unusually small genome, in 1996. Ongoing sequencing projects encompass a variety of multicellular eukaryotes, with an emphasis on those that have been important research tools and on others of agricultural and medical importance. We are actually on the verge of an extraordinary explosion of gene sequence data because much more advanced automation methods, in which thousands of bases can be sequenced on the surface of a single microchip, will soon be widely used.

DNA sequence information is now kept in large computer databases, many of which can be accessed through the Internet. Examples include databases maintained by the National Center for Biotechnology Information (a service of the U. S. National Library of Medicine and the National Institutes of Health) and by the Human Genome Organization (HUGO). These allow investigators to compare newly discovered sequences with those already known and to utilize many other kinds of information. By searching for DNA (and amino acid) sequences in a database, researchers can gain a great deal of insight into the function and structure of the gene product, as well as the evolutionary relationships among genes.

Restriction fragment length polymorphisms (RFLPs) are a measure of genetic relationships

The variability of genes within a population can be studied in a number of different ways. A direct approach is to determine

DNA sequences. The previously mentioned advances in DNA sequencing technology will make this the most widely used method in the future.

A more traditional procedure uses restriction enzymes. It is based on the fact that random DNA mutations and recombination may result in individuals differing in the number and location of sites where a particular restriction enzyme cuts the DNA. Therefore, each individual differs in the lengths of the fragments produced by that enzyme. Such **restriction fragment length polymorphisms** (commonly known as **RFLPs**, or “Riflips”) can be used to determine how closely related different members of the population are. (The term *polymorphism* literally means “many forms.” A genetic polymorphism is said to exist if individuals of two or more discrete genetic types, or “morphs,” are found in a population or species; see Chapter 18.)

Restriction enzymes are used to cut the DNA from two or more individuals, and the fragments are separated by gel electrophoresis (with the DNA from each individual in a separate lane). A Southern blot is made of the DNA on the gel, which is then denatured and allowed to hybridize with a genetic probe representing a sequence that is repeated and interspersed throughout the genome. The resulting patterns of bands, commonly referred to as “DNA fingerprints” can then be compared (Fig. 14–10).

Over the past few years RFLP analysis has been found to be an especially powerful tool in the fields of population and evolutionary biology because it can measure the degree of genetic relatedness between individuals. It has also been very useful in settling cases of disputed parentage.

Figure 14–10 A restriction fragment length polymorphism (RFLP). The lanes marked “M” and “F” contain DNA from a mother and father, respectively, and the two marked “C” contain DNA from their children. Note that every band present in one of the children is also found in at least one of the parents. (David Parker/Science Photo Library/Photo Researchers, Inc.)

The most controversial use of this technology is in the field of forensics. If even small amounts of blood, semen, or other DNA-containing tissue are left at the scene of a crime, one or more target DNA sequences can be amplified by the PCR technique, cut with appropriate restriction enzymes, and subjected to electrophoresis.

If applied properly, DNA fingerprinting has the power to identify the guilty with a high degree of certainty. Conversely, it can exonerate the innocent. In fact, a number of convicted persons have won new trials and have been subsequently released from incarceration based on the application of DNA fingerprinting to physical evidence from the crime scene. Such evidence has been ruled admissible in many court cases, including certain trials that have received a great deal of attention in recent years. One limitation arises from the fact that the DNA samples are usually small and may have been degraded. Obviously, great care must be taken to prevent contamination of the samples. This is especially crucial if the PCR technique is to be used to amplify the DNA.

The development of DNA fingerprinting sparked a lively debate over how “unique” each individual pattern might be. For example, some scientists argued that a pattern that is quite rare in the general population might be more common in a particular ethnic group, and this might significantly affect the calculated probability of a match. As data on the frequency of particular patterns in various populations have accumulated, it has been learned that these concerns are of less practical importance than once thought. For example, the odds that two persons taken at random from the general population would have identical DNA fingerprints may be as low as one in several billion. If two persons are members of the same ethnic group the odds of a match may increase, but are usually still extremely low (perhaps one in several million).

GENETIC ENGINEERING HAS MANY APPLICATIONS

Recombinant DNA technology has provided not only a new and unique set of tools for examining fundamental questions about how living cells work but also new approaches to problems of applied technology in many other fields. In some cases the production of genetically engineered proteins and organisms has begun to have considerable impact on our lives. The most striking of these have been in the fields of pharmacology and medicine.

Human insulin produced by *E. coli* was one of the first genetically engineered proteins to be commercially produced. Prior to the development of the altered bacterium to produce the human hormone, insulin was derived exclusively from other animals. Many diabetic persons become allergic to the insulin from animal sources because its amino acid sequence differs slightly from human insulin. The ability to produce the human hormone by recombinant DNA methods has resulted in significant medical benefits to diabetics.

Genetically engineered human growth hormone (see Chapter 47) is required by some children to overcome growth deficiencies. Human growth hormone could previously be obtained only from cadavers. Only small amounts were available, and evidence suggested that some of the preparations were contaminated with infectious agents. The list of products that can be produced by genetic engineering is ever growing. These include treatments for multiple sclerosis, certain cancers, heart attacks, and certain forms of anemia. Recombinant DNA technology is also increasingly used to produce vaccines that provide safe and effective immunity against infectious diseases such as hepatitis B.

Additional engineering is required for a recombinant eukaryotic gene to be expressed in bacteria

Even if a gene has been isolated and successfully introduced into *E. coli*, the bacterium does not necessarily make the encoded protein in large quantities. Several obstacles stand in the way of producing gene products of eukaryotes in bacteria. One is that the gene has to be correctly associated with an appropriate set of regulatory and promoter sequences that the bacterial RNA polymerase can recognize. Recall from Chapters 12 and 13 that the regulatory regions of prokaryotic and eukaryotic genes are quite different. A usual approach to this problem is to combine the amino acid coding portion of a eukaryotic gene with a bacterial promoter sequence that can be strongly expressed. Some eukaryotic genes, for example, are fused to the lactose operon regulatory region (see Chapter 13); the protein product of the eukaryotic gene is synthesized when the bacterium is fed lactose in the growth medium.

We have already discussed the fact that bacterial cells cannot process RNA molecules containing eukaryotic intron sequences and that one solution to this problem is to introduce a cDNA copy of the gene. Other problems may arise in the expression of a recombinant protein in *E. coli* because of differences in the ways the proteins are expressed in prokaryotic and eukaryotic cells.

Insulin, for example, is made in human cells from a large polypeptide that is folded in a specific way by the formation of three disulfide bonds (see Fig. 3–18), each joining two cysteines (sulfur-containing amino acids). After the polypeptide is folded, parts of the polypeptide are removed by proteolytic (protein-digesting) enzymes, leaving the insulin as two separate polypeptide chains held together by the disulfide bonds. *E. coli* lacks the specific enzymes necessary to cut the larger protein and is not able to fold the molecule properly. To overcome these problems, the gene was engineered to produce the two polypeptides separately. The recombinant proteins are then purified from the cells and allowed to associate in vitro. This procedure results in a relatively low yield of the active hormone, because the insulin can fold in several ways, only one of which results in a functional hormone. It has been possible to circumvent some of these problems by introducing the gene into eukaryotic cells such as yeast or other fungi, or cultured

mammalian cells, that contain the protein-processing machinery required to produce fully functional proteins. As we will see in the next section, some types of genetically engineered plants or animals can also produce foreign proteins.

Transgenic organisms have incorporated foreign DNA into their cells

Plants and animals that have incorporated foreign genes are referred to as **transgenic** organisms. A number of approaches are being used to insert foreign genes into plant or animal cells.

Viruses are often used as vectors, although other methods, such as direct injection of DNA into cells, have also been used.

Transgenic animals are valuable in research and may have commercial uses

One approach to genetic engineering of animal proteins is to use live animals that have incorporated a foreign gene to make the recombinant protein. These transgenic animals are usually produced by microinjecting the DNA of a particular gene into the nucleus of a recipient fertilized egg cell or embryo cells (Fig. 14–11; also see Fig. 16–16*a*). The eggs are then im-

MAKING THE CONNECTION

THE GENETICS OF MICE AND HUMANS

How can the study of the genetics of other organisms further our understanding of human genetics? In this chapter we have seen how recombinant DNA technology was developed using knowledge of the genetics of bacteria, yeast, and other microorganisms. As the available techniques have become more sophisticated, it has become possible to genetically engineer complex organisms, producing transgenic plants and animals.

The laboratory mouse, *Mus*, has become a particularly useful model for studying human genes. One extremely powerful research tool is **gene targeting**, a procedure in which a single gene is chosen and “knocked out” (inactivated) in a mouse. The roles of the inactivated gene can be determined by observing the phenotype of the mice bearing the knockout gene. Because at least 99% of the loci of mice have human counterparts (although the specific alleles are usually different), information about knockout genes in mice provides details about human genes as well.

Gene targeting, pioneered by Mario Capecchi, a molecular geneticist at the University of Utah School of Medicine, is a rather complex and lengthy procedure; it takes about a year to develop a new strain of knockout mice. First a nonfunctional (knockout) gene is introduced into special mouse cells, known as embryo-derived stem (ES) cells. ES cells are particularly easy to handle because, like cancer cells, they can be grown in culture indefinitely. Most important, if they are placed into a mouse embryo, they are capable of dividing and producing all of the cell types normally found in the mouse. In a tiny fraction of these ES cells, the introduced gene will become physically associated with the correspond-

ing gene in a chromosome. If this occurs, the two will tend to exchange DNA segments in a poorly understood process known as *homologous recombination*. In this way, the normal allele in the mouse chromosome is replaced by the knockout allele.

Researchers inject ES cells they hope are carrying a knockout gene into early mouse embryos and allow the mice to develop to maturity. The mice are then bred for several generations, allowing researchers to eventually select any offspring that might be homozygous for the knockout gene.

If the gene is not lethal when inactivated, the researchers generally study homozygous animals that carry the knockout gene in every cell. However, because many genes are essential to life, researchers have modified the knockout technique to develop strains in which a specific gene is selectively inactivated in only one cell type. Today more than 250 different strains of knockout mice, each displaying its own characteristic phenotype, have been developed in various research labs, and the number continues to grow.

Gene targeting is providing answers to basic biological questions, including the development of embryos, the development of the nervous system, and the normal functioning of the immune system.

Gene targeting has great potential for revealing more about various human diseases, more than 5000 of which have a genetic component. Gene targeting is being used to study cancer, heart disease, respiratory diseases such as cystic fibrosis (see *On the Cutting Edge: Using a Mouse Model to Study a Human Genetic Disease*, Chapter 15), sickle cell anemia, and other health problems.

planted into the uterus of a female and allowed to develop.

In a classic pioneering study of this type, reported by the laboratory of R.L. Brinster in 1983, transgenic mice carrying a gene for rat growth hormone were produced. First the gene for growth hormone was isolated from a library of genomic rat DNA. It was then combined with the promoter region of a mouse gene that normally produces metallothionein, a protein whose synthesis is stimulated by the presence of heavy metals such as zinc. The metallothionein regulatory sequences were used as a switch to turn the production of rat growth hormone on and off at will. After the engineered gene was injected into mouse embryo cells, the embryos were implanted into the uterus of a mouse and allowed to develop. Embryos in which the gene transplant had been successful grew rapidly when exposed to small amounts of zinc. One mouse, which developed from an embryo that had received two copies of the growth hormone gene, grew to more than double the normal size. As might be expected, such mice are often able to transmit their increased growth capability to their offspring.

Transgenic offspring have already been shown to have valuable research applications in a wide range of studies. These include regulation of gene expression, immune system function, genetic diseases, viral diseases, and genes responsible for

the development of cancer (see *Making the Connection: The Genetics of Mice and Humans*).

Transgenic animals have been used to develop strains that secrete important proteins in milk. For example, the gene for a human blood clotting factor has been introduced into sheep. These recombinant genes have been fused to the regulatory sequences of the milk protein genes and are therefore activated only in mammary tissues involved in milk production.

The advantage of obtaining the protein from milk is that potentially it can be produced in large quantities and can be harvested simply by milking the animal. The protein is then purified from the milk. The animals are not harmed by the introduction of the gene, and, because usually the progeny of the transgenic animal also produce the recombinant protein, transgenic strains can be established simply by breeding the animals.

Sometimes viruses are used as recombinant DNA vectors. RNA viruses called **retroviruses** make DNA copies of themselves by reverse transcription (see *Focus On: Reverse Transcription, Jumping Genes, and Pseudogenes* in Chapter 12). Sometimes the DNA copies become integrated into the host chromosomes, where they are replicated along with host DNA. For example, genetically altered mouse leukemia viruses are

retroviruses that can be used as vectors to incorporate recombinant genes into cultured cells. Under certain conditions genes carried by the engineered virus can be expressed in the animal cells to produce genetically engineered proteins.

A major disadvantage of introducing genes into cultured animal cells is that the yields of the proteins encoded by the foreign DNA carried by the viruses are generally low. However, these types of vectors show some promise as a means of **gene therapy** for human genetic disorders.

Transgenic plants are increasingly important in agriculture

Plants have been selectively bred for thousands of years. The success of such efforts depends on the presence of desirable traits in the variety of plant being selected, or in closely related wild or domesticated plants whose traits can be transferred by cross-breeding. Primitive varieties or closely related species of cultivated plants often have traits, such as disease resistance, that could be advantageously introduced into varieties more suited to modern needs. If genes are introduced into plants from strains or species with which they do not ordinarily interbreed, the possibilities for improvement are greatly increased. Unfortunately, a suitable vector for the introduction of recombinant genes into many types of plant cells has proved very difficult to find. The most widely used vector system employs the crown gall bacterium, *Agrobacterium tumefaciens*. This bacterium normally produces plant tumors by introducing a special plasmid, called the *Ti* (for *tumor-inducing*) *plasmid*, into the cells of its host (Fig. 14–12). The *Ti* plasmid induces abnormal growth by forcing the plant cells to produce elevated levels of a plant growth hormone called cytokinin (see Chapter 36).

It is possible to “disarm” the *Ti* plasmid so that it does not induce tumor formation and then to use it as a vector to insert genes into plant cells. The cells into which the altered plasmid is introduced are essentially normal except for the genes that have been inserted. Genes placed in the plant genome in this fashion may be transmitted sexually, via seeds, to the next generation, but they can also be propagated asexually if desired.

Unfortunately, not all plants take up DNA readily, and this is particularly true of the grain plants that are the major food source for humans. One very useful approach has been the development of a genetic “shotgun.” Microscopic gold fragments are coated with DNA and then shot into plant cells, penetrating the cell walls. Some of the cells retain the DNA and are transformed by it. Those cells can then be cultured and used to regenerate an entire plant (see Chapter 16). For example, such an approach has been successfully used to transfer a gene for resistance to a bacterial disease from a wild rice variety into cultivated rice.

An additional complication of plant genetic engineering is that a number of important plant genes are located in the DNA of the chloroplasts (see Chapter 4). Chloroplasts are essential in photosynthesis, which is the basis for plant productivity. Obviously, it is useful to develop methods for changing

Figure 14–12 Transformation of plant cells. This SEM shows *Agrobacterium tumefaciens* infecting cultured plant cells. The close contact permits the transfer of plasmid DNA from the bacteria to the larger plant cells. (Courtesy of Ann G. Matthysse)

the portion of the plant’s DNA that resides within the chloroplast. Methods of chloroplast engineering are currently the focus of intense research.

The applications of transgenic plants are not limited to disease resistance and increased production of crops. Like some transgenic animals, certain transgenic plants can potentially be used to produce large quantities of medically important proteins, such as antibodies. The developers of this technology are conducting ongoing field trials to demonstrate the large-scale feasibility of these production methods.

SAFETY GUIDELINES HAVE BEEN DEVELOPED FOR RECOMBINANT DNA TECHNOLOGY

People who have experienced the direct applications of recombinant DNA technology today would undoubtedly agree that those developments have been important and beneficial. When the new technology was introduced in the early 1970s, however, many scientists considered the potential misuses to be at least equally significant. The possibility that an organism with undesirable environmental effects might be accidentally produced was a concern. Totally new strains of bacteria or other organisms, with which the world has no previous experience, might be difficult to control. This possibility was recognized by the scientists who developed the recombinant DNA methods and led them to insist on stringent guidelines for making the new technology safe.

Recent history has failed to bear out these worries. Experiments over the past years in thousands of university and

industrial laboratories have seen recombinant DNA manipulations carried out safely. One of the initial concerns—the accidental release of laboratory bacterial strains containing dangerous genes into the environment—has turned out to be groundless. Laboratory strains of *E. coli* are poor competition for the wild strains in the outside world and quickly perish. Experiments thought to entail unusual risks are carried out in special facilities designed to contain dangerous disease-causing organisms and allow researchers to work with them safely. The fears of accidentally cloning a dangerous gene or releasing a dangerous organism into the environment seem to be laid to rest. This does not mean, however, that *intentional* manipulations of dangerous genes are not a possibility.

Most scientists today recognize the importance of recombinant DNA technology and agree that the perceived threat to humans and the environment was overestimated. Many of the restrictive guidelines for using recombinant DNA have been relaxed as the safety of the experiments has been established. Stringent restrictions still exist, however, in certain areas of recombinant DNA research where there are known dangers, or where questions about possible effects on the environment are still unanswered.

These restrictions are most evident in research that pro-

poses to introduce recombinant organisms into the wild, such as agricultural strains of plants whose seeds or pollen might spread in an uncontrolled manner. A great deal of research activity is now concentrated on determining the effects of introducing recombinant organisms into a natural environment. Carefully conducted tests have shown that recombinant organisms are not dangerous to the environment simply because they are recombinant. However, it is important to assess the biology of each new recombinant organism. In this way scientists will be able to determine if it has characteristics that might cause it to present an environmental hazard under certain conditions. For example, if a transgenic crop plant has been engineered to resist an herbicide, might that gene be transferred, via pollen or by some other route, to that plant's weedy relatives, generating herbicide-resistant "superweeds?" Other concerns relate to plants that have been engineered to produce pesticides, such as insecticides. For example, a transgenic plant may produce a relatively small amount of an insecticide, which may be sufficient to provide protection if the targeted insect population is not very numerous. However, the presence of low levels of the insecticide could potentially provide ideal conditions for selection for resistant individuals in the insect population.

SUMMARY WITH KEY TERMS

I. **Recombinant DNA** technology is concerned with isolating and amplifying specific sequences of DNA by incorporating them into **vector** DNA molecules. The resulting recombinant DNA can then be propagated and amplified in organisms such as *E. coli*.

A. **Restriction enzymes** are used to cut DNA into specific fragments.

1. Each type of restriction enzyme recognizes and cuts DNA at a highly specific base sequence.
2. Many restriction enzymes cleave DNA sequences to produce complementary, single-stranded cut ends (sticky ends).

B. The most common recombinant DNA vectors are constructed from naturally occurring circular DNA molecules called **plasmids**, or from bacterial viruses called **bacteriophages**; both of these are found in some bacteria.

C. Recombinant DNA molecules are often constructed by allowing the ends of a DNA fragment and a plasmid (which have both been cut with the same restriction enzyme) to associate by complementary base pairing. The DNA strands are then covalently linked by **DNA ligase** to form the recombinant molecule.

D. Parts of genes are isolated from recombinant DNA libraries, which are mixtures of DNA fragments inserted into appropriate vectors.

1. **Genomic libraries** are formed from the total DNA of an organism. Genes present in recombinant DNA genomic libraries from eukaryotes contain introns. Those genes can be amplified in *E. coli*, but the protein is not properly expressed.
2. When a **cDNA library** is produced, **reverse transcriptase** is used to make DNA copies of mRNA isolated from eukaryotic cells; these are then incorporated into recombinant DNA vectors. Because the introns have been removed from mRNA molecules, eukaryotic genes in cDNA libraries can sometimes be expressed in *E. coli* to make their protein products.

E. The **polymerase chain reaction (PCR)** is a widely used, usually automated, technique in which a particular DNA sequence can be targeted by specific primers and then cloned in vitro by a special heat-resistant DNA polymerase.

F. Analysis of a cloned sequence can yield useful information about the gene and its protein and can enable investigators to identify and sub-

clone DNA fragments for use as molecular probes.

1. A **DNA sequence** gives information about the structure of the gene and the probable amino acid sequence of the encoded proteins. It can be compared to other sequences stored in massive databases.

2. A radioactive DNA or RNA sequence can be used as a **genetic probe** to identify complementary nucleic acid sequences. In the **Southern blot technique**, DNA fragments are separated by **gel electrophoresis** and then blotted onto a nitrocellulose filter. The radioactive probe is then hybridized by complementary base-pairing to the DNA bound to the filter, and the radioactive band or bands of DNA can be identified by autoradiography.

G. The degree of genetic relationship among the individuals in a population can be determined by comparing nucleotide sequences, or it can be estimated by studying **restriction fragment length polymorphisms (RFLPs)**.

II. **Genetic engineering** is a technology that uses genetic and recombinant DNA methods to devise new combinations of genes to produce improved pharmaceutical and agricultural products.

A. Genes isolated from one organism can be modified and expressed in other organisms ranging from *E. coli* to **transgenic** plants and animals.

1. Expression of eukaryotic proteins in bacteria such as *E. coli* requires that the gene be linked to regulatory elements that the bacterium can recognize. In addition, bacterial cells do not contain many of the enzymes needed for the posttranslational processing of eukaryotic proteins.

2. Expression of eukaryotic genes in eukaryotic host organisms shows great promise, because the processing and modification machinery for eukaryotic proteins is already present in these cells.

a. Production of important pharmaceutical products can be engineered in transgenic animals and possibly in plants.

b. Genetic engineering of plants and domestic animals holds the promise of increasing the availability of food.

B. Recombinant DNA technology is carried out under certain safety guidelines.

POST-TEST

1. A plasmid (a) can be used as a DNA vector (b) is a type of bacteriophage (c) is a type of cDNA (d) is a retrovirus (e) b and c
2. DNA molecules with complementary "sticky ends" associate by (a) covalent bonds (b) hydrogen bonds (c) ionic bonds (d) disulfide bonds (e) phosphodiester linkages
3. Human DNA and a particular plasmid both have sites that can be cut by the restriction enzymes Hind III and EcoRI. To make recombinant DNA, one should (a) cut the plasmid with EcoRI and the human DNA with Hind III (b) use EcoRI to cut both the plasmid and the human DNA (c) use Hind III to cut both the plasmid and the human DNA (d) a or b (e) b or c
4. Which of the following sequences is *not* palindromic?

(a) 5'—AAGCTT—3'	(b) 5'—GATC—3'
3'—TTCGAA—5'	3'—CTAG—5'
(c) 5'—GAATTC—3'	(d) 5'—CTAA—3'
3'—CTTAAG—5'	3'—GATT—5'

 (e) b and d
5. The PCR technique uses (a) heat-resistant DNA polymerase (b) reverse transcriptase (c) DNA ligase (d) a and b (e) b and c
6. A cDNA clone contains (a) introns (b) exons (c) anticodons (d) a and b (e) b and c
7. The dideoxynucleotides ddATP, ddTTP, ddGTP, and ddCTP are important in DNA sequencing because they (a) cause premature termination of a growing DNA strand (b) are used as primers (c) cause the DNA fragments that contain them to migrate more slowly through a sequencing gel (d) are not affected by high temperatures (e) have more energy than deoxynucleotides
8. In restriction fragment length polymorphism (RFLP) analysis to determine parentage, (a) every band present in a child would be expected to be present in both of the true parents (b) every band present in a child would be expected to be present in at least one of the true parents (c) every band present in a true parent would be expected to be present in all of the children (d) a and b (e) b and c
9. In the Southern blot technique, _____ is/are transferred from a gel to a special nitrocellulose filter. (a) protein (b) RNA (c) DNA (d) bacterial colonies (e) reverse transcriptase
10. Gel electrophoresis separates nucleic acids on the basis of differences in (a) length (b) charge (c) nucleotide sequence (d) relative proportions of adenine and guanine (e) relative proportions of thymine and cytosine
11. The Ti plasmid, carried by *Agrobacterium tumefaciens*, is especially useful for introducing genes into (a) *E. coli* (b) plants (c) animals (d) yeast (e) all eukaryotes

REVIEW QUESTIONS

1. What is meant by the term *genetic engineering*?
2. What are restriction enzymes? How are they used in recombinant DNA research?
3. What characteristics should be engineered into a plasmid to make it a useful cloning vector?
4. Diagram the process by which recombinant DNA molecules are usually constructed.
5. How is a gene library constructed? What are the relative merits of genomic libraries and cDNA libraries?
6. Sketch an example illustrating how a restriction map of a gene is made.
7. Why is the PCR technique valuable?

YOU MAKE THE CONNECTION

1. What are some of the problems that might arise if you were trying to produce a eukaryotic protein in a bacterium? How might some of these problems be solved by using transgenic plants or animals?
2. Would genetic engineering be possible if we did not know a great deal about the genetics of bacteria? Explain.
3. What are some of the ecological concerns regarding transgenic organisms? What kinds of information are needed to allay these fears?

CHAPTER 15

Human Genetics

The principles of genetics that apply to other diploid eukaryotic organisms also apply to humans. There are, however, some important differences between human genetic research and genetic research on other organisms. To study aspects of inheritance in other species, geneticists ideally (1) have standard stocks of genetically identical individuals, that is, **isogenic strains**, that are homozygous at virtually all of their loci; (2) conduct **controlled matings** between members of different isogenic strains; and (3) raise the offspring under carefully controlled conditions. Of course, the human population is very diverse, and individuals are heterozygous for many genes. In addition, human families are small, and 20 to 30 years or more elapse between generations. It is therefore virtually impossible, as well as unethical, to conduct research in this way with humans.

Despite the inherent difficulties, knowledge in **human genetics**, the science of inherited variation in humans, is progressing very rapidly. Traditionally, human genetics was examined using such approaches as population studies of large extended families. For example, **albinism**—the lack of pigmentation in the skin, hair, and eyes—is a rare human disorder that is common among the Cuna people that live on the San Blas Islands of Panama. The photograph shows a young albino child from this population. From studies of such human groups, we have inferred that albinism is usually inherited as an autosomal recessive trait. Recessiveness is inferred because the parents of afflicted individuals usually are not affected.

More recently, biochemical and molecular studies have indicated that there are several kinds of albinism. Some albinos lack one of the enzymes needed to synthesize the brown pigment melanin, whereas other albinos produce the necessary enzyme, but it cannot enter the pigment cells where the precursors of melanin are produced.

The field of human genetics has been greatly facilitated by the medical attention given to genetic diseases in humans and by the use of genetic engineering technology. The extensive medical records of diseases serve as a very useful data pool on which hypotheses may be based and against which they may be tested.

Genetic studies of other organisms also have provided invaluable insights. Indeed, many phenomena in human inheritance that were initially puzzling have been explained by solving analogous problems in the inheritance of bacteria, yeasts,

(Anna Zuckerman/Photo Edit)

fruit flies, or mice. Studies with mice, for example, indicated that mice contain several genes (polygenes) for hair color. Mice that are homozygous for the recessive albino allele, however, are albino even though they may have genes for other coat colors. Thus, the gene for albinism is epistatic in mice. (Recall from Chapter 10 that *epistasis* is a gene interaction in which the presence of a particular allele of one gene pair determines whether certain alleles of another gene pair are expressed.) Extending this knowledge of mouse inheritance to humans, it has now been demonstrated that human hair color is also polygenic, and albinism in humans exhibits epistasis.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Given a simple pedigree for a particular trait, determine the probable genotypes for all individuals in the pedigree.
2. Distinguish between environmentally induced and inherited abnormalities and between chromosome abnormalities and single gene defects.
3. Make a sketch illustrating how nondisjunction can occur in meiosis. Show how nondisjunction can be responsible for specific chromosome abnormalities such as Down syndrome, Klinefelter syndrome, and Turner syndrome.
4. Describe how amniocentesis is used in the prenatal diagnosis of human genetic abnormalities; state the relative advantages and disadvantages of amniocentesis and chorionic villus sampling.
5. State whether each of the following genetic defects is inherited as an autosomal recessive, autosomal dominant, or X-linked recessive: phenylketonuria, sickle cell anemia, cystic fibrosis, Tay-Sachs disease, Huntington disease, and hemophilia A.
6. Discuss the scope and implications of genetic counseling.
7. Relate each ABO blood type to the appropriate genotype(s). Explain the genetic and physiological basis for Rh incompatibility between a mother and a fetus.
8. Explain why quantitative traits in humans are thought to be under the control of polygenes.
9. Discuss the implications of the Human Genome Project, including the costs and possible benefits.
10. List some of the ways that genetics affects human society.

THE STUDY OF HUMAN GENETICS REQUIRES ALTERNATIVE METHODS

Early studies of human heredity usually dealt with readily identified pairs of contrasting traits and their distribution among members of a family, as illustrated by the **pedigree** in Figure

15–1. This method is still useful, but because human families tend to be small and information on certain family members may be lacking, it has serious limitations.

Human geneticists therefore also use methods that allow them to make inferences about a trait's mode of inheritance based on studies of its distribution in an entire population. By

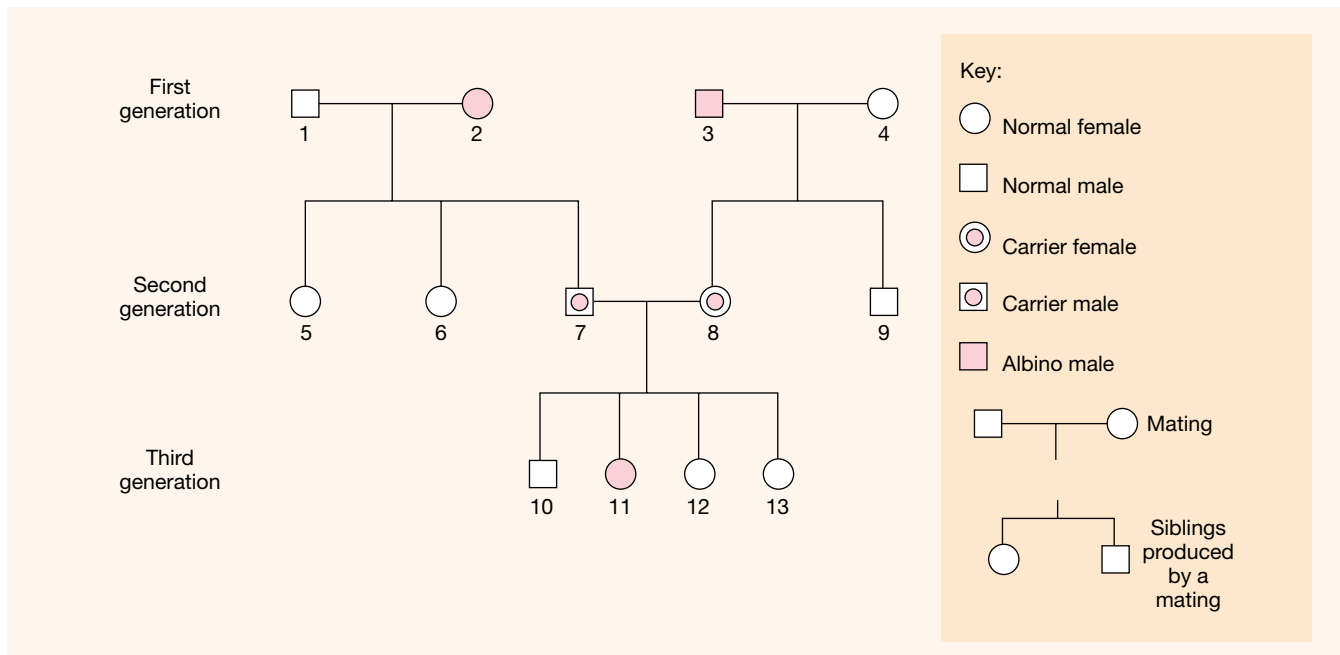

Figure 15–1 Pedigree analysis of albinism. By studying family histories, it is often possible to determine the genetic nature of the trait being studied. Consider 11, an albino girl with two phenotypically normal parents, 7 and 8. Albinism cannot be a dominant allele because if it were, at least one of 11's parents would have to be an albino. Also, albinism cannot be an X-linked recessive allele because if it were, her father would have to be an albino (and her mother would have to be a heterozygous carrier). This pedigree is easily explained if albinism is inherited as an autosomal (not carried on a sex chromosome) recessive allele; with an autosomal recessive allele, two phenotypically normal parents could produce an albino offspring.

(d)

applying the laws of probability to data obtained from a relatively large sample of individuals who are representative of the population, it is often possible to determine if the mode of inheritance is simple or complex and if more than one locus is involved. Some of the methods used by population geneticists are discussed in Chapter 18. As we will see later in this chapter, human inheritance can be studied most effectively by combining these and other approaches with the methods of molecular biology and recombinant DNA technology.

Karyotyping is the analysis of chromosomes

Cytogenetics is the study of chromosomes and their role in inheritance. Many of the basic principles of genetics were dis-

covered by experiments with simpler organisms, in which it was possible to relate genetic data to the number and structure of specific chromosomes. Some of the organisms used in genetics, such as the fruit fly *Drosophila*, have very few chromosomes (only four pairs in *Drosophila*). In *Drosophila* salivary glands and certain other tissues, the chromosomes are large enough that their structural details are readily evident. This organism, therefore, has provided unique opportunities for correlating certain kinds of genetic changes with certain kinds of alterations in chromosome structure.

Recall from Chapter 10 that the number of chromosomes for the human species is 46: 44 autosomes (22 pairs) and 2 sex chromosomes (1 pair). The term **karyotype** refers both to the chromosome composition of an individual and to a photomicrograph showing that composition. In karyotyping, cells from the bone marrow, skin, or blood (white blood cells) are cultured and then treated with the drug **colchicine**, which arrests them at mitotic metaphase by preventing the assembly of spindle microtubules (Fig. 15-2). Next they are placed into a hypotonic solution that causes them to swell; this spreads out the chromosomes so they can be readily observed. The cells are then flattened on microscope slides, and the chromosomes are stained to reveal the patterns of bands, which are unique for each homologous pair.

After the microscopic view has been entered into a computer, the homologous pairs are electronically matched and placed together. Chromosomes are identified by length, position of the centromere, banding patterns, and other features such as *satellites*, which are darkly staining regions. The largest chromosome (chromosome 1) is about five times as long as the smallest one (chromosome 22), but there are only slight size differences among some of the intermediate-sized chromosomes.

ABNORMALITIES IN CHROMOSOME NUMBER CAUSE CERTAIN HUMAN DISORDERS

Polyploidy, the presence of multiple chromosome sets, is common in plants but rare in animals. It may arise from failure of chromosomes to separate during meiosis, or from fertilization of an egg by more than one sperm. Polyploidy is lethal in humans and many other animals when it occurs in all the cells of the body. Triploidy ($3n$) is sometimes found in embryos that have been spontaneously aborted in early pregnancy. The few triploid or tetraploid ($4n$) individuals that have been born alive and survived for a few days have been found to contain a mixture of diploid and polyploid cells.

Abnormalities involving the presence or absence of a single extra chromosome are much more common in humans. These conditions are called **aneuploidies**. Recall that ordinarily there are two of each kind of chromosome. An individual with an extra chromosome, that is, with three of one kind, is said to be **trisomic** for that kind of chromosome. An individual lacking one member of a pair of chromosomes is said to be **monosomic**. Table 15–1 summarizes some disorders produced by aneuploidies.

Aneuploidies generally arise as a result of an abnormal meiotic (or mitotic) division in which chromosomes fail to separate at anaphase. This phenomenon is called **nondisjunction**. In meiosis, chromosome nondisjunction may occur during the first or second meiotic division (or both). For example, two X chromosomes that fail to separate at either the first or the second meiotic division might both enter the egg nucleus. Alternatively, the two joined X chromosomes might go into a po-

lar body, leaving the egg with no X chromosome. (Recall from Chapter 9 that a polar body is a nonfunctional haploid cell produced during oogenesis.)

Nondisjunction of the XY pair in the male might lead to the formation of sperm with both an X and a Y chromosome, or sperm with neither an X nor a Y chromosome. Similarly, nondisjunction at the second meiotic division can produce sperm with two X's or two Y's. Some of these examples of meiotic nondisjunction are illustrated in Figure 15–3. When an abnormal gamete unites with a normal one, the resulting zygote has a chromosome abnormality that is present in every cell of the body.

Nondisjunction during a mitotic division leads to the establishment of a clone of abnormal cells in an otherwise normal individual. Such an individual therefore contains a mixture of normal and abnormal cells.

Persons with Down syndrome are usually trisomic for chromosome 21

Down syndrome¹ is one of the most common chromosome abnormalities in humans. It was named after John Down, the British physician who first described the condition in 1866. Affected individuals have abnormalities of the face, eyelids, tongue, hands, and other parts of the body, and are mentally and physically retarded (Fig. 15–4*a*). They are also unusually susceptible to certain diseases, such as leukemia and Alzheimer's disease.

¹The term *syndrome* refers to a set of symptoms that usually occur together in a particular disorder.

TABLE 15–1 Chromosome Abnormalities: Some Disorders Produced by Aneuploidies

Karyotype	Common Name	Clinical Description
Trisomy 13	Patau syndrome	Multiple defects, with death by age 1 to 3 months
Trisomy 18	Edwards syndrome	Ear deformities, heart defects, spasticity, and other damage; death by age 1 year
Trisomy 21	Down syndrome	Overall frequency is about 1 in 700 live births. True trisomy is most often found among children of older (age 40+) mothers, but translocation resulting in the equivalent of trisomy is not age-related. A similar, though less marked, influence is exerted by the age of the father. Trisomy 21 is characterized by a fold of skin above the eye, varying degrees of mental retardation, short stature, protruding furrowed tongue, transverse palmar crease, cardiac deformities, and increased risk of leukemia and Alzheimer's disease.
Trisomy 22	—	Similar to Down syndrome but with more skeletal deformities
XO	Turner syndrome	Short stature, webbed neck, sometimes slight mental retardation; ovaries degenerate in late embryonic life, leading to rudimentary sexual characteristics; gender is female; no Barr bodies
XXY	Klinefelter syndrome	Male with slowly degenerating testes, enlarged breasts; one Barr body per cell
YYY	YYY karyotype	Unusually tall male with heavy acne, some tendency to mild mental retardation
XXX	Triplo-X	Despite three X chromosomes, usually fertile females with normal intelligence; two Barr bodies per cell

(a)

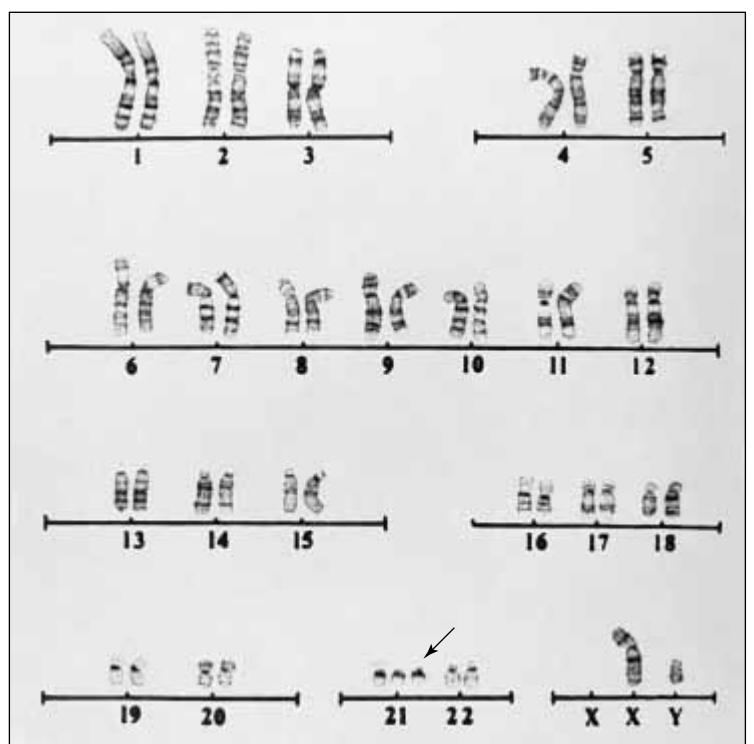

(b)

Figure 15-3 Meiotic nondisjunction. In these examples of nondisjunction of the sex chromosomes in the human male, only the X (red) and Y (brown) chromosomes are shown. (a) Nondisjunction in the first meiotic division results in two XY sperm and two sperm with neither an X nor a Y. (b) Second-division nondisjunction of the X chromosome results in one sperm with two X chromosomes, two with one Y each, and one with no sex chromosomes. Similarly, nondisjunction of the Y results in one sperm with two Y chromosomes, two with one X each, and one with no sex chromosome.

(a)

Figure 15-4 Down syndrome. (a) This male child with Down syndrome is working on a science experiment in his kindergarten class. (b) Note the presence of an extra chromosome 21 in this karyotype of a male with Down syndrome. (a, Richard Hutchings/Photo Researchers, Inc.; b, Courtesy of Dr. Leonard Sciorra)

(b)

Cytogenetic studies have revealed that most people with Down syndrome have 47 chromosomes because they are trisomic for all or part of chromosome 21, one of the smaller chromosomes (Fig. 15–4*b*). Nondisjunction during meiosis is thought to be responsible for the presence of the extra chromosome. Although no genetic information is missing in these individuals, the extra copies of chromosome 21 genes bring about some type of genetic imbalance that is responsible for abnormal physical and mental development. Down syndrome is quite variable in expression, with some individuals far more severely affected than others. Researchers are using genetic engineering methods to attempt to pinpoint genes on chromosome 21 that affect mental development, as well as possible oncogenes (see *Focus On: Oncogenes and Cancer* in Chapter 16) and genes that may be involved in Alzheimer's disease.

Down syndrome occurs in only about 0.15% of all births, but its incidence increases markedly with increasing maternal age (Fig. 15–5). It is 100 times more likely in the offspring of mothers who are 45 years of age or older than it is in the offspring of mothers who are under 19 years of age. The occurrence of Down syndrome is affected much less by the age of the father. The reason for the relationship between increased

incidence in Down syndrome and maternal age is not known. Several hypotheses have been proposed to explain the maternal age effect, for example, one hypothesis is that an aging womb is less likely to reject an abnormal fetus, but none are supported unequivocally.

In general, chromosome aneuploidies involving the autosomes are devastating in their consequences. Other than Down syndrome, very few autosomal trisomies are known (see Table 15–1). The condition known as autosomal **monosomy**, in which only one member of a pair is present, is apparently incompatible with life because it is not seen in live births.

Most sex chromosome aneuploidies are less severe than autosome aneuploidies

Sex chromosome aneuploidies appear to be relatively well tolerated (see Table 15–1), apparently at least in part because of the phenomenon of dosage compensation discussed in Chapter 10. According to the *single active X hypothesis*, mammals compensate for extra X chromosome material by rendering all but one X chromosome inactive. The inactive X is seen as a Barr body, a region of darkly staining, condensed chromatin next to the nuclear envelope of an interphase nucleus (see Fig. 10–16).

The presence of the Barr body in the cells of normal females (but not of normal males) has been used as an initial screen to determine whether an individual is genetically female or male. As we will see in our discussion of sex chromosome aneuploidies, however, the Barr body test has serious limitations.

Persons with **Klinefelter syndrome** have 47 chromosomes, including two X's and one Y. They have small testes, produce few or no sperm, and are therefore sterile. Evidence that the Y chromosome is the major determinant of the male phenotype has been substantiated by the fact that there is at least one gene on the Y chromosome that appears to act as a genetic switch, directing male development. People with Klinefelter syndrome tend to be unusually tall and to have female-like breasts. About half show some degree of mental retardation, but many live relatively normal lives. However, when their cells are examined they are found to have one Barr body per cell. On the basis of such a test, they would be erroneously classified as females.

We designate the sex chromosome constitution for **Turner syndrome**, in which an individual has only one X chromosome and no Y chromosome, as XO; the O refers to the absence of a second sex chromosome. Because of the absence of the strong male-determining effect of the Y chromosome, these persons develop as females. However, both their internal and external genital structures are undeveloped, and they are sterile. Apparently a second X chromosome is necessary for the normal development of the ovaries in a female embryo. Examination of their cells reveals no Barr bodies because there is no extra X chromosome to be inactivated. Using the standards of the Barr body test, such an individual would be classified erroneously as a male.

Figure 15–5 Down syndrome and maternal age. The probability of the birth of an infant with Down syndrome rises as maternal age increases. (The fractions indicate estimated probabilities of Down syndrome.)

People with an X chromosome plus two Y chromosomes are phenotypically males, and they are fertile. Other characteristics of these individuals (unusually tall, with severe acne) hardly merit the term *syndrome*; hence the designation **XXX karyotype**. Some years ago there was a widely publicized suggestion that persons with this condition are more likely to display criminal tendencies and to be imprisoned, but further studies have shown this to be incorrect.

Aneuploidies usually result in prenatal death

Recognizable chromosome abnormalities are seen in less than 1% of all live births, but substantial evidence suggests that the rate at conception is much higher. At least 17% to 20% of pregnancies recognized at 8 weeks will end in spontaneous abortion (miscarriage). Approximately half of these spontaneously aborted embryos have major chromosome abnormalities, including autosomal trisomies (e.g., trisomy 21), triploidy and tetraploidy, and Turner syndrome (XO). Autosomal monosomies are exceedingly rare. It is unlikely that they never occur. It is far more probable that autosomal monosomy is so incompatible with life that a spontaneous abortion occurs very early, before the woman is even aware that she is pregnant. Some investigators place surprisingly high estimates (50% or more) on the rate of loss of very early embryos. It is widely assumed that chromosome abnormalities are responsible for a substantial fraction of these.

ABNORMALITIES IN CHROMOSOME STRUCTURE CAUSE CERTAIN DISORDERS

Chromosome abnormalities are not only caused by changes in chromosome *number* but also by distinct changes in the *structure* of one or more chromosomes. Here we consider three simple examples of structural abnormalities: translocations, deletions, and fragile sites.

Translocation is attachment of part of a chromosome to a nonhomologous chromosome

In some cases part of one chromosome may break off and attach to a nonhomologous chromosome (a **translocation**), or two nonhomologous chromosomes may exchange parts (a **reciprocal translocation**). The consequences of translocations vary considerably but include situations in which some genes are missing (**deletions**) and extra copies of other genes are present (**duplications**).

In about 4% of individuals with Down syndrome, only 46 chromosomes are present, but one is abnormal. Extra genetic material from chromosome 21 has been translocated onto one of the larger chromosomes, such as chromosome 14. We refer to the abnormal translocation chromosome as a *14/21*

chromosome. Affected persons have one chromosome 14, one 14/21 chromosome, and two normal copies of chromosome 21. All or part of the genetic material from chromosome 21 is thus present in triplicate. When the karyotypes of such an individual's parents are studied, either the mother or the father is usually found to have only 45 chromosomes, although he or she is generally phenotypically normal. Such a person has one chromosome 14, one 14/21 chromosome, and one chromosome 21. Although the karyotype is abnormal, there is no extra genetic material. In contrast to trisomy 21, this translocation form of Down syndrome can run in families, and its incidence is not related to maternal age.

A deletion is loss of part of a chromosome

Sometimes chromosomes break but fail to rejoin. Such breaks result in deletions of as little as a few base pairs to as much as an entire chromosome arm. As you might expect, large deletions are lethal, whereas small deletions cause several recognizable human disorders.

The most frequently encountered deletion disorder in human infants is **cri-du-chat syndrome**, in which part of the short arm of chromosome 5 is deleted. As in most deletions, the exact point of breakage in chromosome 5 varies from one person to another; some cases of cri-du-chat involve a small loss, whereas others involve a more substantial loss. Infants born with cri-du-chat syndrome typically have a small head with altered features described as a “moon face,” severe mental retardation, and a distinctive cry that sounds like a kitten mewling. (The name *cri-du-chat* literally means “cry of the cat.”) Affected individuals usually die in infancy or childhood.

Fragile sites are weak points at specific sites in chromatids

A **fragile site**, in which part of a chromatid appears to be attached to the rest of the chromosome by a thin thread of DNA, may occur at a specific location on both chromatids of a particular chromosome; such sites have been identified on the X chromosome as well as on certain autosomes. The location of a fragile site is exactly the same in all of an individual's cells as well as in cells of other family members.

In **fragile X syndrome** the fragile site occurs near the tip on the X chromosome (Fig. 15–6). At the tip of an X chromosome, a nucleotide triplet (CGG, or cytosine, guanine, guanine) is normally repeated up to 50 times. The fragile X chromosome, however, repeats CGG from 200 to more than 1000 times. Fragile X syndrome occurs in 1 out of every 2000 males and in 1 out of every 4000 females. The effects of fragile X syndrome range from mild learning and attention disabilities to severe mental retardation and hyperactivity in affected males. Females with fragile X syndrome are usually heterozygous (because their other X chromosome is normal) and generally have normal intelligence, although occasionally a heterozygous female has borderline intelligence. The discovery of the fragile X gene in 1991 and the development of the first

Figure 15–6 Fragile X syndrome. (a) Region on the X chromosome associated with fragile X syndrome. (b) The normal allele at the tip of the X chromosome repeats the nucleotide triplet CGG up to 50 times. (c) The defective allele repeats CGG more than 200 times.

fragile X mouse model in 1994 have provided researchers with ways to test potential treatments, including gene replacement therapy.

MOST GENETIC DISEASES ARE INHERITED AS AUTOSOMAL RECESSIVE TRAITS

We have seen that several human disorders involve chromosome abnormalities. Hundreds of human disorders, however, involve enzyme defects caused by mutations of single genes. These disorders, sometimes referred to as **inborn errors of metabolism**, include phenylketonuria (PKU) and alkaptonuria (see Chapter 11). Both of these genetic disorders involve blocks in the metabolism of the amino acid phenylalanine. Not all human genetic diseases have a simple inheritance pattern, but most of those that do are transmitted as autosomal recessive traits and so are expressed only in the homozygous state.

Phenylketonuria (PKU) results from an enzyme deficiency

Phenylketonuria (PKU), which is most common in persons of western European descent, is an autosomal recessive disease. Homozygous recessive individuals lack an enzyme that converts the amino acid phenylalanine to another amino acid, tyrosine. These persons instead convert phenylalanine into toxic phenylketones that accumulate and damage the central nervous system. The ultimate result is severe mental retardation. A homozygous PKU infant is usually healthy at birth because its mother, who is heterozygous, produces enough enzyme to prevent phenylalanine accumulation before birth. However, during infancy and early childhood, the toxic products eventually cause irreversible damage to the central nervous system.

In the 1950s it was found that if PKU infants are identi-

fied and placed on a special low-phenylalanine diet early enough, the symptoms can be dramatically alleviated. Biochemical tests for PKU have been developed, and screening of newborns through a simple blood test is required in the United States. More than 90% of all infants born in the United States are tested. Because of these screening programs and the availability of effective treatment, thousands of children have not developed severe mental retardation. Most such children are able to discontinue the diet by adolescence. Although they still produce phenylketones, the sensitive period is past.

Ironically, the success of PKU treatment in childhood presents a new problem today. If a homozygous female who was saved from mental retardation becomes pregnant, the high phenylalanine levels in her blood can damage the brain of the fetus she is carrying, even though that fetus is heterozygous. Therefore, she must resume the diet, preferably before becoming pregnant. This procedure is usually (although not always) successful in preventing the effects of **maternal PKU**. Therefore it is especially important that females with PKU be aware of their condition so that they may obtain appropriate counseling and medical treatment during pregnancy.

Sickle cell anemia results from a hemoglobin defect

Sickle cell anemia is inherited as an autosomal recessive trait. The disease is most common in persons of African descent, and about 1 in 12 African-Americans is heterozygous for it. The blood cells of a person with sickle cell anemia are shaped like sickles, or half-moons, whereas normal red blood cells are biconcave discs.

The mutation that causes sickle cell anemia was first identified more than 50 years ago. The sickle cell contains abnormal hemoglobin molecules, which have the amino acid valine instead of glutamic acid at position 6 (the sixth amino acid from the amino terminal end) in the beta chain (see Chapter 3). The substitution of an amino acid with a hydrophobic, uncharged side chain (valine) for one with a hydrophilic, charged side chain (glutamic acid) makes the hemoglobin less soluble. As a result, it tends to form crystal-like structures that change the shape of the red blood cells (Fig. 15–7). This sickling occurs in the veins after the oxygen has been released from the hemoglobin. The blood cells' abnormal sickled shape slows blood flow and blocks small blood vessels, with resulting tissue damage (from lack of oxygen and essential nutrients) and painful episodes. Sickled red blood cells also have short life spans, leading to severe anemia in affected persons. Individuals with sickle cell anemia generally lead shortened, painful lives.

Available treatments for sickle cell anemia include pain-relief measures, transfusions, and some forms of drug therapy, but these are of limited effectiveness. Ongoing research is directed toward eventually providing gene replacement therapy for these individuals. Bone marrow transplants are also a promising future treatment for seriously ill individuals. The development of a mouse model of sickle cell anemia, which

Figure 15–7 Sickled red blood cells. Some of the red blood cells from this individual with sickle cell anemia show an abnormal sickle shape. (G.W. Willis/Biological Photo Service)

was reported in 1997, will allow researchers to test potential drug and genetic therapies.

The reason that the sickle cell allele (s) occurs at a higher frequency in parts of Africa is well known. Individuals who are heterozygous (Ss) and carry alleles for both normal hemoglobin (S) and sickle cell hemoglobin are more resistant to falciparum malaria, a severe form of malaria that is often fatal. Areas in Africa where falciparum malaria occurs correlate well with areas in which the frequency of the sickle cell allele is more common in the human population. Thus, individuals possessing one copy of the mutant sickle cell allele have a selective advantage over homozygous individuals, both SS and ss . This phenomenon, known as **heterozygote advantage**, is discussed further in Chapter 18.

Cystic fibrosis results from defective ion transport

Cystic fibrosis is the most common autosomal recessive disorder in children of European descent. About 1 of every 20 persons in the United States is a heterozygous carrier of the cystic fibrosis gene. This disorder is characterized by abnormal secretions in the body; its most severe effect is on the respiratory system, which produces abnormally viscous mucus. The cilia that line the bronchi (see Chapter 44) cannot easily remove the mucus, and it thus becomes a culture medium for dangerous bacteria. These bacteria or their toxins attack the surrounding tissues, leading to recurring pneumonia and other complications. The heavy mucus also occurs elsewhere in the body (e.g., in the ducts of the pancreas and liver and in the intestines), causing digestive difficulties and other effects.

The gene responsible for cystic fibrosis codes for a protein that controls the transport of chloride ions across cell membranes. The mutant protein is responsible for the production of the unusually thick mucus that eventually leads to tissue damage in the respiratory and digestive systems. Although many mutant forms exist and these vary somewhat in severity of symptoms, the disease is usually very serious.

Antibiotics are used to control bacterial infections, and daily physical therapy is required to clear mucus from the respiratory system (Fig. 15–8). Treatment with an enzyme (produced by recombinant DNA technology) that breaks down the mucus is also helpful. Without treatment, death would occur in infancy. With treatment, about 50% of affected persons live into their 20s, only to die in what should be the prime of life after having spent the equivalent of about four years in the hospital. Because of the serious limitations of available treatments, gene replacement therapy for cystic fibrosis is under development.

The most severe mutant allele for cystic fibrosis predominates in northern Europe, and another, somewhat less serious, mutant allele is more prevalent in southern Europe. Presumably these mutant alleles are independent mutations that have been maintained by natural selection. Some experimental evidence supports the hypothesis that heterozygous individuals

Figure 15–8 Treatment of cystic fibrosis. The traditional treatment for cystic fibrosis has been chest percussion, or gentle pounding on the chest, to clear mucus from clogged airways in the lungs. (© 1999 Abraham Menashe)

Using a Mouse Model to Study a Human Genetic Disease

- HYPOTHESIS:** The alleles responsible for cystic fibrosis confer a heterozygote advantage because heterozygous individuals are less likely to die from certain types of life-threatening diarrhea.
- METHOD:** The effects of cholera toxin, which is produced by a bacterial infection and causes severe diarrhea, were studied in mice. The responses of three groups of mice were evaluated (1) mice homozygous for an allele that causes cystic fibrosis, (2) heterozygous mice, and (3) normal mice.
- RESULTS:** Mice homozygous for a cystic fibrosis allele did not respond to cholera toxin. Cholera toxin caused heterozygotes to lose only half as much fluid from the cells of the intestinal lining as did homozygous “normal” animals.
- CONCLUSION:** These results support the hypothesis that individuals heterozygous for cystic fibrosis are less likely to die from certain kinds of diarrhea.

Human geneticists have long been puzzled by the fact that heterozygosity for cystic fibrosis alleles is so common among Caucasians (1/20), particularly among Northern Europeans and those of Northern European descent. Recent advances in our understanding of the molecular biology of this genetic disease have led to a new explanation of why these alleles are maintained in the population. This new hypothesis is that heterozygous individuals are less likely to die from certain types of potentially fatal diarrhea.

In severe diarrhea, large amounts of water and electrolytes are lost from the intestine. If unchecked, particularly in infants and young children, this condition can result in death. It has been found that the allele that causes cystic fibrosis is a mutant form of a gene involved in controlling the body's water and electrolyte balance. This gene has been cloned and found to code for a plasma membrane chloride ion channel protein known as the *CFTR* protein. (CFTR stands for *cystic fibrosis transmembrane conductance regulator*.) This ion channel is responsible for transporting chloride ions out of the cells lining the digestive tract and the respiratory system. When the chloride ions leave the cells, water follows by osmosis. Thus the normal secretions of these cells are relatively watery.

Because the cells of individuals with cystic fibrosis lack normal ion channels, their secretions have a very low water content. Cells of heterozygous individuals have only half the usual number of functional CFTR ion channels, but these are sufficient to maintain adequate fluidity of their secretions. However, this ion channel deficiency might be an advantage if an individual is infected by a pathogen that produces a toxin that causes the ion channels to remain constantly open (precipitating diarrhea). With only half as many ion channels, a heterozygote might lose only half as much chloride and water.

Research on any disease is greatly facilitated if an animal model can be used for experimentation. Such a model became available when strains of mice homozygous for cystic fibrosis, as well as those that were heterozygous, were produced by targeted gene replacement (see *Making the Connection: The Genetics of Mice and Humans* in Chapter 14).

Sherif E. Gabriel and his colleagues at the University of North Carolina used the cystic fibrosis mouse model to test the heterozy-

gote advantage hypothesis.* They treated mice with cholera toxin produced by *Vibrio cholerae*, the bacterium that causes cholera. Cholera toxin is known to affect the functioning of the CFTR ion channels, causing the uncontrolled loss of chloride ions and water.

Their results neatly fit the predictions of the heterozygote advantage hypothesis. Animals homozygous for cystic fibrosis, that is, those with no CFTR channels, did not lose any fluid through their intestinal cells when exposed to cholera toxin. The toxin caused heterozygotes (with only half the normal number of CFTR channels) to lose only half as much fluid as mice with the normal number of channels.

Despite the success of this demonstration, it is not thought that cholera itself is the selective force responsible for the high incidence of cystic fibrosis alleles today. Cystic fibrosis is thought to have arisen over 50,000 years ago, whereas European cholera epidemics were first recognized in the early 1800s. Rather, other diarrhea-causing infections are the probable culprits.

Researchers have continued to test candidates likely to be responsible for a possible heterozygote advantage of cystic fibrosis alleles. In 1998 Gerald Pier and his colleagues at the Harvard Medical School, University of Bristol, and University of Cambridge announced that the cystic fibrosis allele protects against typhoid fever, a diarrheal disease caused by the bacterium *Salmonella typhi*†. This bacterium enters human gastrointestinal cells using the CFTR channel protein, but does not easily enter cells expressing a cystic fibrosis allele. These data are supported by studies using mice homozygous and heterozygous for a cystic fibrosis allele: no *S. typhi* entered cells of mice homozygous for the cystic fibrosis allele, and 86% fewer *S. typhi* entered heterozygous mouse cells compared with homozygous normal mouse cells.

are less likely to die from infectious diseases that produce severe diarrhea. (See *On the Cutting Edge: Using a Mouse Model to Study a Human Genetic Disease*.)

Tay-Sachs disease results from abnormal lipid metabolism in the brain

Tay-Sachs disease is an autosomal recessive disease that affects the central nervous system and results in blindness and severe mental retardation. The symptoms begin within the first year of life and result in death before the age of five. Because of the absence of an enzyme, a normal membrane lipid in the brain cells fails to break down properly and accumulates in the lysosomes. Although research is ongoing, no effective treatment for Tay-Sachs disease is available at this time. However, an effective strategy for the treatment of Tay-Sachs in a mouse model was reported in 1997. This treatment, which involves oral administration of an inhibitor that reduces the synthesis of the lipid that accumulates in the lysosomes, offers the hope of an effective way to deal with Tay-Sachs in humans in the future.

The abnormal allele is especially common in the United States among Jews whose ancestors came from Eastern Europe (Ashkenazi Jews). By contrast, Jews whose ancestors came from the Mediterranean region (Sephardic Jews) have a very low frequency of the allele.

History provides one hypothesis for the high frequency of the Tay-Sachs allele in Ashkenazi Jews. During the Middle Ages, Eastern European Jews were subjected to widespread persecution. They were forced into ghettos, and the population decreased (a phenomenon known to population geneticists as a **population bottleneck**; see Chapter 18). A coincidental high frequency of the Tay-Sachs allele in the small surviving population, which remained isolated and married within their group, might explain the high frequency (1/28) of this allele in the Ashkenazi Jewish population today. However, molecular analysis has revealed that there are at least two mutant alleles for Tay-Sachs disease in that population. The simplest hypothesis is that these mutations arose independently and were maintained because they conferred some kind of heterozygote advantage. People living in ghettos were vulnerable to a variety of infections, such as tuberculosis; resistance to one of these diseases could have been the basis of a heterozygote advantage.

A FEW GENETIC DISEASES ARE INHERITED AS AUTOSOMAL DOMINANT TRAITS

Huntington disease, named after George Huntington, the American physician who first described it in 1872, is due to a rare autosomal dominant allele that affects the nervous system. The disease causes severe mental and physical deterioration, uncontrollable muscle spasms, personality changes, and ultimately death. No effective treatment has been found. Every

Figure 15-9 Cumulative percent of persons with Huntington disease who express symptoms. The onset of Huntington disease occurs relatively late in life (usually between the ages of 30 and 45 for most affected individuals). (Adapted from Reed, T.E. and J.H. Chandler, 1958, *Am. J. Hum. Genet.*, Vol. 10)

child of an affected individual has a 50% chance of also being affected (and, if a carrier, of passing the abnormal allele to his or her offspring). Ordinarily we would expect a dominant allele with such devastating effects to occur only as a new mutation and not to be transmitted to future generations. This disease is characterized by onset relatively late in life (almost all heterozygotes have developed the disease by age 50, however), so an individual may have children before the disease develops (Fig. 15-9).

More than a decade of basic research was required to pin down the gene after its chromosome location was first identified by recombinant DNA technology. The complexity of the task required extensive international collaboration among researchers in different disciplines. One gene isolation strategy used was to isolate DNA from persons who carry the abnormal allele and to compare it to DNA from close relatives who do not have the allele. This approach is generally done by restriction fragment mapping (see Chapter 14).

One advantage of studying close relatives is that one can minimize other genetic differences and concentrate on the gene of interest. The optimal approach is to study large families, carefully construct pedigrees, and obtain DNA samples from affected and unaffected individuals across generations. A large extended family with a very high incidence of Huntington disease was discovered in Venezuela and has been the subject of exhaustive pedigree and DNA analysis. This made possible the identification of a **DNA marker** for Huntington disease. A DNA marker is not the DNA of the gene of interest, but it is the next best thing: a piece of DNA that is closely associated with the abnormal allele on the chromosome and inherited along with it.

The gene responsible for Huntington disease was finally cloned in 1993. The mutation is a nucleotide triplet (CAG, or cytosine, adenine, guanine) that is repeated many times; the normal allele repeats CAG from 6 to 35 times, whereas the mutant allele repeats CAG from 40 to more than 100 times. Because the triplet CAG codes for the amino acid glutamine, the resulting proteins have long strands of glutamine. Interestingly, the number of nucleotide triplet repeats seems to be important in determining the age of onset and the severity of the disease.

Much research is now directed at studying how the mutation is linked to neurodegeneration in the brain. A mouse model of Huntington is providing valuable clues about the development of the disease.

The Huntington disease DNA marker became the basis for tests that allowed those at risk to learn if they carry the allele. The decision to be tested for any genetic disease is understandably a highly personal one. Certainly, the information can be very useful for those who must make decisions such as whether or not to have children. However, someone who tests positive for the Huntington disease allele must then live with the virtual certainty of eventually developing this devastating and incurable disease. It is hoped that affected persons who choose to be identified before the onset of symptoms may ultimately contribute to the development of effective treatments.

SOME GENETIC DISEASES ARE INHERITED AS X-LINKED RECESSIVE TRAITS

Hemophilia A was once referred to as a disease of royalty because of its high incidence among male descendants of Queen Victoria, but it is also found in many nonroyal pedigrees. Characterized by the lack of a blood-clotting factor, Factor VIII, it causes severe internal bleeding in the head, joints, and other areas from even a slight wound. Because the mode of inheritance is X-linked recessive, affected persons are almost exclusively male, having inherited the abnormal allele on the X chromosome from their heterozygous carrier mothers.

Treatments for hemophilia A consist of blood transfusions and administration of Factor VIII by injection. Unfortunately, these treatments are costly, and, because a lot of blood and blood products come from paid human donors, many Factor VIII preparations were contaminated with HIV-1, the virus that causes AIDS, during the 1980s. Factor VIII produced using recombinant DNA technology (see Chapter 14) provides a safer source of the clotting factor because human donors are not used.

BOTH GENETIC AND ENVIRONMENTAL FACTORS CAUSE BIRTH DEFECTS

A **birth defect**, or congenital defect, is one that is present at birth; it may or may not be inherited. We have seen that some genetic birth defects are caused by chromosome abnormalities,

whereas others are caused by a change in a single gene, that is, by a mutation involving a single locus.

Some birth defects are not genetic but are caused by environmental factors that affect prenatal development. For example, if a woman contracts the viral disease rubella (commonly known as German measles) during the first three months of pregnancy, a substantial risk exists that her offspring will develop blindness, deafness, or damage to the heart or brain. Also, when a woman drinks even small amounts of alcohol during pregnancy, the baby may be born with **fetal alcohol syndrome**, which includes a variety of mental and physical defects. Low birth weight and certain structural abnormalities in body organs have been associated with as few as two drinks a day by the mother. Other environmental factors that have been linked to birth defects are discussed in Chapter 49.

Some birth defects can be detected before birth

Genetic abnormalities may become apparent during early intrauterine life or not until late in adult life. Given that early detection increases the possibilities for prevention or alleviation of the effects of genetic abnormalities, efforts have been made over the years to detect such abnormalities before birth. In the past 20 years physicians have become increasingly successful at prenatal diagnosis and treatment, including transfusion and surgical correction of malformations. Intrauterine diagnosis of a number of genetic abnormalities is now possible.

In one diagnostic technique known as **amniocentesis**, a sample of the fluid surrounding the fetus (the *amniotic fluid*) is obtained. A needle is inserted through the walls of the pregnant woman's abdomen and into the uterine cavity, where some of the amniotic fluid is withdrawn from the amniotic cavity into a syringe. This procedure is safe, partly because the positions of the fetus, placenta, and the needle can be determined through **ultrasound imaging** (Fig. 15–10).

The amniotic fluid contains living cells sloughed off the body of the fetus and hence genetically identical to the cells of the fetus. These amniotic fluid cells can be cultured in the laboratory. After two to three weeks, dividing cells from the culture can be karyotyped to detect chromosome abnormalities (Fig. 15–11).

Amniocentesis is performed on pregnant women whose fetuses have a higher than normal risk of Down syndrome. Many other tests have been developed to detect a number of simply inherited genetic disorders, but these disorders are rare enough that the tests are usually done only if a particular problem is suspected. Enzyme deficiencies can often be detected through incubation of cells recovered from amniotic fluid with the appropriate substrate and measurement of the product; this technique has been useful in the prenatal diagnosis of disorders such as Tay-Sachs disease. The tests for a number of other diseases, including sickle cell anemia, Huntington disease, and cystic fibrosis, are less direct, requiring the use of genetic engineering methods. Methods for detecting many more genetic diseases are now being actively sought by researchers.

Figure 15–10 **Ultrasound image of a 12 $\frac{1}{2}$ -week-old fetus.** A fetus of this age is typically about 8.5 centimeters long; the head is to the left, and the fetus appears to be sucking its thumb. (Courtesy of F. R. Batzer, M.D., Philadelphia Fertility Institute)

Figure 15–11 **Amniocentesis.** Certain genetic diseases and other abnormal conditions can be diagnosed prenatally by amniocentesis.

Amniocentesis is also useful in detecting a condition known as *spina bifida*, in which the spinal cord does not close properly during development. A relatively common (about 1 in 300 births) nongenetic malformation, this birth defect is associated with abnormally high levels of a normally occurring protein, alpha-fetoprotein, in the amniotic fluid. Abnormally low levels are associated with Down syndrome. Alpha-fetoprotein levels can also be measured by testing the mother's blood, but the results are less reliable, and any unusual findings should be confirmed by amniocentesis or other tests.

One problem with amniocentesis is that most of the conditions it detects are incurable, and the results are generally not obtained until well into the second trimester when abortion is both psychologically and medically more difficult than earlier. Therefore, efforts have been made to develop tests that yield results earlier in the pregnancy. One such test, **chorionic villus sampling (CVS)**, involves removing and studying cells that will form the fetal contribution to the placenta (Fig. 15–12). CVS may be associated with a slightly higher risk of infection or miscarriage than is amniocentesis, but its advantage is that results can usually be obtained within the first trimester.

Although both amniocentesis and CVS can diagnose certain genetic disorders with a high degree of accuracy, they are not foolproof, and many disorders cannot be diagnosed. Therefore, the lack of an abnormal finding is no guarantee of a normal pregnancy. The frequency of errors in amniocentesis and CVS diagnosis has not been determined, but it is quite low.

GENETIC COUNSELORS EDUCATE PEOPLE ABOUT GENETIC DISEASES

Couples who are concerned about the risk of abnormality in their children, either because they have had an abnormal child or have a relative affected by a hereditary disease, may seek **genetic counseling**. Genetics clinics are available in most metropolitan centers.

Genetic counselors, who have specialized training in human genetics, give people information needed to make reproductive decisions. Advice, however, can be given only in terms of the *probability* that any given offspring will have a particular condition. The geneticist needs complete family histories of both the man and the woman and may use tests for the detection of heterozygous carriers of certain conditions. When a disease involves only a single gene locus, probabilities can usually be easily calculated. For example, if one prospective parent is affected with a trait that is inherited as an autosomal dominant disorder, such as Huntington disease, the probability that any given child will have the disease is 0.5.

The birth to phenotypically normal parents of a child affected with an autosomal recessive trait, such as albinism or PKU, establishes that both parents are heterozygous carriers. The probability that any subsequent child will be affected is therefore 0.25. (In this context, the term *carrier* is used specifically to refer to an individual who is heterozygous for a re-

Figure 15–12 Chorionic villus sampling (CVS). This test allows the early diagnosis of some genetic abnormalities. Samples may be obtained by inserting a needle (1) through the uterine wall or through (2) the cervical opening.

cessive allele that causes a genetic disease. Homozygous recessive persons are referred to as *affected* individuals; they are not called *carriers* even though they also carry alleles for the disease.)

For a disease inherited through a recessive allele on the X chromosome, such as hemophilia A, the probability depends on the genotypes of the parents. A normal woman and an affected man will have daughters who are carriers and sons who are normal. The probability that the son of a carrier mother and a normal father will be affected is 0.5; the probability that their daughter will be a carrier is also 0.5.

It is now possible to detect carriers of several genetic diseases. In these cases counseling can be provided when both prospective parents are heterozygous. For diseases that involve an enzyme defect, carriers often show only half the level of enzyme activity characteristic of normal homozygotes. Voluntary screening programs have been set up by synagogues and other organizations to detect couples who are carriers of Tay-Sachs disease among Jews of Eastern European descent.

Persons heterozygous for sickle cell anemia can be readily identified with a simple blood test. They have a mixture of normal and abnormal hemoglobin in their red blood cells, with about 45% of their total hemoglobin being abnormal. Such persons, said to have **sickle cell trait**, are not ill, and their blood cells do not usually undergo sickling (although they can be made to do so by reducing the amount of oxygen). Carrier testing for some other diseases, such as cystic fibrosis and hemophilia A, is much more complicated and is usually done only if family history suggests that a person may be a carrier.

It is very important that identified carriers receive appropriate genetic counseling. A genetic counselor is trained not only to give information needed for reproductive decisions but also to help individuals understand their situation and avoid feeling stigmatized.

Inquiries are commonly made about mental retardation, epilepsy, deafness, congenital heart disease, and other conditions. It is possible that some environmental factor may have played a role in producing the abnormality in the affected child. Did the mother have an infectious disease during pregnancy (e.g., rubella)? Was she receiving some kind of drug therapy, or was she subjected to ionizing radiation? Had the father been exposed to any potentially hazardous agents? By dissecting the environmental contributions, the geneticist can more accurately estimate the probability of the trait's recurrence in subsequent offspring.

GENE REPLACEMENT THERAPY IS BEING USED FOR SEVERAL GENETIC DISEASES

Because many difficulties are inherent in treating most serious genetic diseases, scientists have dreamed of developing actual cures. Today, genetic engineering is bringing these dreams closer to reality. Such therapy could take two main forms.

One approach would be to introduce copies of a normal gene into a fertilized egg, using modifications of the technology already used to produce transgenic animals (see Chapter 14). In some transgenic animals the introduced gene can remain stable from generation to generation, constituting a true "genetic cure." However, this approach raises such complex ethical problems when applied to humans that it is not being actively pursued at this time.

A second strategy receiving increased attention today is to introduce the normal gene into only some body cells (somatic cell gene therapy). The rationale is that, although a particular gene may be present in all cells, it is expressed only in some (see Chapter 16). Expression of the normal allele in only the cells that require it may be sufficient to give a normal phenotype. Needless to say, this approach presents a number of technical obstacles.

The solutions to these problems must be tailored to the nature of the gene itself, as well as to its product and the types of cells in which it must be expressed. First the gene must be cloned and the DNA introduced into the appropriate cells. One of the most successful techniques is to use a virus as the vector. Ideally the virus should infect a high percentage of the cells and facilitate the integration of the introduced gene into a chromosome. Most important, the virus should do no harm, especially over the long term. This is a large order, and a great deal of attention is being paid to the development of viral strains with just such desirable characteristics.

The overall process can be illustrated by the first gene replacement therapy approved for clinical trials. Individuals with a genetic disorder called *severe combined immune deficiency* (SCID) have an immune system that is essentially nonfunctional. Because an affected baby has no defenses, it will die unless isolated from possible sources of infection. Because the cells that constitute the immune system are certain white blood cells that originate in the bone marrow, SCID has been treated successfully in some cases by transplanting healthy bone marrow cells from a normal donor.

About one-quarter of all affected individuals are known to lack a specific enzyme, adenosine deaminase (ADA); it is the absence of ADA in the immune system cells that causes affected individuals to die. These individuals have been treated successfully by providing them with ADA, linked to a molecule that makes the enzyme more stable in the bloodstream. This enzyme-replacement therapy is not a cure, for the ADA treatments must continue throughout life.

Gene replacement therapy for this condition was thought to be feasible because the normal ADA gene had been cloned and successfully introduced into cells through a viral vector. In the first clinical trials, in 1990, a virus was used to introduce the ADA gene into white blood cells from SCID individuals; these cells were then transfused back into the individuals. The results have been encouraging, but because white blood cells have limited lifetimes, such treatments must be repeated.

Although many obstacles must be overcome, gene therapies for a number of other genetic diseases (including cystic

Figure 15–13 Gene replacement therapy for cystic fibrosis. A vector carrying the normal allele is introduced into the affected individual's respiratory system through a fiberoptic bronchoscope. The physician (*left front*) is positioning a catheter through the bronchoscope, enabling the vector to be administered. (Courtesy of Dr. Ronald Crystal, The New York Hospital—Cornell Medical Center)

fibrosis) are undergoing development or are being tested on individuals in clinical trials (Fig. 15–13). Scientists are currently addressing some of the unique problems presented by each disease. Not all types of cells can be removed from the body, infected with a virus, and then replaced. For example, successful gene replacement therapy for cystic fibrosis will require introduction of normal genes directly into lung cells. A method that has shown some promise is to use as the vector a weakened form of the virus that causes the common cold. The field of gene replacement therapy is expected to develop considerably in the future, although such treatments may not become routinely available for some years.

MUCH NATURAL VARIATION EXISTS IN THE HUMAN POPULATION

One does not need to be a geneticist to recognize that humans are very diverse, and it is widely acknowledged that much human variation has a genetic basis. However, it is difficult to determine the genetic contribution to characteristics that are hard to assess, such as intelligence and behavior.

Humans have several genetically determined blood groups

It is not difficult to understand why so much knowledge of human variation is based on studies of blood. Blood samples are relatively easy to obtain, and blood is a complex tissue consisting of a number of cell types and extracellular molecules that can be studied.

The ABO alleles control the expression of certain red blood cell antigens

The human blood cell types O, A, B, and AB are inherited through multiple alleles representing a single locus. Allele I^A provides the code for the synthesis of a specific glycoprotein, antigen A, which is expressed on the surface of the red blood cells. (Immunity is discussed in Chapter 43; for now we define antigens simply as substances capable of stimulating an immune response.) Allele I^B leads to the production of a different (but related) glycoprotein, antigen B. The allele i^O does not code for an antigen, although it is allelic to I^A and I^B . Allele i^O is recessive to the other two. Neither allele I^A nor allele I^B is dominant to the other; they are both expressed phenotypically in the heterozygote and are therefore **codominant**.

Persons with the genotype $I^A I^A$ or $I^A i^O$ have **blood type A** (Table 15–2); those with genotype $I^B I^B$ or $I^B i^O$ have **blood type B**; and those with genotype $i^O i^O$ have **blood type O**. When both the I^A and I^B alleles are present, both antigen A

TABLE 15–2 ABO Blood Types*

Phenotype (blood type)	Genotypes	Antigen on RBC	Antibodies in Plasma	Frequency in U.S. Population (%)	
				Western European Descent	African Descent
A	$I^A I^A$, $I^A i^O$	A	Anti-B	45	29
B	$I^B I^B$, $I^B i^O$	B	Anti-A	8	17
AB	$I^A I^B$	A, B	None	4	4
O	$i^O i^O$	None	Anti-A, anti-B	43	50

*This table and the discussion of the ABO system have been simplified somewhat. Note that persons produce antibodies against the antigens *lacking* on their own red blood cells (RBCs).

Figure 15–14 Rh incompatibility. Serious problems can occur when an Rh-negative woman and an Rh-positive man produce Rh-positive offspring.

and antigen B are produced in the red blood cells; persons with this I^AI^B genotype have **blood type AB**.

Antibodies anti-A and anti-B are proteins that appear in the plasma (the fluid component of blood) of persons lacking the corresponding antigens on their red blood cells. **Antibodies** are proteins produced by the immune system that combine with specific antigens; hence, anti-A combines with antigen A. Because of their specificity for the corresponding antigens, these antibodies are used in standard tests to determine blood type.

Determining blood types was one of the traditional ways of settling cases of disputed parentage. However, blood type tests can never prove that a certain person *is* the parent of a particular child; they can determine only whether he or she *could* be. Could a man with blood type AB be the father of a child with blood type O? Could a woman with blood type O be the mother of a child with blood type AB? Could a type-B child with a type-A mother have a type-A father or a type-O father?²

More than a dozen other sets of blood types, including the Rh group (discussed in the next section), are inherited through other loci, independently of the ABO blood types. Determining some of these types in a given person may be useful in establishing relationships that could not be made with certainty by ABO blood typing alone.

Today more sophisticated types of genetic tests are used to determine parentage. These include **DNA fingerprinting** (see Chapter 14) and **tissue typing**, which is an examination of inherited antigens found on the surfaces of the body's cells

(see Chapter 43). Theoretically, only identical twins would be expected to have the same DNA fingerprint and the same tissue type. If properly performed, these tests have greater than 99% certainty and can come close to proving parentage.

Rh alleles control the expression of other red blood cell antigens

Named for the rhesus monkeys in whose blood it was first found, the Rh system consists of at least eight different kinds of Rh antigens, each referred to as an **Rh factor**. By far the most important of these factors is **antigen D**. About 85% of those United States residents who are of Western European descent are Rh-positive. This means that they have antigen D on the surfaces of their red blood cells (in addition to the antigens of the ABO system and other blood groups). The 15% or so of this population who are Rh-negative have no antigen D. Unlike the situation discussed for the ABO blood group, Rh-negative persons do not naturally produce antibodies against antigen D (anti-D). However, they produce anti-D antibodies if they are exposed to Rh-positive blood. The allele coding for antigen D is dominant to the allele for the absence of antigen D. Hence, Rh-negative persons are homozygous recessive, and Rh-positive persons are heterozygous or homozygous dominant.

Although several kinds of maternal-fetal blood type incompatibilities are known, **Rh incompatibility** is probably the most important (Fig. 15–14). If a woman is Rh-negative and the father of the fetus she is carrying is Rh-positive, the fetus may also be Rh-positive, having inherited the D allele from the father. Ordinarily no mixing of maternal and fetal blood

²The answer to all these questions is no.

occurs; nutrients, oxygen, and other substances are exchanged between these two circulatory systems across the placenta. However, late in pregnancy or during the birth process, a small quantity of blood from the fetus may pass through some defect in the placenta.

The fetus's red blood cells, which bear antigen D, activate the mother's white blood cells, inducing them to form antibodies to antigen D. If the woman becomes pregnant again, her sensitized white blood cells produce anti-D antibodies that can cross an intact placenta and enter the fetal blood. There they combine with the antigen D molecules on the surface of the fetal red blood cells, causing the cells to rupture. Break-down products of the hemoglobin released into the circulation damage many organs, including the brain. In extreme cases of this disease, known as **erythroblastosis fetalis**, so many fetal red blood cells are destroyed that the fetus may die.

When Rh-incompatibility problems are suspected, fetal blood can be exchanged by transfusion before birth, but this is a risky procedure. Rh-negative women are treated just after childbirth (or at termination of pregnancy by miscarriage or abortion) with a preparation of anti-D antibodies known as RhoGAM. These antibodies apparently clear the Rh-positive fetal red blood cells from the mother's blood very quickly, minimizing the chance for her own white blood cells to be sensitized. The antibodies are also soon eliminated from her body. As a result, if she becomes pregnant again, her blood does not contain the anti-D that could harm her baby.

Quantitative traits are controlled by polygenes

Many human characteristics are **quantitative traits**; that is, they represent some measurable quantity such as height. Such characteristics usually show continuous phenotypic variation in the population because of the number of loci involved, which can range from a few to a great many (polygenic inheritance), and also because of environmental factors, whose role is both significant and difficult to quantify. In humans, examples of polygenic inheritance include height and skin color (see Figs. 10–21 and 10–23).

Many common physical traits are inherited

We are often curious about the inheritance of certain physical characteristics. Some of these traits have relatively complex modes of inheritance. For example, dark hair color is due to heavy deposits of the pigment melanin in the hair shaft. There are probably multiple alleles of the locus governing the deposition of melanin, the “darker” alleles being somewhat, but incompletely, dominant to the “lighter” alleles. Red hair color is governed by another unlinked locus with at least two incompletely dominant alleles, one coding for reddish pigment, the other for lack of such pigment. The appearance of red hair is determined by the presence of one or two “red” alleles, but the expression of these alleles can be partially or completely blocked by other genes that code for heavy melanin deposits.

Eye color is determined by the pattern of melanin distribution in the iris. Blue pigment does not exist, only brown or yellowish melanin. If the melanin is deposited in such a way that much of the light is reflected back from the eye, the iris appears blue. Although inheritance of eye color is not simple, the inheritance patterns seen in most families can be explained if we assume that one locus is involved and that the alleles that govern the darker colors are dominant to the alleles that govern the lighter colors (e.g., blue, gray, hazel). It is not uncommon for two dark-eyed parents to have a light-eyed child; it is relatively rare for two light-eyed parents to have a dark-eyed child, but this does occasionally occur.

Several other human characteristics show relatively simple inheritance patterns. For example, the allele for dimples is generally dominant to the allele for no dimples, and the allele for freckling is usually dominant to that for no freckles.

THE HUMAN GENOME PROJECT IS STUDYING ALL HUMAN GENES

Along with advances in technology to determine the base sequences of DNA came the realization that it is possible to study the human genome in great depth. Some scientists envisioned a coordinated effort to determine the total informational content of the human genome. The **Human Genome Project**, initiated in the late 1980s, is an international undertaking that will occur over a 15-year period; researchers hope it will be completed by the year 2003, but information as we go to press indicates that the completion date will probably be a few years later. In its most direct sense the information content is the sequence of 3 billion base pairs in a haploid human genome. However, only a tiny fraction of human DNA is known to code for protein or RNA; the rest (95% or more) is either non-coding or has some function that has not yet been identified.

The project includes not only sequencing but also a broad-based, multifaceted strategy that involves scientists from many disciplines. This approach has concentrated on various types of mapping studies that will allow us to understand the physical and functional relationships among genes and groups of genes as revealed by their order on the chromosomes.

Comparative mapping studies are being carried out simultaneously on several other organisms, especially the laboratory mouse, which has long been the favorite model organism for the study of mammalian genetics. Comparisons of the DNA sequences and chromosome organization of related genes and clusters of genes from different species are powerful tools for identifying the elements essential for their functions. Large-scale analyses of base sequences are also underway. Automation is making the task of sequencing less laborious, and powerful computer programs manage and analyze the data.

The Human Genome Project has been controversial for several reasons. Many scientists are concerned that the Human Genome Project has been funded at the expense of other meritorious science that is equally or more likely to improve the

well-being of humankind. Some scientists have also argued that the conventional approach of first identifying an important gene, then cloning and studying it, is scientifically more interesting and more cost-effective over the long run. Supporters of the project, however, argue that many important genes that might be very difficult to identify will be uncovered in the course of the investigation. Even apparently nonfunctional DNA (sometimes called “junk DNA”) may turn out to be important.

Our knowledge of human genetics clearly will continue to expand at a great rate over the coming years. The information gained from the comparative mapping studies of other organisms will add greatly to our understanding of evolutionary relationships. Many genes known to be responsible for genetic diseases are being studied, and many others appear to be associated with predispositions to diseases such as heart disease and cancer. Understanding the relationships between genes and disease promises more effective treatments of causes, not just symptoms, in the future.

BOTH HUMAN GENETICS AND BELIEFS ABOUT GENETICS AFFECT SOCIETY

Many misconceptions exist about genetic diseases and their effects on society. Some people erroneously think of certain individuals or populations as genetically unfit and responsible for many of society's ills. They argue, for example, that medical treatment of persons affected with genetic diseases, especially those who are able to reproduce, increases the frequency of abnormal alleles in the population. This is true for autosomal dominant and X-linked diseases, but most genetic diseases that are simply inherited show an autosomal recessive inheritance pattern. Only homozygous persons actually have the disease; heterozygous carriers, present in far greater numbers in the population, are phenotypically normal.

For example, if 1 in 20 persons in the United States is heterozygous for cystic fibrosis, the chance that two parents will both be heterozygous is $1/20 \times 1/20 = 1/400$. On average, one-fourth of the children of such a couple would have cystic fibrosis, so the frequency of affected individuals in the population is about $1/400 \times 1/4 = 1/1600$. Because their numbers are usually very small compared with heterozygotes, reproduction by homozygotes contributes very little to overall frequencies of abnormal alleles.

Abnormal alleles are present in *all* individuals and *all* ethnic groups; no one is exempt. According to one estimate, each of us is heterozygous for several (3 to 15) very harmful alleles, any of which could cause debilitating illness or death in the homozygous state. Why, then, aren't genetic diseases more common? Each of us has many thousands of essential genes, any of which can be mutated. It is very unlikely that the abnormal alleles carried by one person are also carried by that person's mate. Of course, this possibility is more likely if the

harmful allele is a relatively common one, such as the one responsible for cystic fibrosis.

Relatives are more likely than nonrelatives to carry the same harmful alleles, having inherited them from a common ancestor. In fact, a greater than normal frequency of a particular genetic disease among offspring of **consanguineous matings** (matings of close relatives) is often the first clue that the mode of inheritance is autosomal recessive. The offspring of consanguineous matings have a small but significantly increased risk of genetic disease. In fact, they can account for a disproportionately high percentage of those individuals in the population with autosomal recessive disorders. Because of this perceived social cost, first-cousin marriages are prohibited in many states in the United States. However, consanguineous marriages are still relatively common in many developing countries, where other factors may outweigh the genetic costs. A high incidence of infectious disease, for example, may result in so many deaths that the health effects of relatively uncommon genetic diseases are largely ignored. The ability of a society to concern itself with genetic diseases is a luxury that comes with affluence.

Genetic discrimination has provoked heated debate

One of the fastest growing areas of medical diagnostics is genetic testing, and the number of new genetic tests that screen for diseases such as cystic fibrosis, sickle cell anemia, Huntington disease, colon cancer, and breast cancer increases each year. However, genetic testing raises many social, ethical, and legal issues that society must address.

One of the most difficult issues is whether genetic information should be made available to health and life insurance companies. Many people think genetic information should not be given to insurance companies, but others, including employers, insurers, and many organizations representing people affected by genetic disorders, say such a view is unrealistic. If people use genetic tests to help them decide when to buy insurance and how much to buy, then insurers insist they should also have access to this information. Insurers say they need access to genetic data to help calculate equitable premiums (the whole idea of insurance is to average risk over a large population). However, there are concerns that insurers might use the results of genetic tests to discriminate against people with genetic diseases or to deny them coverage.

Doctors are concerned that people at risk for a particular genetic disease might delay being tested because they fear genetic discrimination from insurers and employers. The perception of genetic discrimination already exists in society. In a 1996 study, 25% of 332 people with family histories of one or more genetic disorders thought they had been refused life insurance, 22% thought they had been refused health insurance, and 13% thought they had been denied employment because of genetic discrimination.

Making the issue even more complicated is the fact that genetic tests are sometimes difficult to interpret, in part be-

cause there are many complex interactions between genes and the environment. If a woman tests positive for a gene that has been linked to breast cancer, for example, she is at significant risk, but testing positive does not necessarily mean that she will get breast cancer. Moreover, if she gets breast cancer, the age of onset and severity of the disease are not predicted by genetic tests. These uncertainties also make it difficult to decide what form of medical intervention, from frequent mammograms to surgical removal of healthy breasts, is appropriate.

The Ethical, Legal, and Social Implications (ELSI) Research Program of the National Human Genome Research Institute has developed principles designed to protect people against genetic discrimination. As we go to press, several bills are up for consideration by Congress that prohibit workplace discrimination, health discrimination, and invasion of privacy.

SUMMARY WITH KEY TERMS

- I. **Human genetics** is the science of inherited variation in humans.
 - A. Geneticists investigating human inheritance cannot make specific crosses of pure genetic strains; instead, they must rely on studies of populations, analyses of family **pedigrees**, and molecular studies.
 - B. Studies of the **karyotype** (the number and kinds of chromosomes present in the nucleus) permit detection of individuals with various chromosome abnormalities.
- II. **Aneuploidy**, in which there are either missing or extra copies of certain chromosomes, causes certain human disorders. Aneuploidies include **trisomy**, in which an individual possesses an extra chromosome, and **monosomy**, in which one member of a pair of chromosomes is lacking.
 - A. **Trisomy 21**, the most common form of **Down syndrome**, and **Klinefelter syndrome** (XXY) are examples of trisomy.
 - B. **Turner syndrome** (XO) is an example of monosomy.
 - C. Trisomy and monosomy are caused by **nondisjunction**, in which sister chromatids or homologous chromosomes fail to disjoin (move apart) properly during meiosis or mitosis.
- III. Structural abnormalities in chromosomes cause certain human disorders.
 - A. In a **translocation**, part of one chromosome becomes attached to another. About 4% of individuals with Down syndrome have a translocation in which part of chromosome 21 is attached onto one of the larger chromosomes, such as chromosome 14.
 - B. In a **deletion**, chromosomes break but fail to rejoin. The deletion may range in size from a few base pairs to an entire chromosome arm. The most common deletion disorder in human infants is **cri-du-chat syndrome**, in which part of the short arm of chromosome 5 is deleted.
 - C. **Fragile sites** may occur at specific locations on both chromatids of a particular chromosome. In **fragile X syndrome** the fragile site occurs near the tip on the X chromosome; at that site the nucleotide triplet CGG is repeated many more times than is normal.
- IV. Most human genetic diseases that show a simple inheritance pattern are transmitted as autosomal recessive traits.
 - A. **Phenylketonuria (PKU)** is an autosomal recessive disorder in which toxic phenylketones damage the developing nervous system.
 - B. **Sickle cell anemia** is an autosomal recessive disorder in which abnormal hemoglobin (the protein needed to carry oxygen in the blood) is produced.
 - C. **Cystic fibrosis** is an autosomal recessive disorder in which abnormal secretions are produced in the respiratory and digestive systems.
 - D. **Tay-Sachs disease** is an autosomal recessive disorder caused by abnormal lipid metabolism in the brain.
 - E. **Huntington disease** has an autosomal dominant inheritance pattern. It results in mental and physical deterioration, usually beginning in middle age.
 - F. **Hemophilia A** is an X-linked recessive disorder. It results in a defect in one of the components of blood required for clotting.
- V. Some genetic diseases and chromosome abnormalities can be diagnosed before birth.
 - A. In **amniocentesis**, the amniotic fluid surrounding the fetus is sampled and the fetal cells suspended in the fluid are cultured and screened for genetic defects. Amniocentesis provides results in the second trimester of pregnancy.
 - B. In **chorionic villus sampling (CVS)**, some chorion cells are removed and studied. CVS provides results in the first trimester of pregnancy.
- VI. **Genetic counselors** can advise prospective parents with a family history of genetic disease about the probabilities of having offspring with **birth defects**.
- VII. Variation in the human population is exemplified by human blood types, among which are the **ABO blood group** and the **Rh system**.
- VIII. The effect of human genetics on society is complex.
 - A. The fact that a particular abnormal allele is especially common in a certain population does not mean that group has a higher frequency of abnormal alleles in general.
 - B. Some alleles that cause a genetic disease when they are homozygous may confer a **heterozygote advantage**, at least in a particular environment. For example, the allele responsible for sickle cell anemia in homozygous individuals appears to confer resistance to malaria in heterozygotes.
 - C. Because most abnormal alleles are recessive, they are manifested phenotypically only in homozygotes, who constitute a tiny fraction of the individuals with the allele. Virtually every individual in the population is a heterozygous carrier of several abnormal alleles.

POST-TEST

1. The array of chromosomes present in a given cell is called a(an) (a) karyotype (b) ABO blood group (c) aneuploidy (d) inborn error of metabolism (e) translocation
2. An abnormality that is present and evident at birth is called a(an) (a) karyotype (b) birth defect (c) quantitative trait (d) ultrasound image (e) DNA marker
3. An abnormality in which there is one more or one fewer than the normal number of chromosomes is called a(an) (a) karyotype (b) inborn error of metabolism (c) aneuploidy (d) DNA marker (e) translocation
4. A person with one extra chromosome (three of one kind) is said to be (a) monosomic (b) triploid (c) trisomic (d) consanguineous (e) isogenic
5. A person who is missing one chromosome, having only one member of a pair, is said to be (a) monosomic (b) haploid (c) trisomic (d) consanguineous (e) isogenic

6. The failure of chromosomes to separate normally during cell division is called (a) amniocentesis (b) an inborn error of metabolism (c) nuclear sexing (d) translocation (e) nondisjunction
7. The transfer of a part of one chromosome to a nonhomologous chromosome is called (a) a karyotype (b) an inborn error of metabolism (c) nuclear sexing (d) a translocation (e) nondisjunction
8. Individuals with trisomy 21, or _____, are mentally and physically retarded and have abnormalities of the face, tongue, and eyelids. (a) Down syndrome (b) Klinefelter syndrome (c) Turner syndrome (d) Huntington disease (e) Rh incompatibility
9. An XXY individual has the disorder known as _____; an XO individual has _____. (a) Down syndrome; hemophilia A (b) Klinefelter syndrome; Down syndrome (c) Turner syndrome; Tay-Sachs disease (d) Rh incompatibility; Turner syndrome (e) Klinefelter syndrome; Turner syndrome
10. An inherited disorder caused by a defective or absent enzyme is called a(an) (a) karyotype (b) quantitative trait (c) ultrasound image (d) inborn error of metabolism (e) DNA marker
11. In _____, a genetic mutation codes for an abnormal hemoglobin molecule that is less soluble than usual and more likely than normal to crystallize and deform the shape of the red blood cell. (a) Down syndrome (b) Tay-Sachs disease (c) sickle cell anemia (d) PKU (e) hemophilia A
12. In a person with _____, the mucus is abnormally viscous and tends to plug the ducts of the pancreas and liver and to accumulate in the lungs. (a) Down syndrome (b) Tay-Sachs disease (c) sickle cell anemia (d) PKU (e) cystic fibrosis
13. During this procedure, a sample of the fluid that surrounds the fetus is obtained by insertion of a needle through the walls of the abdomen and uterus. (a) DNA marker (b) chorionic villus sampling (c) ultrasound imaging (d) consanguineous mating (e) amniocentesis

REVIEW QUESTIONS

1. What means have been devised for overcoming some of the difficulties in studying human inheritance?
2. What is meant by nondisjunction? What are some human abnormalities that appear to be the result of nondisjunction?
3. What is meant by inborn errors of metabolism? Give an example.
4. To be expressed, an autosomal recessive genetic disease must be homozygous. What relationship does this fact have to consanguineous matings?
5. Are all birth defects hereditary? Explain.
6. What are some of the ways that carriers of certain genetic diseases can be identified?
7. What are the relative advantages and disadvantages of amniocentesis and chorionic villus sampling?
8. Examine the following pedigrees and decide whether each disorder is most likely inherited by an autosomal recessive, an autosomal dominant, or an X-linked recessive allele. Determine the probable genotypes for all persons shown in the following three pedigrees.

9. Complete the following table by checking the correct box for each genetic disorder.

Disease	Chromosome Abnormality	Autosomal Recessive	Autosomal Dominant	X-Linked Recessive
Down syndrome				
Tay-Sachs disease				
Phenylketonuria				
Hemophilia A				
Sickle cell anemia				
Turner syndrome				
Huntington disease				
Klinefelter syndrome				
Cri-du-chat syndrome				
Fragile X syndrome				
Cystic fibrosis				

YOU MAKE THE CONNECTION

1. Mrs. Doe and Mrs. Smith had babies in the same hospital at the same time. Mrs. Doe took home a girl and named her Nancy. Mrs. Smith took home a boy and named him Richard. However, because she was sure that she had given birth to a girl, she filed suit against the hospital. Blood tests showed that Mr. Smith was blood type A, Mrs. Smith was type B, and Mr. and Mrs. Doe were both type AB. Nancy was type A, and Richard was type B. Had an exchange occurred? What other kinds of genetic information would help resolve this question?
2. Imagine that you are a genetic counselor. What advice or suggestions might you give in the following situations?
 - a. A couple has come for advice because the woman had a sister who died of Tay-Sachs disease.
 - b. A pregnant woman has learned that as a newborn she suffered a mild case of erythroblastosis fetalis; she is concerned that she might have a similarly affected child.
 - c. A young man and woman who are not related are engaged to be married. However, they have learned that the man's parents are first cousins. They are worried about the possibility of increased risk of genetic defects in their own children.
 - d. A young woman's paternal uncle (her father's brother) has hemophilia A. Her father is free of the disease, and there has never been a case of hemophilia A in her mother's family. Should she be concerned about the possibility of hemophilia A in her own children?
 - e. A 20-year-old man is seeking counseling because his father has just been diagnosed with Huntington disease.
3. A deletion of part of an X chromosome may be lethal in a male but cause few problems in a female. Explain.
4. A common misconception about human genetics is that a person's genes alone determine his or her destiny. Explain why this myth is incorrect. How is the perpetuation of this myth harmful to society?

CHAPTER 16

Genes and Development

The study of **development**, the process by which cells specialize and organize into a complex organism, encompasses some of the most fascinating and difficult problems in biology today. During the many cell divisions required for a single cell to develop into a multicellular organism, groups of cells become gradually committed to specific patterns of gene activity through a process called **determination**. The final step leading to cell specialization is cell **differentiation**. A differentiated cell can be recognized by its characteristic appearance and activities.

Morphogenesis, the development of form, is an even more intriguing piece of the developmental puzzle. It involves a multistep process known as **pattern formation** by which cells in specific locations become progressively organized into recognizable structures.

Until the late 1970s, little was known about how certain genes interact with various signals from other genes and from the environment to control development. Although certain genes affecting developmental pathways had been identified, their specific functions in the organism were not well understood. Because these networks are too complex to unravel using only traditional methods, it had been thought that it might be impossible to understand development. However, rapid progress in recombinant DNA technology led scientists to renew their search for developmental mutants and to apply the most sophisticated techniques to study them.

Today scientists interested in development study a variety of carefully chosen mutant organisms with altered developmental patterns. They use the tools of genetic engineering combined with more conventional descriptive and experimental approaches to derive fresh insights into the role of genetic information in the control of development. The organism in the photograph is *Caenorhabditis*, a nematode worm that has a number of attributes that make it unusually attractive for developmental studies. For example, its small transparent body allows researchers to locate cells in which a specific developmentally important protein is active; these cells can be recognized because they have been genetically engineered to produce a green fluorescent protein known as GFP. Work with

(Courtesy of Dr. Martin Chalfie, Columbia University)

such organisms has profound implications for our understanding of both normal human development and the kinds of malfunctions that can lead to birth defects and even “normal” aging. Although these worms may seem to have little in common with humans, scientists are learning that many of the genes important in development are quite similar in a wide range of organisms. These similarities have led to new ways to unravel evolutionary relationships, through the study of developmentally important genetic mechanisms that appear to be deeply rooted in the evolutionary history of multicellular organisms.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Distinguish between cell determination and cell differentiation.
2. Relate the process of pattern formation to morphogenesis.
3. Describe the kinds of experiments that indicate the totipotency of some differentiated plant cells and some animal nuclei. Discuss how these findings support the idea of nuclear equivalence.
4. Identify the attributes of an organism that would make it especially useful in studies on the genetic control of development. Discuss the value of transgenic organisms in research on the genetic control of development.
5. Indicate the features of the development and genetics of *Drosophila*, *Caenorhabditis*, and the mouse (*Mus*) that have made these organisms so valuable to researchers.
6. Distinguish among maternal effect genes, zygotic genes, and homeotic genes in *Drosophila*.
7. Explain the relationship between transcription factors and genes that control development. Provide some examples of genes that are known to function as genetic switches in development.
8. Define the phenomena of induction and programmed cell death and give examples of the roles they play in development.
9. Describe the functions of some homeotic-like genes in plants.
10. Point out some of the known exceptions to the general phenomenon of nuclear equivalence.

CELL DIFFERENTIATION USUALLY DOES NOT INVOLVE CHANGES IN DNA

The human body, like those of other vertebrates, contains more than 200 recognizably different types of cells (Fig. 16–1). Combinations of those cells are organized into remarkably diverse and complex structures such as the eye, the hand, and the brain, each capable of carrying out many sophisticated activities. Most remarkable of all, however, is the fact that all the structures of the body and the different cells within them are descended from a single fertilized egg.

All multicellular organisms undergo complex patterns of development. The root cells of plants, for example, have structures and functions very different from those of the various types of cells located in leaves. Remarkable diversity can also be found at the molecular level; most strikingly, each type of plant or animal cell makes a highly specific set of proteins (Fig. 16–2). In some cases, such as the protein hemoglobin in red blood cells, one cell-specific protein may make up more than 90% of the total mass of protein in the cell. Other cells may have a complement of cell-specific proteins that are each present in small amounts but still play an essential role. However, because certain proteins are required in every type of cell (all cells, for example, require certain enzymes for glycolysis), cell-specific proteins usually make up only a fraction of the total number of different kinds of proteins.

One explanation for the fact that each type of differentiated cell makes a unique set of proteins might be that during development each group of cells loses the genes it does not need and retains only those that are required. With just a few exceptions, however, this does not seem to be true. According to the concept of **nuclear equivalence**, the nuclei of essentially all differentiated adult cells of an individual are genetically (though not necessarily metabolically) identical to each other and to the nucleus of the fertilized egg cell from which

they descended. This means that virtually all the **somatic**¹ cells in an adult have the same genes, but different cells express different subsets of these genes.

The evidence for nuclear equivalence comes from cases in which differentiated cells or their nuclei have been found to be capable of supporting normal development. Such cells or nuclei are said to be **totipotent**.

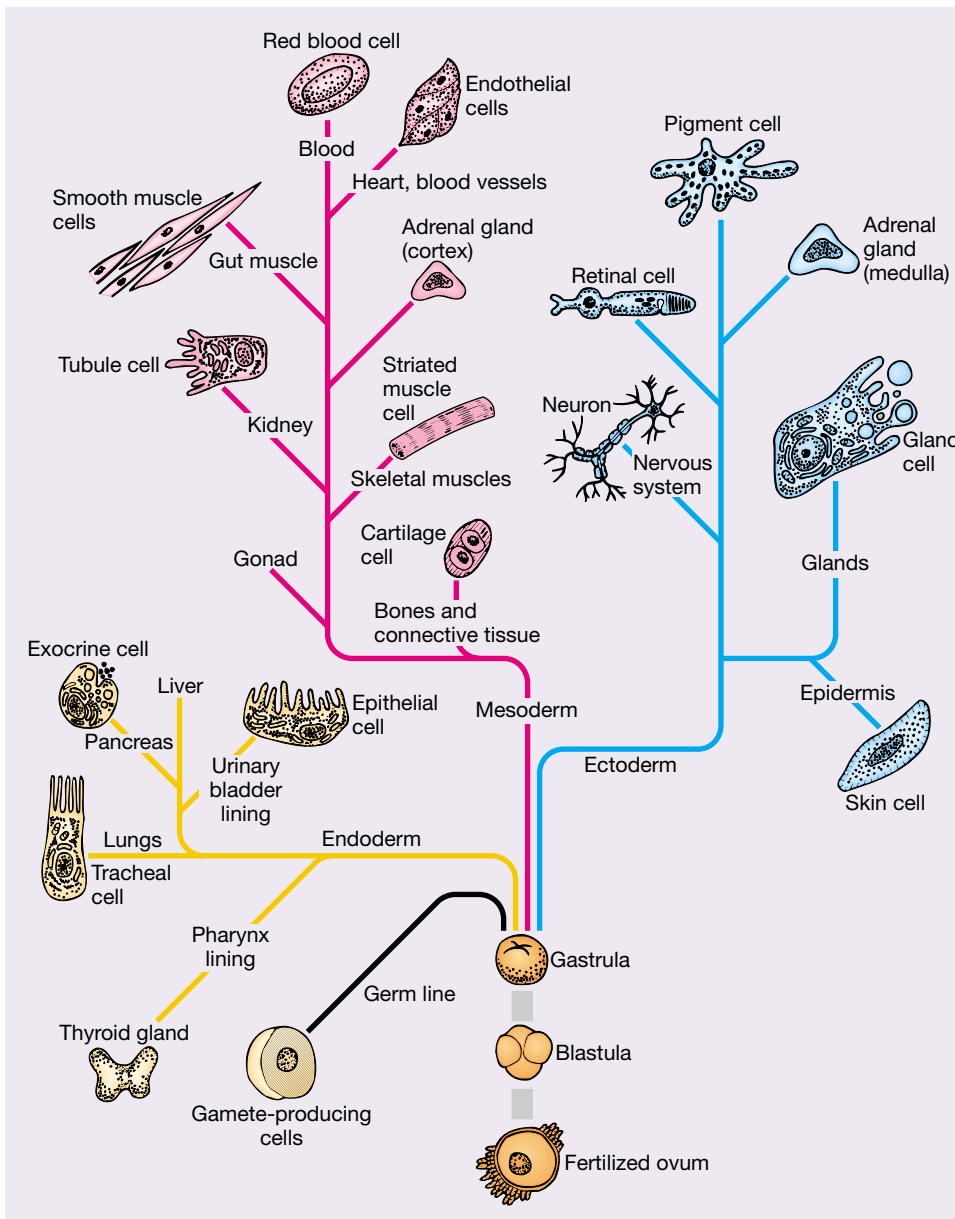

A totipotent nucleus contains all the information required to direct normal development

In plants it is possible to demonstrate that at least some differentiated cells can be induced to become the equivalent of embryonic cells (Fig. 16–3). **Tissue culture** techniques are used to isolate individual cells from certain plants and to allow them to grow in a nutrient medium.

In some of the first experiments on cell totipotency in plants, conducted at Cornell University by F. C. Steward and others, root cells from a carrot were induced to divide in a liquid nutrient medium and to form groups of cells called “embryoid” (embryo-like) bodies. These clumps of dividing cells could then be transferred to an agar medium, which provides nutrients plus a solid supporting structure for the developing plant cells. After transfer to the agar, some of the embryoid cells gave rise to roots, stems, and leaves. The resulting small plants, called plantlets to distinguish them from true seedlings,

¹Somatic cells are cells of the body and are distinguished from *germ-line cells*, which ultimately give rise to a new generation. In animals, germ-line cells, whose descendants ultimately undergo meiosis and differentiate as gametes, are generally set aside early in development. In plants, the distinction between somatic cells and germ-line cells is not clear-cut, and the determination that certain cells will undergo meiosis is made much later in development.

Figure 16-1 Vertebrate cell lineages. Repeated divisions of the fertilized egg (*bottom of the figure*) result in the establishment of tissues containing groups of specialized cells (see Chapters 37 and 49 for a discussion of how these are formed). Germ-line cells (cells that produce the gametes) are set aside early in development. Somatic cells progress along the developmental pathways, undergoing a series of commitments that progressively determine their fates.

were then transplanted to soil, where they ultimately developed into adult plants capable of producing flowers and viable seeds. If these plants are all derived from the same parent plant, they are genetically alike and therefore constitute a **clone**. The methods of plant tissue culture are now extensively used to produce genetically engineered plants, for they allow the regeneration of whole plants from individual cells that have incorporated recombinant DNA molecules (see Chapter 36, *Focus On: Cell and Tissue Culture*).

Similar experiments have been attempted with animal cells, but so far it has not been possible to induce a fully differentiated somatic cell to behave like a zygote. Instead, it has been possible to test whether steps in the process of determination are reversible by transplanting the *nucleus* of a cell in a relatively late stage of development into an egg cell that has

been enucleated (i.e., its own nucleus has been destroyed) (Fig. 16-4).

In the 1950s R. Briggs and T. J. King conducted experiments in which nuclei from amphibian cells at different stages of development were transplanted into egg cells. Some of the transplants proceeded normally through a number of developmental stages, and a few even developed into normal tadpoles. As a rule, the nuclei transplanted from cells at earlier stages were most likely to support development to the tadpole stage. As the fate of the cells became more and more determined, the probability that a transplanted nucleus could control normal development diminished rapidly.

In experiments carried out in England in the 1960s by J. Gurdon, in a few cases nuclei isolated from the specialized intestinal cells of a tadpole were able to direct development up

Figure 16-2 Cell-specific proteins. The spots in the photographs are proteins from (a) muscle and (b) liver cells of a mouse. The proteins were separated by two-dimensional gel electrophoresis, a method that separates the proteins in the horizontal direction by their electric charge, followed by a second separation in the vertical direction by molecular weight. Several hundred proteins can be distinguished in each panel. The spots that are labeled with numbers are present in all tissues, but notice that many of them are present in different amounts from one tissue to another. The proteins that are labeled with letters are found only in that specific tissue. (Patrick O'Farrell, from Darnell, Lodish, and Baltimore, *Molecular Cell Biology*, Fig. 12-1, *Scientific American Books*)

to the tadpole stage. This occurred infrequently, but in such experiments success counts more than failure, and we can safely conclude that at least some nuclei of differentiated animal cells are in fact totipotent.

For many years these successes with amphibia could not be repeated with mammalian embryos, leading many developmental biologists to conclude that some fundamental feature of mammalian reproductive biology might be an impen-

Figure 16-3 Cell totipotency. A complete carrot plant can develop from differentiated somatic cells. Discs of phloem cells, which are specialized for nutrient transport, were isolated from carrot root tissues. When the cells were cultured in a liquid nutrient medium, individual phloem cells divided to form clumps of undifferentiated cells. These clumps (embryoids), which closely resembled plant embryos in their early stages of development, then progressed to form embryonic shoots and roots. Transferring the embryonic tissue to a solid nutrient medium stimulated the tissues to form small plants, called plantlets, which then developed into mature plants.

Figure 16–4 Nuclear totipotency. In nuclear transplantation experiments in amphibians, nuclei of differentiated cells at different stages of development were injected into eggs whose own nuclei had been destroyed by ultraviolet radiation. As shown in the lower panel, if a nucleus was taken from a cell at the blastula stage of development (when cell division has produced about 1000 cells formed in the shape of a ball), about half the time it would program normal development that would result in a tadpole or fertile adult. However, as

seen in the upper panel, most trials using nuclei from tadpole intestinal cells (a much later developmental stage) resulted in no growth, probably as a result of damage to the egg or the nucleus by the procedure. In a small number of trials (about 1–2% of the total) normal development proceeded to the tadpole stage, indicating that the genes necessary to program development to that point were still present.

etrable barrier to mammalian cloning. This perception changed markedly in 1996 and 1997 with the first reports of the birth of cloned mammals (see *Focus On: Mammalian Cloning*).

It may not be particularly surprising that nuclei do not usually lose genetic material during development; after all there should be no loss of chromosomes in the course of normal mitotic cell divisions. These demonstrations of nuclear totipotency also imply that apparently inactive genes are capable of being reactivated when cells or nuclei are placed in a suitable environment. Nevertheless, it is important to recognize that the nuclei of embryonic cells progressively undergo metabolic changes that make it more difficult to remain in a totipotent state. This is especially true of animal nuclei, although various kinds of animals may differ considerably in this regard.

Most differences among cells are due to differential gene expression

Because genes do not appear to be lost regularly during development, the differences in the molecular composition of cells must occur by regulating the activities of different genes. This process of developmental gene regulation is often referred to as **differential gene expression**. As discussed in Chapter 13, the expression of eukaryotic genes can be regulated in many different ways and at many levels. For example, a particular

enzyme may be produced in an inactive form and then be activated later. However, much of the regulation that is important in development occurs at the transcriptional level. The transcription of certain sets of genes is repressed, whereas other sets are activated. Even expression of genes that are constitutive (i.e. constantly transcribed; see Chapter 13) and active in all cells can be regulated during development so that the *quantity* of each product varies from one tissue type to another.

We can think of differentiation as a series of pathways leading from a single cell to cells in each of the different specialized tissues, arranged in an appropriate pattern. There are times when a cell makes genetic “commitments” to the developmental path its descendants will follow. These commitments gradually restrict the development of the descendants to a limited set of final tissue types. Determination, then, is a progressive fixation of the fate of a cell’s descendants.

As the development of a cell becomes determined along a particular differentiation pathway, the physical appearance of the cell may not change significantly. Nevertheless, when a particular stage of determination is complete, the changes in the cell usually become self-perpetuating and are not easily reversed. Differentiation, then, is usually the last stage in the developmental process. At this stage, a precursor cell becomes structurally and functionally recognizable as a bone cell, for example, and its pattern of gene activity is different from that of a nerve cell.

FOCUS ON

MAMMALIAN CLONING

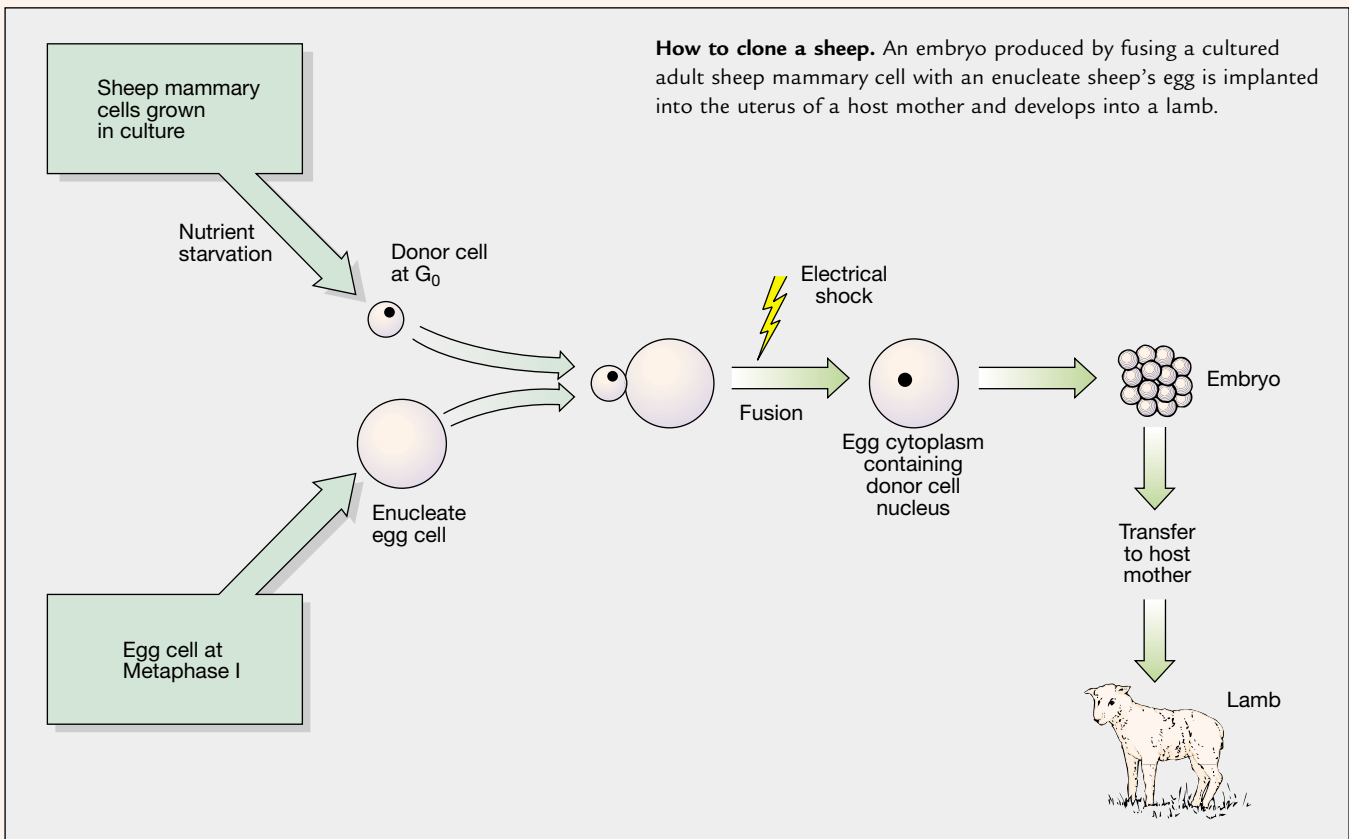

In 1996 Ian Wilmut and coworkers at the Roslin Institute in Scotland reported that they had succeeded in cloning sheep, using nuclei from early sheep embryos (blastocyst stage; see Chapter 49). These scientists subsequently received worldwide attention in early 1997 when they announced the birth of a lamb, nicknamed “Dolly,” derived from a cultured mammary gland cell (from an adult sheep) fused with an enucleated sheep’s egg. The resulting cell divided and developed into an embryo that was then cultured *in vitro* until it reached a stage at which it could be transferred to a host mother. As might be expected, the overall success rate was low: out of 277 fused cells, only 29 developed into embryos that could be transferred, and Dolly was the only live lamb produced (see Chapter 1). These researchers have also produced cloned transgenic lambs derived from fetal cells.

Why was Wilmut’s team apparently successful when so many other researchers had failed? Applying the basic principles of cell biology, they recognized that the cell cycles of the egg cytoplasm and the donor nucleus were incompatible; i.e., the egg cell is a noncycling cell, arrested at metaphase II, while the actively growing donor cell is usually in the DNA synthesis phase (S), or in G_2 . By withholding certain nutrients from the donor cells, they were able to cause them to enter a noncycling state referred to as G_0 (see Chapter 9). This had the effect of synchronizing the donor nucleus to the cell cycle of the egg. They then used an electrical shock to cause the donor nucleus to fuse readily with the egg and initiate the development of the embryo.

Although an extremely high level of technical expertise is required, these and other researchers have been able to use

modifications and extensions of these techniques to produce cloned transgenic calves, and there is reason to think that the list of mammals that have been successfully cloned will continue to grow. The production of transgenic animals continues to be the main focus of this line of research (see Chapter 14), and it is expected that when this technology is perfected it will be possible to efficiently produce transgenic farm animals that can be used for a variety of purposes.

Results such as these continue to fuel an ongoing debate regarding the potential for human cloning and its ethical implications. In the United States, the National Bioethics Advisory Commission, whose recommendations are posted on the Internet, has been established to study this and other questions:

MOLECULAR GENETICS IS REVOLUTIONIZING THE STUDY OF DEVELOPMENT

Development has been an important area of research for many years, and considerable effort has been expended on studying the development of invertebrate and vertebrate animals. By identifying patterns of tissue development in different animals, researchers have been able to identify similarities, as well as differences, in the basic plan of development from a fertilized egg to an adult in organisms ranging from the sea urchin to mammals (see Chapter 49).

In addition to descriptive studies, a number of classic experiments have established important evidence concerning how groups of cells become determined along particular developmental pathways. Researchers have developed elaborate screening programs to detect mutations that allow them to identify large numbers of developmental genes in both plants and animals. They then exploit a wide variety of molecular genetic techniques and other sophisticated methodologies to determine how those genes work and how they interact to coordinate developmental processes.

Certain organisms are well suited for studies on the genetic control of development

In studies of the genetic control of development, the choice of an organism to use as an experimental system has become increasingly important. One of the most powerful approaches

involves the isolation of mutants with arrested or abnormal development at a particular stage. Not all organisms have useful characteristics that allow developmental mutants to be isolated and maintained for future study. The genetics of the fruit fly, *Drosophila melanogaster*, is so thoroughly understood that this organism has become one of the most important systems for such studies. Other organisms such as the nematode worm, *Caenorhabditis elegans*, and the laboratory mouse, *Mus musculus*, as well as various plants and some simple eukaryotes, have also become important in developmental genetics. Each of these organisms has attributes that make it particularly useful for examining certain aspects of development.

DROSOPHILA MELANOGASTER PROVIDES RESEARCHERS WITH A WEALTH OF DEVELOPMENTAL MUTANTS

Undoubtedly the most extensive (and spectacular) examples of genes that control development have been identified in the fruit fly, *Drosophila melanogaster*. One of the main advantages of using *Drosophila* as a research organism is the abundance of mutants (including developmental mutants) available for study and the relative ease with which a new mutation can be directly mapped on the chromosomes. The genetic analysis is greatly facilitated by special chromosomes found in certain tissues with large, metabolically active cells, including the salivary glands of the larvae. These **polytene** (“many-stranded”) chromosomes (Fig. 16–5) are unusual interphase chromo-

Figure 16–5 *Drosophila* polytene chromosomes. These large chromosomes, found in cells of the salivary gland and some other tissues, aid in locating genes. (a) A region of a polytene chromosome showing the pattern of stained bands of condensed chromatin (B) and decondensed puffed bands (P), which are the sites of intense gene activity. Although the chromosome banding patterns vary from tissue to tissue, those in a particular tissue are constant and can be associated with the locations of mutant genes by genetic mapping and DNA hybridization methods. (b) In contrast to the chromosomes of most somatic cells, homologous polytene chromosomes are paired and each consists of more than 1000 parallel longitudinal DNA fibers. (a, Courtesy of U. Clever)

somes formed when the DNA replicates many times but without mitosis and cytokinesis.

A typical polytene chromosome may consist of more than 1000 DNA double helices (along with associated histones and other proteins) aligned side by side. Polytene chromosomes are therefore quite large and show a pattern of bands that is very useful in assigning a particular gene to a particular location on the chromosome. When a gene is active, the chromosome band in which it resides uncoils and forms a **puff**, which is a site of intense RNA synthesis. This evidence of gene activity is similar to that observed in lampbrush chromosomes of certain female meiotic cells (see Chapter 9).

Once the chromosomal position of the mutant gene is determined, the gene can be cloned, using a technique called **chromosome walking**, from a nearby gene that has been previously cloned. Studies of *Drosophila* are also facilitated by the fact that foreign DNA can be injected into eggs and become incorporated into the fly's DNA in a process called **transformation** (by analogy with transformation in prokaryotes).

The *Drosophila* life cycle includes egg, larval, pupal, and adult stages

The life cycle of *Drosophila* consists of several distinct stages (Fig. 16–6). After the egg is fertilized, a period of embryogenesis occurs during which the zygote develops into a sexually immature form known as a **larva** (pl., *larvae*). After hatching from the egg, each larva undergoes several molts (shedding of the external covering or cuticle). Each molt allows an increase in size until the larva is ready to pupate. **Pupation** involves a molt and the hardening of the new external cuticle, so that the pupa is completely encased. The insect then undergoes a complete **metamorphosis** (change in form). During that time, most of the larval tissues degenerate and other tissues differentiate to form the body parts of the sexually mature adult fly.

The larvae are wormlike in appearance and look nothing like the adult flies. However, very early in embryogenesis of the developing larvae, precursor cells of many of the adult structures are organized as relatively undifferentiated paired structures called **imaginal discs**. This term comes from **imago**, the name given to the adult form of the insect. Each imaginal disc occupies a definite position in the larva and will form a specific structure, such as a wing or a leg, in the adult body (Fig. 16–7). The discs are formed by the time embryogenesis is complete and the larva is ready to begin feeding. In some respects the larva can be thought of as a complex developmental stage that is simply used to feed and nurture the precursor cells that give rise to the adult fly (which is the only form that can reproduce).

The organization of the precursors of the adult structures, including the imaginal discs, is under complex genetic control. So far more than 50 genes have been identified that specify the formation of the discs, their positions within the larva, and their ultimate functions within the adult fly. Those genes have

Figure 16–6 *Drosophila* development. A *Drosophila* passes through a number of stages as it develops from the egg to the adult fly. (The dotted lines within the pupa represent the animal undergoing metamorphosis.)

Figure 16–7 Imaginal discs. Each pair of discs in a *Drosophila* larva develops into a specific pair of structures in the adult fly.

been identified through mutations that either prevent certain discs from forming or alter their structure or ultimate fate.

Many *Drosophila* developmental mutants affect the body plan

Many developmental mutants of *Drosophila* have been identified. Their effects on development in various combinations have been examined and studied extensively at the molecular level. In our discussion we pay particular attention to those that affect the segmented body plan of the organism, both in the larva and in the adult.

Maternal effect genes organize the egg cytoplasm

The earliest stages of *Drosophila* development are controlled by maternal genes that act to organize the structure of the egg

cell. As the egg develops in the ovary of the female, stores of messenger RNA (mRNA), along with yolk proteins and other cytoplasmic molecules, are passed into it from the surrounding maternal cells. Therefore, all these mRNA molecules are transcribed exclusively from genes found in the mother. The genes that code for these mRNA molecules are referred to as **maternal effect genes**. Analysis of mutants defective in these genes has revealed that many are involved in establishing the polarity of the embryo by designating which parts of the egg are dorsal or ventral and which are anterior or posterior (see Chapter 28).

Figure 16–8*a* illustrates concentration gradients for particular types of maternal mRNA in the very early embryo. These mRNA transcripts of some of the maternal effect genes can be identified by their ability to hybridize with radioactive DNA probes derived from cloned genes. Alternatively, their protein products can be identified by antibodies that specifically bind to them. The protein produced by translation of the

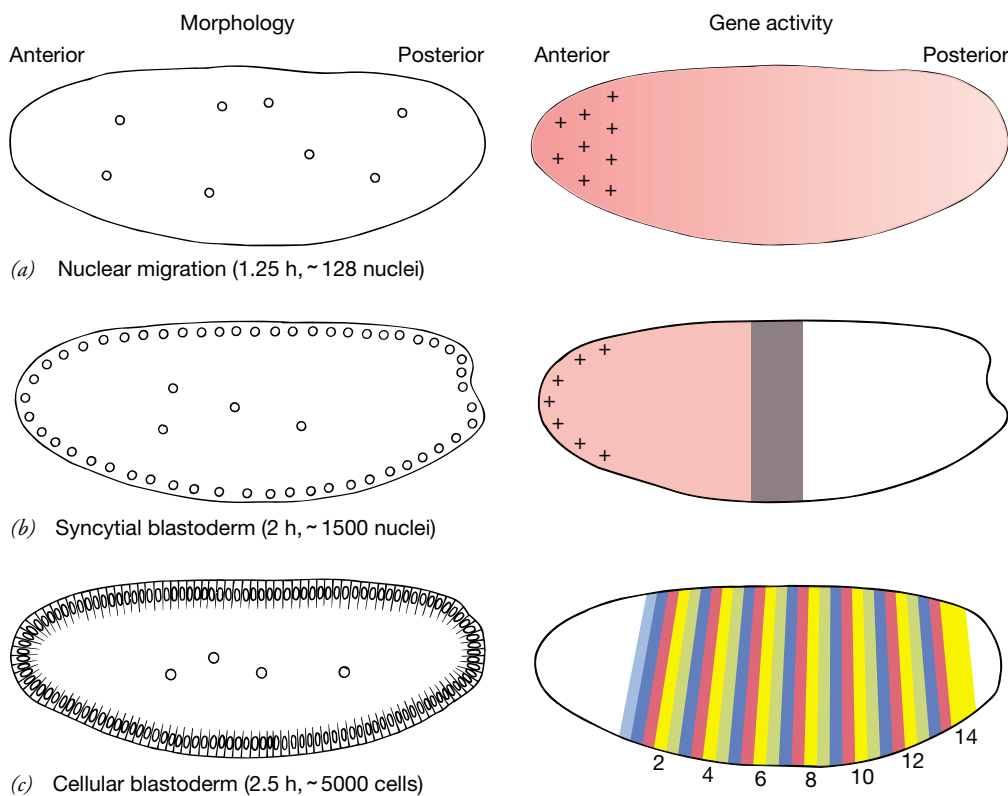

Figure 16–8 Early development of *Drosophila*. Longitudinal sections illustrating the morphology of the embryo at different times after fertilization (*left*) are matched with greatly simplified representations of the patterns of gene activity at each stage (*right*). (*a*) At 1.25 hours (about 128 nuclei). Between the seventh and eighth nuclear divisions, the nuclei start to migrate to the periphery of the egg. The products of several maternal genes can be located in different regions of the egg. The crosses mark the location of maternal mRNA transcribed from a gene that defines the anterior (head) end of the egg. The pink shading represents a concentration gradient of a maternal mRNA extending from the anterior to the posterior end. (*b*) At 2

hours (about 1500 nuclei). Most of the nuclei have reached the periphery of the egg and have started to make their own mRNA. The maternal mRNA shown in pink in the previous panel is now being transcribed from the corresponding zygotic gene by the nuclei in the anterior part of the embryo. The mRNA from a zygotic gap gene is transcribed from cells in only one segment in the middle of the embryo. (*c*) At 2.5 hours (about 5000 cells). Membranes start to form around nuclei located at the periphery of the egg. Messenger RNAs can be detected as a series of stripes around the embryo. (After Akam, *Development* 101:1–22.)

Is There a Master Control Gene for Eye Development?

- HYPOTHESIS:** The *eyeless* locus of *Drosophila* and homologous loci found in other animals are very similar versions of a “master control gene” for eye development.
- METHOD:** The wild type allele of the *eyeless* locus of *Drosophila* was activated in imaginal discs other than the eye discs in which it is normally expressed. The normal allele of a related locus in mice (*Pax-6*, also known as *Small eye*) was expressed in *Drosophila* in similar experiments.
- RESULTS:** Normal compound eyes were produced ectopically, that is, in unusual locations, in the structures that developed from *Drosophila* imaginal discs in which either the normal fly allele or the normal mouse allele was activated. Eyes were formed on wings, legs, and antennae.
- CONCLUSION:** These results support the hypothesis that the *eyeless* locus of *Drosophila* and the *Pax-6* locus of the mouse function similarly as developmental switches in eye formation.

Is it possible that there is a master control gene for the development of eyes? If we survey the animal kingdom, we find several types of apparently very dissimilar types of eyes. For example, if we compare the eyes of vertebrates with the compound eyes of insects (see Chapter 41), they appear so different morphologically that it would seem unlikely that they could develop under the control of similar genes.

The first clues that there could be a link between the genes responsible for eye formation in *Drosophila* and in vertebrates came from the work of R. Quiring and other researchers working in the laboratory of Walter Gehring in Basel, Switzerland.* They discovered a *Drosophila* transcription factor that was coded by *eyeless*, a well known *Drosophila* locus. Mutant alleles of the *eyeless* locus cause the compound eyes to be small or absent. Subsequently, these researchers found that the nucleotide sequence of the *eyeless* locus is very similar to that of the *Pax-6* locus of mice (also known as *Small eye*). Mutant *Pax-6* alleles cause the mice to develop small eyes when heterozygous, and no eyes when homozygous. There is

Compound eye on a *Drosophila* leg. (BIOZENTRUM/University of Basel, Switzerland/Courtesy of Professor W.H. Gehring)

even a human counterpart to these genes; the eyes of a person heterozygous for a mutant allele of the locus known as *Aniridia* have defects of the iris, cornea, lens, and retina.

G. Halder and P. Callaerts, two other scientists in Gehring's laboratory, tested the hypothesis that these genes are master switches in eye development.† They knew that the *eyeless* locus is normally active in the paired eye imaginal discs. They predicted that if the *eyeless* locus were really a master switch, it would be capable of causing eye development wherever it was active. Using a technique known as *targeted gene expression*, they activated the normal *eyeless* allele in various imaginal discs. The experiment worked; compound eyes formed on legs, wings, and antennae! Even more surprisingly, similar results were obtained when normal *Pax-6* alleles (from mice) were expressed in *Drosophila*.

These findings are consistent with the hypothesis that the transcription factors encoded by *eyeless* and by *Pax-6* act as developmental switches, turning on the genes necessary for the formation of the compound eyes of *Drosophila* and vertebrate eyes, respectively.

One interpretation of these findings is that a single “master control gene” for the formation of a “prototypic eye” evolved only once and that both vertebrate and invertebrate eyes evolved from that prototype. Others contend that “master control genes” originated long before the evolution of the structures they currently control. According to this view, such genes provide for general types of control mechanisms, which were subsequently recruited for specific purposes. Studies of recently discovered genes that also play important roles in vertebrate and/or invertebrate eye development may help resolve these issues and will almost certainly raise new questions to be answered.‡

mRNA appears to be part of a system of determinants that organize the early pattern of development in the embryo. A combination of these protein gradients may provide positional information that specifies the fate of each nucleus or cell within the embryo. That information may then be interpreted by a cell as signals specifying the developmental path it should follow. For example, due to the absence of specific signals in the egg, maternal effect mutations can produce an embryo with two heads or two posterior ends.

In many cases, the phenotype associated with a maternal effect mutation can be reversed by injecting normal maternal mRNA into the mutant embryo. When this is done, the fly develops normally, indicating that the gene product is needed only for a short time at the earliest stages of development.

Zygotic segmentation genes continue and extend the developmental program

Immediately after fertilization, the zygote nucleus in the *Drosophila* egg divides, beginning a remarkable series of 13 mitotic divisions. Each of these divisions takes only 5 or 10 minutes, which means that the DNA in the nuclei is replicated constantly at a very rapid rate. During that time the nuclei do not synthesize RNA. Cytokinesis does not take place, and the several thousand nuclei produced by the first seven divisions remain at the center of the embryo until the eighth division occurs.

At that time, most of the nuclei start to migrate out from the center to the periphery of the embryo (Fig. 16–8*b*). Embryonic mRNA production begins, and some of the **zygotic genes** begin to be expressed. (It is customary to refer to the genes of the embryo itself as zygotic genes, even though the embryo is no longer a zygote.) Certain zygotic genes begin to extend the developmental program beyond the pattern established by the maternal genome.

So far geneticists have identified at least 24 **zygotic segmentation genes** that are responsible for generating a repeating pattern of segments within the embryo. The segmentation genes, illustrated in Figure 16–9, fall into three classes—gap genes, pair-rule genes, and segment polarity genes—representing a rough hierarchy of gene action.

The **gap genes** are apparently the first sets of zygotic genes to act. These genes seem to interpret the maternal anterior-posterior information in the egg and begin organization of the segments. A mutation in one of the gap genes usually causes one or more missing segments in an embryo.

The other two classes of segmentation genes do not act on small groups of segments but rather affect all of the segments. For example, mutations in the **pair-rule** genes delete every other segment, whereas mutations in genes belonging to the **segment polarity** class produce segments in which one part is missing and the remaining part is duplicated as a mirror image. The effects of the different classes of mutants are summarized in Table 16–1.

Each gene can be shown to have distinctive times and places in the embryo in which it is active (Fig. 16–10). The

Figure 16–9 Three classes of zygotic segmentation genes in *Drosophila*. Gap genes, pair-rule genes, and segment-polarity genes control the pattern of segments in a *Drosophila* embryo. The blue bands mark the regions in which the protein products of these genes are normally expressed in wild type embryos. When mutated, each gene produces a phenotype that is characteristic of the class to which it belongs. (After Nüsslein-Volhard and Wieschaus, 1980)

observed pattern of expression of the maternal and zygotic genes controlling segmentation indicates that cells destined to form adult structures are determined by a progressive series of developmental decisions. First, the anterior-posterior (head-to-tail) axis and the dorsal and ventral regions of the embryo are determined by maternal segmentation genes thought to form gradients of **morphogens** in the egg. (A morphogen is a chemical agent that affects the differentiation of cells and the development of form.)

Zygotic segmentation genes then respond to the amounts of various morphogens at each location to control the production of a series of segments from the head to the posterior region. Then, within each segment, other genes are activated that read the position of the segment and interpret that information to specify which body part that segment should become. Within every segment, each cell's position is further specified so that it now has a specific “address” that is designated by combinations of the activities of the various regulatory genes.

It is thought that the zygotic segmentation genes act in sequence, with the gap genes acting first, then the pair-rule genes, and finally the segment polarity genes. In addition, members of each group can interact with each other. Each time a new group of genes acts, cells of a particular group become more finely restricted in the way that they will develop. As the embryo develops, it is progressively subdivided into smaller specified regions.

Most, if not all, of the segmentation genes (maternal and zygotic) code for **transcription factors** (see Chapter 13). For example, some of the segmentation genes code for a “zinc-finger” type of DNA-binding regulatory protein (see Fig. 13–7*b,c*). Others code for other types of transcription factors; these are discussed in the next section. The fact that many of the

TABLE 16–1 Classes of Genes Involved in Pattern Formation of Embryonic Segments in *Drosophila*

Type of Gene	Site of Gene Activity	Effects of Mutant Alleles and Proposed Function(s) of Genes
Maternal effect genes	Maternal tissues (ovary)	Many maternal effect mutations alter the polarity of the embryo; initiate pattern formation by activating regulatory genes in nuclei in certain locations in embryo
Zygotic segmentation genes		
Gap genes	Embryo	Mutant alleles cause one or more segments to be missing; some may influence activity of pair-rule genes, segment polarity genes, and homeotic genes
Pair-rule genes	Embryo	When mutated, cause alternate segments to be missing; some may influence activity of segment polarity genes and homeotic genes
Segment polarity genes	Embryo	Mutant alleles delete part of every segment; replace with mirror image of remaining structure; may influence activity of homeotic genes
Homeotic genes	Embryo	Homeotic mutations cause parts of fly to form structures normally formed in other segments; control the identities of the segments

genes involved in the control of development code for transcription factors indicates that those proteins indeed act as genetic “switches” regulating the expression of other genes. Once proteins that function as transcription factors have been identified, it is possible to use the purified proteins to identify the DNA target sequences to which they bind. This approach has

been increasingly useful in identifying additional parts of the regulatory pathway involved in different stages of development. Transcription factors also play a role in cancer (see *Focus on: Oncogenes and Cancer*).

Homeotic genes specify the identity of each segment

One function of the zygotic segmentation genes is to regulate the expression of a separate set of genes that actually designates the final adult structure formed by each of the imaginal discs. These genes are called **homeotic genes**. Because of their involvement in segment identity, mutations in homeotic genes cause one body part to be substituted for another and therefore produce some very peculiar changes in the adult. Among the most striking examples are the *Antennapedia* mutants, which have legs that grow from the head at a position where the antennae would normally be found (Fig. 16–11).

Homeotic genes in *Drosophila* were originally identified by the altered phenotypes produced by mutant alleles. When geneticists analyzed the DNA sequences of a number of homeotic genes, they discovered a short DNA sequence of approximately 180 base pairs that is characteristic of many homeotic genes as well as some other genes that play a role in development. This sequence has been termed the **homeobox**. Using the homeobox as a molecular probe made it possible to clone new homeotic genes in *Drosophila* that had not been previously identified. Surprisingly, the homeobox probe has detected homologous DNA sequences in a wide range of other organisms, including humans. This finding generated consid-

Figure 16–10 Activity of a developmental gene. The bright bands in this fluorescence LM reveal the presence of mRNA transcribed from one of the zygotic pair-rule loci known as *fushi tarazu* (Japanese for “not enough segments”). The segments of the larva that are normally derived from these bands are absent when this locus is mutated. (Courtesy of Steve Paddock, Jim Langeland, Sean Carroll, Howard Hughes Medical Institute, University of Wisconsin)

Figure 16-11 The *Antennapedia* locus. *Antennapedia* mutations of *Drosophila* cause homeotic transformations in which the antennae are replaced by legs or parts of legs. (a) Head of a normal fly and a fly with an *Antennapedia* mutation. (b) SEM of the head of a fly with a mutant allele of the *Antennapedia* locus that produces an extreme phenotype. Most of the mutant alleles of this locus produce only incomplete legs in place of the structures of the antennae. (b, Dr. Thomas Kaufman)

erable excitement because developmental mutants can be difficult to obtain in many organisms, especially vertebrates. The homeobox has allowed researchers to identify and clone a number of genes thought to control development in complex organisms (see *Making the Connection: Evolution of Gene Complexes That Control the Body Plan*).

The homeobox sequences of a large number of genes have been determined. Comparisons have shown that the DNA sequence itself has been highly conserved during evolution and shows remarkable similarities among organisms as diverse as sea urchins, yeasts, and humans. Each homeobox codes for a protein functional region called a **homeodomain**, consisting of 60 amino acids that form four alpha helices. One of these serves as a recognition helix, which can bind to specific DNA sequences and affect transcription. Thus the products of the homeotic genes, like those of the earlier acting segmentation genes, are transcription factors. In fact, some of the segmentation genes also contain homeoboxes.

CAENORHABDITIS ELEGANS HAS A VERY RIGID EARLY DEVELOPMENTAL PATTERN

Caenorhabditis elegans, a roundworm or nematode (see Chapter 28), has one of the simplest systems of genetic control of development. The study of this animal was begun in the 1960s by Sydney Brenner, a molecular biologist. Today it is an important tool for answering basic questions about the development of individual cells within a multicellular organism.

Even as an adult, *Caenorhabditis* is only 1.5 millimeters long and contains only about 1000 somatic cells (the exact number depends on the sex) and about 2000 germ-line cells. Individuals can be either **hermaphrodites** (organisms with both sexes in the same individual) or males. Hermaphroditic individuals are self-fertilizing, which makes it easy to obtain offspring homozygous for newly induced recessive mutations. The availability of males that can mate with the hermaphrodites makes it possible to do genetic crosses as well.

Because the worm's body is transparent, researchers can follow the development of literally every one of its somatic cells (Fig. 16-12 on p.358) using a Nomarski differential interference microscope (see Chapter 4). As a result of efforts by several laboratories, the lineage of each somatic cell in the adult has now been determined. Those studies have shown that the nematode has a very rigid developmental pattern. After fertilization, the egg undergoes repeated divisions to produce about 550 cells that make up the small, sexually immature larva. After the larva hatches from the egg case, further cell divisions give rise to the adult worm.

The lineage of each somatic cell in the adult can be traced to a single cell in a small group of **stem cells**, or **founder cells**, that are formed early in development (Fig. 16-13 on p.359). If a particular founder cell is destroyed or removed, the structures that would normally develop from that cell are missing. Such a rigid developmental pattern, in which the fates of the cells are largely predetermined, is referred to as **mosaic development**. Each cell has a specific fate in the embryo, just as in art a specific tile forms a particular part of the pattern of a mosaic picture.

ONCOGENES AND CANCER

A cancer cell lacks normal biological inhibitions. Normal cells are tightly regulated by control mechanisms that cause them to divide when necessary and prevent them from growing and dividing at inappropriate times. Cells of many tissues in the adult are normally prevented from dividing; they reproduce only to replace a neighboring cell that has died or become damaged. Cancer cells have escaped such controls and can divide continuously.

As a consequence of their abnormal growth pattern, some cancer cells eventually form a mass of tissue called a **tumor**. If the tumor remains at the spot where it originated, it can usually be removed by surgery. One of the major problems with certain forms of cancer is that the cells can escape from the controls that maintain them in their proper location. These cells can **metastasize**, or spread, to different parts of the body, invading other tissues and forming multiple tumors. Lung cancer, for example, is particularly deadly because its cells are highly metastatic and can enter the blood and spread to form tumors in other parts of the lungs, or in other organs such as the liver and the brain. Tumors with cells that can metastasize are referred to as **malignant tumors**.

We now know that cancer is a disease caused by altered gene expression. Using recombinant DNA methods, researchers identified many of the genes that transform normal cells into cancer cells when they function abnormally. Each kind of cancer cell apparently owes its traits to at least one, and possibly several, of a relatively small set of genes known as **oncogenes** (cancer-causing genes). Oncogenes arise

from changes in the expression of certain genes called **proto-oncogenes**, which are *normal* genes found in all cells and involved in the control of growth and development.

Oncogenes were first discovered in viruses that can infect mammalian cells and transform them into cancer cells (*malignant transformation*). Such viruses can incorporate DNA sequences of the proto-oncogenes into their own nucleic acid. In some cases, the viruses alter the expression of the proto-oncogenes, converting them into oncogenes. This may happen if the DNA sequences come under the control of viral regulatory elements, which cause the gene to be transcribed at much higher than normal levels, or if the captured gene mutates so that its protein product is more active than the product of the normal proto-oncogene.

A proto-oncogene in a cell that has not been infected by a virus can also mutate and become an oncogene. One of the first oncogenes identified was isolated from a bladder tumor. In the cell that gave rise to the tumor, a proto-oncogene had undergone a single base-pair mutation; the result was that the amino acid glycine was replaced by a valine in the protein product of the gene. This subtle change was apparently a critical factor in the conversion of the normal cell into a cancer cell.

By means of recombinant DNA technology and other techniques of molecular biology, it has been possible for researchers to identify more than 60 oncogenes and their corresponding proto-oncogenes. Because the fundamental controls of normal cell division and differentiation probably evolved very early in the evolutionary his-

tory of eukaryotes, it is not surprising that very similar proto-oncogenes have been found in a diverse array of organisms, ranging from yeasts to humans. For example, the proto-oncogene counterpart of the oncogene found in some bladder tumors (mentioned previously) has also been found in yeast cells. Some of these controls are illustrated in greatly simplified form in the accompanying figure. The growth and division of cells can be triggered by one or more external signal molecules (see *Making the Connection: Information Transfer Across the Plasma Membrane*, Chapter 5). These substances, known as **growth factors**, bind to specific **growth factor receptors** associated with the cell surface, initiating a cascade of events inside the cell. Often the growth factor receptor complex acts as a **protein kinase** (an enzyme that phosphorylates proteins), which then phosphorylates specific amino acids of a number of cytoplasmic proteins. This posttranslational modification usually results in the activation of previously inactive enzymes. These activated enzymes are then able to catalyze the activation of certain nuclear proteins, many of which are **transcription factors**.

Activated transcription factors bind to their DNA targets and stimulate transcription of specific sets of genes that initiate growth and cell division. Even in the simplified scenario presented in the figure, it is evident that multiple steps are required to control cell proliferation. Remarkably, the proto-oncogenes that encode the products responsible for many of these steps have been identified. The current list of known proto-oncogenes includes genes that code for various growth factors or growth factor

It was originally thought that each organ in *Caenorhabditis* is derived from only one founder cell. Detailed analysis of cell lineages, however, reveals that many of the structures found in the adult, such as the nervous system and the musculature, are in fact derived from more than one founder cell (see Figure 16–13*h*). Conversely, a few lineages have been identified in which a nerve cell and a muscle cell are derived from the division of a single cell. A number of mutations affecting cell lineages have been isolated, and many of these appear to

have properties that would be expected of genes involved in control of developmental decisions.

By using microscopic laser beams small enough to destroy individual cells, it is possible to determine what influence one cell may have on the development of a neighbor. Consistent with the rigid pattern of cell lineages, destruction of an individual cell in *Caenorhabditis* results, in most cases, in the absence of all of the structures derived from that cell, but with the normal differentiation of all of the neighboring somatic

Simplified view of part of a growth control cascade. In this example, a growth factor stimulates cell growth. The growth factor receptor, as well as some of the other components of the system, are coded for by proto-oncogenes. When a proto-oncogene mutates, becoming an oncogene, the cell grows and divides even in the absence of the growth factor. Conversely, other growth control cascades are regulated by growth inhibiting factors. The receptor for the growth inhibiting factor, as well as other parts of the system, are coded for by tumor suppressor genes. When a tumor suppressor gene mutates, the cell grows and divides even if the growth inhibiting factor is present.

receptors and genes that respond to stimulation by growth factors (including a number of transcription factors). When one of these proto-oncogenes is expressed inappropriately, the cell may misinterpret the signal and respond by growing and dividing.

Not all genes that cause cancer when mutated are proto-oncogenes. About one half of all cancers are caused by a mutation in a **tumor suppressor gene**. These genes, also known as **anti-oncogenes**, normally interact with growth inhibiting factors to

block cell division. When mutated they lose their ability to “put on the brakes,” and uncontrolled growth ensues.

Certain oncogenes appear to be particularly common and are found in a variety of tumors. However, a change in a single proto-oncogene is usually insufficient to cause a cell to become malignant. The development of cancer is usually a multistep process involving both oncogenes and mutated tumor suppressor genes. Additional factors, such as the inappropriate activation

of the enzyme responsible for the maintenance of telomeres, also play a role (see Chapter 11, *On the Cutting Edge: Telomerase, Cellular Aging, and Cancer*). As more of these genes are discovered and their complex interactions are unraveled, we will gain a fuller understanding of the control of growth and development. This understanding is leading to improved diagnosis and treatment of various cancers.

cells. This suggests that development in each cell is regulated through its own internal program.

However, there are cases in which differentiation of a cell can be influenced by interactions with particular neighboring cells, a phenomenon known as **induction**. One example is the formation of the vulva (pl., *vulvae*), the structure through which the eggs are laid. A single nondividing cell, called the *anchor cell*, is a part of the ovary (the structure in which the germ-line cells undergo meiosis to produce the eggs). The an-

chor cell attaches to the ovary and to a point on the outer surface of the animal, triggering the formation of a passage through which the eggs pass to the outside. When the anchor cell is present, cells on the surface organize to form the vulva and its opening. If the anchor cell is destroyed by a laser beam, however, the vulva does not form and the cells that would normally form the vulva remain as surface cells (Fig. 16–14 on p.360). The anchor cell therefore induces the surface cells to form a vulva.

(The abbreviated labels “exc,” “i,” and “vcn” refer to certain cells of the excretory, digestive and nervous system respectively.) (b) Diagram illustrating structures in the adult hermaphrodite. The sperm-producing structures are not shown. (a, Courtesy of Dr. John Sulston, Medical Research Council; b, from Walbot and Holder, *Developmental Biology*, p. 607, Figure 22.6a, Random House)

Analysis of certain cell lineage mutations has been useful in understanding such inductive interactions. For example, several types of mutations cause more than one vulva to form. In such mutant animals, multiple vulvae form even if the anchor cell is destroyed. Thus, the mutant cells do not require an inductive signal from an anchor cell to form a vulva. Evidently in these mutants the gene or genes responsible for vulva formation are constitutive. Conversely, mutants lacking a vulva are also known. In some of these, the cells that would normally form the vulva appear unable to respond to the inducing signal from the anchor cell.

During development in *Caenorhabditis*, a number of instances occur in which cells die shortly after they are produced. This phenomenon, known as **apoptosis** or **programmed cell death** (see Chapter 4) has been observed in a wide variety of organisms, both plant and animal. For example, the human hand is formed as a webbed structure, but the fingers become individualized when the cells between them die. In *Caenorhabditis*, these programmed cell deaths are under genetic control, and several mutants have been isolated that alter the pattern of these deaths. The loci identified by these mutations, in addition to mutations with similar effects in other organisms, are being analyzed at the molecular level and should shed considerable light on the general phenomena of cellular aging and programmed cell death.

Mutations are also known that appear to identify genes involved in developmental timing, known as **chronogenes**. One such locus has recessive alleles that cause certain cells to

adopt fates that would ordinarily be seen later in development. Dominant alleles of the same locus cause certain cells to adopt fates that would usually be expressed earlier. Such genes appear to be good candidates for “switches” that control developmental timing.

Genes that contain homeobox-like sequences have been discovered in *Caenorhabditis*. They are sufficiently different from the *Drosophila* homeobox genes that they were not identified by molecular probes from *Drosophila*. Now that the *Caenorhabditis* sequences can be used as probes, researchers are identifying additional homeobox genes in this worm and other organisms.

THE MOUSE IS A MODEL FOR MAMMALIAN DEVELOPMENT

Mammalian embryos develop in markedly different ways from the embryos of *Drosophila* and *Caenorhabditis*. The laboratory mouse, *Mus*, is the best studied example of early mammalian development.

Cells of very early mouse embryos are totipotent

The early development of the mouse and other mammals is similar in many ways to human development, which is de-

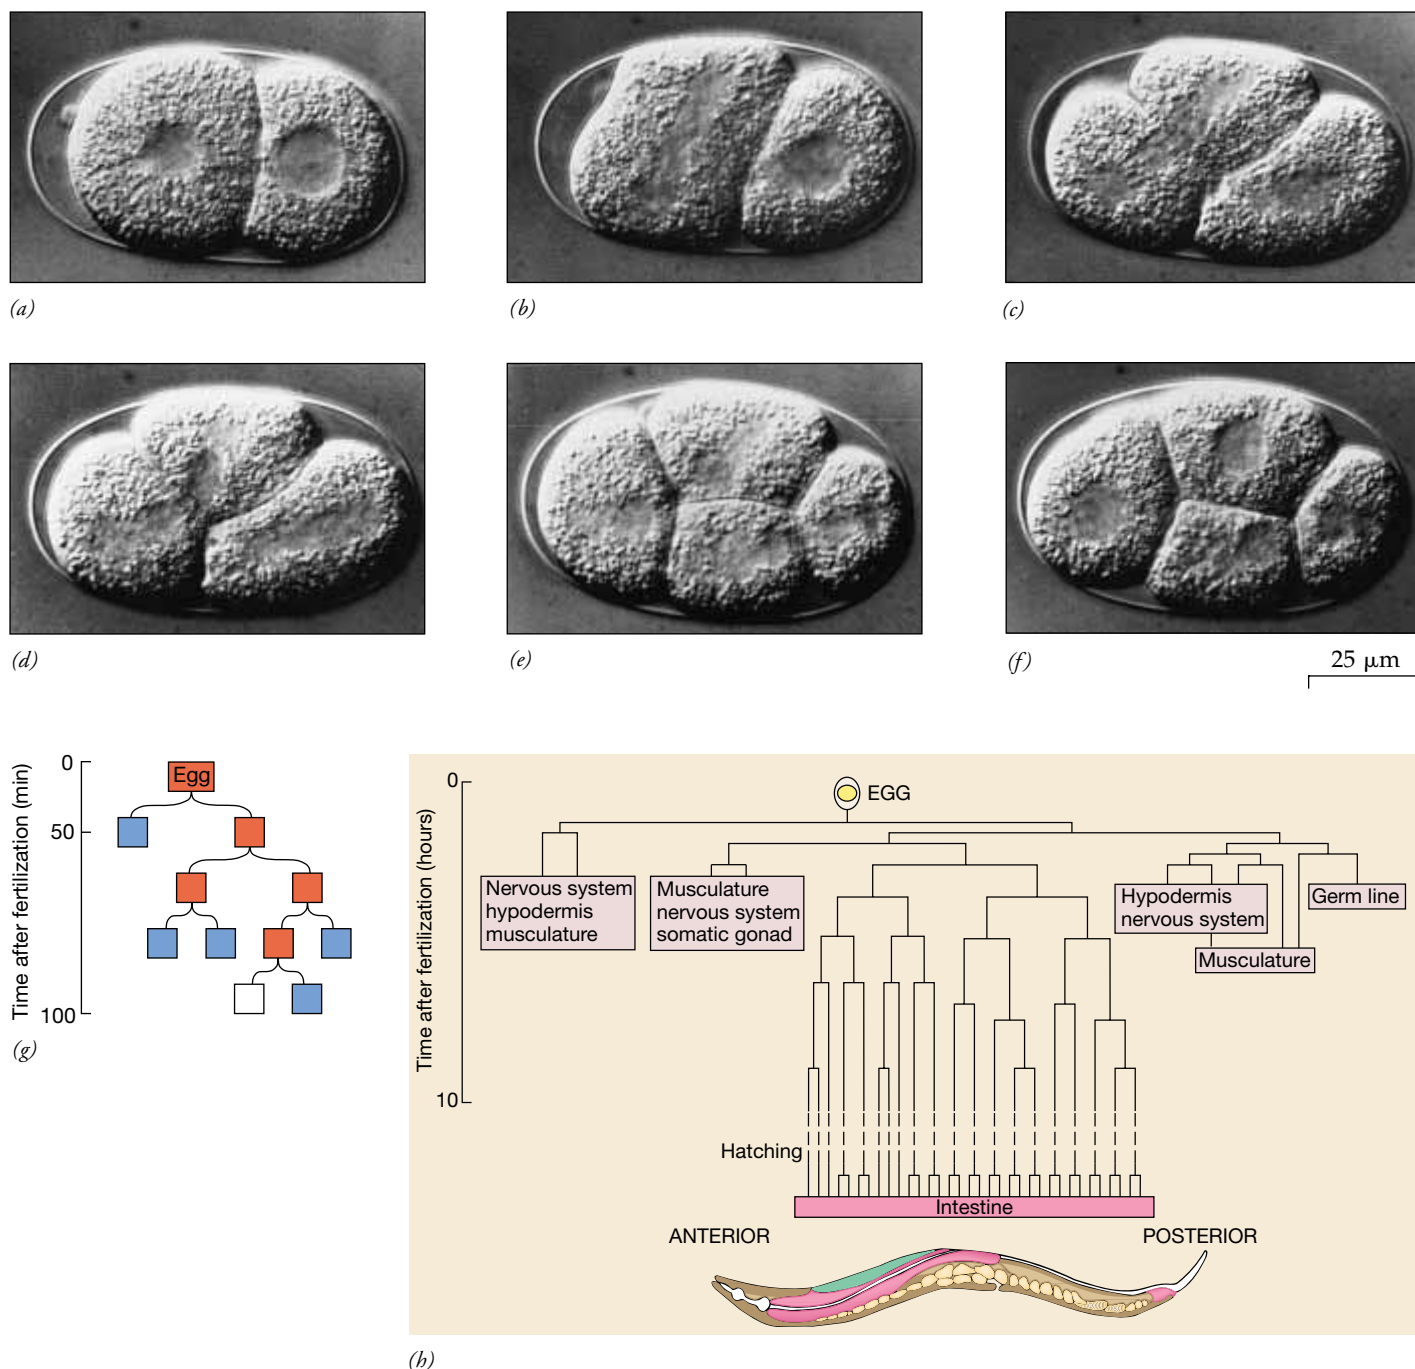

Figure 16-13 Cell lineages of *C. elegans*. All somatic cells of *C. elegans* are derived from five somatic founder cells produced during the early cell divisions of the embryo. (a–f) Nomarski interference LMs showing the early cell divisions of the embryo. (g) A lineage map showing the origins of the five somatic founder cells (blue). The cell shown in white will give rise to the germ cells. (h) This lineage map traces the development of the cells that form the intestine. (a–f, E. Schierenberg, from G. von Ehrenstein and E. Schierenberg, in *Nematodes as Biological Models*, Vol 1, B. Zuckerman, ed., New York: Academic Press, 1980)

scribed in detail in Chapter 49. During the early developmental period, the embryo lives free in the reproductive tract of the female. It then implants in the wall of the uterus, after which its needs are met by the mother. Consequently, mammalian

eggs are very small and contain little in the way of food reserves. Almost all research on mouse development has concentrated on the stages leading to implantation because during those stages the embryo is free-living and can be

Figure 16–14 Induction. A single anchor cell induces neighboring cells to form the vulva in *C. elegans*. This schematic diagram shows how laser destruction of single cells or a group of cells can be used to demonstrate the influence of a cell on its neighbors.

experimentally manipulated. During that period, critical developmental commitments take place that have a significant effect on the future organization of the embryo.

Following fertilization, a series of cell divisions gives rise to a loosely packed group of cells. It has been possible to show that all the cells in the very early mouse embryo are equivalent. For example, at the two-cell stage of mouse embryogenesis, one of the two cells can be destroyed by pricking it with a fine needle. Implanting the remaining cell into the uterus of

a surrogate mother in most cases leads to the development of a normal mouse.

Conversely, two embryos at the eight-cell stage of development can be fused together and implanted into a surrogate mother, resulting in the development of a normal-sized mouse (Fig. 16–15). By using two embryos with different genetic markers (such as coat color), it can be demonstrated that the resulting mouse has four genetic parents. These mice have fur with patches of different colors derived from clusters of ge-

Figure 16–15 Chimeric mice. Embryos can be removed from females of two different strains and the cells combined in vitro. The resulting aggregate embryo continues to develop and is implanted in the uterus of a surrogate mother. The offspring has four different genetic parents. Although the surrogate mother is the birth mother, she is not genetically related.

MAKING THE CONNECTION

EVOLUTION OF GENE COMPLEXES THAT CONTROL THE BODY PLAN

Why do scientists use a wide variety of organisms to study genes that control development? Not only do certain organisms have particular advantages for certain types of investigations, but comparisons among organisms are providing important (and often surprising) insights into evolutionary relationships. This approach is exemplified by studies on clusters of homeobox-containing genes, now generally referred to as Hox genes, which were initially discovered in *Drosophila*.

The Hox genes of *Drosophila* form two adjacent groups on the chromosome: the *Antennapedia* complex and the *bithorax* complex. As homeobox-containing genes have been identified in other animals, including other arthropods and annelids (segmented worms), it has been found that these genes are also clustered and that their organization is remarkably similar to that seen in *Drosophila*. The figure compares the organization of the Hox gene clusters of *Drosophila*, *Caenorhabditis*, and the mouse. These images are matched with the regions where they are expressed in the animals. Remarkably, the *Drosophila* and mouse Hox genes are located in the same order along the chromosome, although the correlation is less clear for *Caenorhabditis*. Furthermore, the order of the genes on the chromosome reflects the order of the corresponding segments they control (from anterior to posterior) in the animal. This organization apparently reflects the need for these genes to be transcribed in a specific sequence.

Drosophila has only the *Antennapedia/bithorax* complex. However, vertebrates have four similar Hox complexes, each located in a different chromosome. These complexes probably arose through gene duplication. The fact that extra copies of these genes are present helps explain why mutations causing homeotic-like transformations are seldom seen in vertebrate animals. However, one particular type of Hox mutation that has been described in both mice and humans causes abnormalities in the limbs and genitalia. The involvement of the genitalia provides a further explanation for the rarity of these mutant alleles, because affected individuals are unlikely to reproduce.

It is now thought that the homeobox genes are generally responsible for specifying position in the developing animal embryo, particularly the position along the anterior-posterior axis. The fact that very similar developmental controls are seen in organisms as diverse as insects, unsegmented roundworms, and vertebrates (including humans) indicates that the basic mechanism evolved early and has been highly conserved in all animals that have an anterior-posterior axis, even those that are not segmented. The system has apparently been modified in segmented animals such as insects and vertebrates to provide for control of segmentation and specification of segment identity. The idea that homeobox genes are involved in specifying position in the embryo has been strengthened by findings that they not only control the formation of the body axis but also have a role in vertebrate limb development. It is becoming clear that once a successful way of controlling groups of genes and integrating their activities evolved, it was retained, although it has apparently been modified in various ways to provide for alterations of the body plan.

The finding of homeobox-like genes in plants suggests that these genes may be of ancient origin and may in fact be the genes that made multicellularity possible. Further investigations may allow researchers to develop an overall model of how the rudiments of morphogenesis are controlled in both plants and animals. These systems of master genes that control development are proving to be a rich source of "molecular fossils" that are illuminating evolutionary history in new and exciting ways.

Hox gene clusters. The Hox gene clusters of *Drosophila* and the laboratory mouse are correlated with the parts of the body in which each gene is expressed. (Only one of the four mouse clusters is shown. Although not evident in the figure, some of these regions of expression overlap.) Note that in each organism the order of the genes on the chromosome reflects their spatial order of expression in the embryo. The most anteriorly expressed genes are shown to the left, while those expressed most posteriorly are at the right. *Caenorhabditis* also has similar clustered genes, although their relationships are less well understood. (After Lenyon et al., Science 253: 516)

Figure 16-16 Producing a transgenic mouse. (a) Cloned DNA fragments are injected into the nucleus of a fertilized mouse egg by a glass needle, shown entering from the right, which is about 1 μm in diameter at the tip. The egg is held in place by suction on a holding pipet (left). (b) The injected eggs are then surgically transferred to a surrogate mother. The presence of the foreign gene can be examined in the transgenic animal, or the animal can be bred to establish a transgenic line of mice. (a, R. L. Brinster, University of Pennsylvania School of Veterinary Medicine)

netically different cells. Animals formed in this way are called **chimeras**. (The term *chimera*, derived from the name of a mythical beast that had the head of a lion, the body of a goat, and the tail of a snake, is used today to refer to any organism that contains two or more kinds of genetically dissimilar cells arising from different zygotes.) Chimeras have been important in allowing the use of genetically marked cells to trace the fates of certain cells during development.

The responses of mouse embryos to these kinds of manipulations are in marked contrast to the mosaic or predetermined nature of early *Caenorhabditis* development, in which the destruction of one of the founder cells results in loss of a significant portion of the embryo. For this reason, we say that the mouse (and presumably other mammals) has highly **regulative development**. This means that the early embryo acts as a self-regulating whole that can accommodate missing or extra parts. On the other hand, it has not been possible so far to demonstrate totipotency of either cells or nuclei from slightly later stages of mouse development. (This may change soon, given the success with nuclear transplantation experiments on sheep, discussed earlier in the chapter.)

Transgenic mice are used in studies on developmental regulation

In transformation experiments similar to those done with *Drosophila*, foreign DNA injected into fertilized mouse eggs can be incorporated into the chromosomes and expressed (Fig. 16–16). The resulting **transgenic** (see Chapter 14) mice have given researchers insights into how genes are activated during development. In addition, mouse genes can be inactivated (“knocked out”) by the technique of targeted gene replacement (see Chapter 14, *Making the Connection: The Genetics of Mice and Humans*). For example, a locus known as *engrailed* is a homeobox-containing gene that functions as a segment polarity gene in *Drosophila*. When its counterpart, known as *Engrailed-1*, is knocked out in mice, the resulting embryos exhibit lethal abnormalities in brain development.

Scientists can identify a transgene (foreign gene) that has been introduced into a mouse and determine whether it is active by marking the gene in several ways. Sometimes a similar gene from a different species is used; its protein can be distinguished from the mouse protein by specific antibodies. It is

also possible to construct a “hybrid gene” that contains the regulatory elements of a mouse gene of interest together with part of another gene that codes for a “reporter” protein, such as an enzyme not normally found in the mouse. Such studies have been important in showing which DNA sequences of a mouse homeobox gene determine where the gene is expressed in the embryo.

Many developmentally controlled genes have been introduced into mice and have yielded important information about gene regulation. Most important, when developmentally controlled genes from other species such as humans or rats have been introduced into mice, they are regulated in the same way that they normally are in the donor animal. For example, when introduced into the mouse, human genes encoding insulin, globin, and crystallin—which are normally expressed in cells of the pancreas, blood, and eye lens, respectively—are expressed only in those same tissues in the mouse. The fact that these genes are correctly expressed in their appropriate tissues indicates that the signals for tissue-specific gene expression are highly conserved through evolution. This is an exciting finding because it means that information on the regulation of genes controlling development in one organism can have valuable applications to other organisms, such as humans.

HOMEOTIC-LIKE MUTATIONS OCCUR IN PLANTS

Certain well characterized plants are also being used in the study of the genetic control of development. Many of these are economically important crop plants such as corn, *Zea mays*. A number of genes with developmental effects are known in corn, including some that can be thought of as analogous to the homeotic genes of *Drosophila*.

Another plant being used increasingly to study genetics and development in plants is a member of the mustard family, *Arabidopsis*. Although *Arabidopsis* itself is of no economic importance, it has several advantages for research. The plant is quite small, so thousands of individuals can be grown in limited space. Chemical mutagens can be used to produce mutant strains, and a number of developmental mutants, including some that have homeotic-like characteristics, have been isolated. For example, the genes that control flower development have been particularly well characterized (Fig. 16–17). The plant has a very small and simple genome, which greatly facilitates cloning of genes. In addition, cloned foreign genes can be inserted into *Arabidopsis* cells, and these can be integrated into the chromosomes and expressed. These transformed cells can be induced to differentiate into transgenic plants.

Several homeotic-like genes in plants have been shown to code for transcription factors. For example, homeobox-containing genes are involved in the development of the shoot (above-ground portion) of the corn plant. Similarly, the genes

(a)

(b)

Figure 16–17 Homeotic transformations in *Arabidopsis*. (a) A normal flower of *A. thaliana* has four outer leafy green sepals (hidden by the petals), four white petals, six stamens (the male reproductive structures), and a central pistil (the female reproductive structure). (b) This homeotic mutant has only sepals and petals because the gene normally responsible for the development of the stamens and pistil is missing. (Dr. Elliot Meyerowitz, California Institute of Technology)

that specify the identities of the parts of the *Arabidopsis* flower code for transcription factors, although they do not contain homeoboxes. Interestingly, these genes appear to be controlled by regulatory genes that are very similar to genes that are known to regulate the expression of homeotic genes in *Drosophila*. Now that suitable molecular probes are available from plants, many more such genes are being identified in a wide range of organisms. This information will lead to a deeper understanding of the functions and evolutionary history of these genes.

SOME EXCEPTIONS TO THE PRINCIPLE OF NUCLEAR EQUIVALENCE HAVE BEEN FOUND

Although the concept of nuclear equivalence appears to apply to most cells in higher organisms, certain types of developmental regulation can involve physical changes in the DNA. Such changes in the structure of the genome are not common.

Genomic rearrangements involve structural changes in DNA

The activity of some genes may be modified during development by different types of **genomic rearrangements** that lead to actual physical changes in the structure of the gene. In some cases, parts of genes are rearranged to make new coding sequences. This is an important mechanism for the development of the immune system (see Chapter 43).

Another type of rearrangement involves the replacement of an active gene with a copy of a “silent” gene located on a different part of the same chromosome. The baker’s yeast *Saccharomyces cerevisiae* is a simple eukaryote that has two sexes or mating types called *a* and α . The mating type of a cell is determined by an active gene located close to the middle of one of the yeast chromosomes; this is called the mating type locus. At some distance on either side of the active gene are two silent genes called *MAT a* and *MAT α* . If a copy of the *MAT a* gene occupies the mating type locus, the mating type is *a*; if a copy of the *MAT α* gene occupies that site, the mating type of the cell is α . These yeast strains can switch their mating type from one form to the other as frequently as every generation (Fig. 16–18). Each time this occurs, the gene located at the mating type locus is removed and replaced by a DNA sequence copied from the silent gene that corresponds to the opposite mating type.

A somewhat similar system of gene replacement takes place in the unicellular parasite *Trypanosoma brucei*, which is a protozoan (see Chapter 24). Trypanosomes carried by the tsetse fly in Africa cause sleeping sickness in humans and related diseases in other animals (Fig. 16–19). When the parasite infects humans, it is able to defeat the immune system by repeatedly changing the glycoprotein molecules that are exposed on the surface of its cell.

Unlike yeast, which has only two basic copies of the mating type gene per cell, the trypanosome cell contains as many as 1000 different genes for cell surface molecules. The differences among their amino acid sequences are so great that an antibody that recognizes one of them would not recognize another. Only one or a few of those copies are expressed at any one time, depending on which copy is present at an **expression site**, which is usually located near the end of a chromosome. The genes in the expression site are exchanged in about

Figure 16–18 Mating type switching in yeast. The active form of the mating type gene resides at the *MAT* locus near the center of the chromosome. Silent copies of the *a* and α genes are located near either end of the chromosome. During cell division, a copy of the opposite mating type is transferred to the *MAT* locus, resulting in the reversal of the mating type of the cell by the new resident gene.

one out of every 10^4 to 10^6 cells, causing trypanosomes with novel antigens to appear every 7 to 10 days. Thus the infection is maintained by constant supply of new cells that cannot be recognized by the immune system. Although gene replacement clearly offers a mechanism that could serve as a regulatory “genetic switch,” it is not known at present whether these mechanisms are relevant to development in multicellular eukaryotes.

Gene amplification increases the number of copies of specific genes

Some gene products are required in such large quantities during certain stages of development that a single copy of a gene cannot be transcribed, nor can its mRNA be translated, rapidly enough to fill the needs of the developing cells. In certain cases, the number of gene copies may be increased, through a process known as **gene amplification**, to meet the demand. For example, the *Drosophila* chorion (eggshell) gene product is a protein made specifically in cells of the insect oviduct. These cells make massive amounts of the particular protein that envelops and protects the fertilized egg. The demand for chorion mRNA in those cells is met by specifically amplifying the gene by DNA replication so that the DNA in that small region of the chromosome is copied many times (Fig. 16–20). In other cells of the insect body, however, the gene appears to exist as a single copy in the chromosome.

(a)

2.5 μm

Figure 16–19 Gene rearrangement in trypanosomes. (a) LM of blood infected with *Trypanosoma brucei*. (b) Trypanosomes change the molecules coating their surfaces frequently and are thus able to “outrun” the immune system of their human host. Each cell contains as many as a thousand silent genes, each coding for a different surface coat glycoprotein. Only one of those genes, which is located at a position near the end of a chromosome, called the expression site, is active at any one time. As the trypanosomes multiply in the blood, occasionally a copy of one of the silent genes replaces the gene currently in the expression site, leading to the production of organisms with a new surface glycoprotein that is not recognized by the immune system. (a, Ed Reschke)

(b)

Figure 16–20 Gene amplification. In *Drosophila*, multiple replications of a small region of the chromosome result in the amplification of the chorion (egg shell) protein genes. Replication is initiated at a discrete chromosome origin of replication for each copy of the gene that is produced, and is randomly terminated, resulting in a series of forked structures in the chromosome.

THE STUDY OF DEVELOPMENTAL BIOLOGY PRESENTS MANY FUTURE CHALLENGES

New model organisms, each with characteristics that uniquely suit it for developmental studies, are now being added to the list of well characterized experimental systems. In a herculean effort spearheaded by Christiane Nüsslein-Volhard of the University of Tübingen, Germany, researchers have identified over 2000 developmental mutants of the zebrafish (*Danio rerio*) and are now embarking on molecular genetic studies. Previously

best known to tropical fish enthusiasts, the zebrafish was chosen as a research subject mainly for its transparent embryos (see chapter opener 49).

Scientists are now learning how genes are activated, inactivated, and modified and how batteries of master regulatory genes interact to control development. Eventually researchers expect to understand not only how differentiation and morphogenesis are controlled but also how the basic control systems have evolved. The identification of certain features common to many organisms, such as homeobox genes, will make the task easier, but the work has just begun. Many complex interactions remain to be explored, and many revelations await us.

S U M M A R Y W I T H K E Y T E R M S

- I. **Development** is the process by which the descendants of a single cell specialize and organize into a complex organism.
 - A. An organism contains many types of cells that are specialized both structurally and chemically to carry out specific functions. These cells are the product of a process of gradual commitment, called cell **differentiation**, which ultimately leads to the final step in cell specialization, called cell **differentiation**.
 - B. **Morphogenesis**, the development of form, occurs through stages, referred to as **pattern formation**, in which the various specialized cells become organized into structures.
 - C. There is no evidence that genes are normally lost during most developmental processes.
 1. At least some nuclei from differentiated plant and animal cells are **totipotent** and contain all the genetic material that would be present in the nucleus of a zygote.
 2. **Nuclear equivalence** is the concept that, with a few exceptions, all of the nuclei of the differentiated somatic cells of an organism are identical to each other and to the nucleus of the single cell from which they descended.
 3. Differences among various cell types are apparently due to **differential gene expression**.
- II. Several organisms have characteristics that make them especially useful in studies of the genetic control of development.
 - A. Many types of developmental mutants have been identified in the fruit fly, *Drosophila melanogaster*. Many of these mutations affect the segmented body plan of the organism.
 1. The earliest developmental program to operate in the egg is established by **maternal effect genes**; these are active prior to fertilization, and some produce gradients of **morphogens**, thereby affecting the segmentation pattern that is progressively established in the embryo.
 2. **Zygotic segmentation genes** do not become active until much later, when the embryo is no longer a zygote. They continue and extend the developmental program initiated by the maternal effect genes.
 3. The zygotic segmentation genes and their products interact with each other and with the products of the maternal effect genes according to a hierarchical pattern, with certain earlier-acting genes controlling particular later-acting genes.
 4. The later-acting **homeotic genes** are responsible for specifying the identity of each segment.
 5. Many of the segmentation genes are known to code for **transcription factors**. Some of these contain a DNA sequence called a **homeobox**, which codes for a protein with a DNA-binding region called a **homeodomain**.
 - B. *Caenorhabditis elegans* is a roundworm with **mosaic development**, an extremely rigid developmental pattern in which the fates of cells are largely predetermined.
 1. The lineage of every somatic cell in the adult is known, and each can be traced to a single **founder cell** in the early embryo.
 2. A number of mutations affecting cell lineages have been identified, and many of these appear to identify genes that control developmental processes such as **induction** (developmental interactions with neighboring cells), **programmed cell death (apoptosis)**, and developmental timing (i.e. **chronogenes**).
 - C. The laboratory mouse, *Mus*, is extensively used in studies of mammalian development.
 1. In contrast to *Caenorhabditis*, the mouse shows **regulative development**, which means that the very early embryo is a self-regulating whole and can develop normally even if it has extra or missing cells.
 2. Transgenic mice have been extremely useful in determining how genes are activated and regulated during development.
 - D. Genes affecting the developmental pattern have also been identified in certain plants, including *Zea mays* (corn) and *Arabidopsis*. Some of these code for transcription factors.
 - E. Some homeobox genes are organized into complexes that appear to be systems of master genes specifying an organism's body plan. Remarkable parallels exist between the homeobox complex of *Drosophila* and those of other animals, including the laboratory mouse and *Caenorhabditis*.
- III. A few exceptions to the general rule of nuclear equivalence are known. Among these are **genomic rearrangement** (physical rearrangements of the DNA) and **gene amplification**, which provides more copies of certain genes for transcription.

P O S T - T E S T

1. Morphogenesis occurs through a series of stages known as (a) differentiation (b) determination (c) pattern formation (d) totipotency (e) selection
2. The "cloning" experiments carried out on amphibians demonstrated that (a) all differentiated amphibian cells are totipotent (b) some differentiated amphibian cells are totipotent (c) all nuclei from differentiated amphibian cells are totipotent (d) some nuclei from differentiated amphibian cells are totipotent (e) the mechanism of cellular differentiation always requires the loss of certain genes
3. *Drosophila* is a particularly good model for developmental studies because (a) a large number of developmental mutants are available (b) it has a fixed number of somatic cells in the adult (c) its embryos are trans-

- parent (d) it is a vertebrate (e) all of the above
- The anterior-posterior axis of a *Drosophila* embryo is first established by certain (a) homeotic genes (b) maternal effect genes (c) zygotic segmentation genes (d) chronogenes (e) pair-rule genes
 - You discover a new *Drosophila* mutant in which mouthparts appear where the antennae are normally found. You would predict that the mutated gene is most likely a (a) homeotic gene (b) gap gene (c) pair-rule gene (d) maternal effect gene (e) segment polarity gene
 - Most zygotic segmentation genes code for (a) special transfer RNAs (b) enzymes (c) transcription factors (d) histones (e) transport proteins
 - The developmental pattern of *Caenorhabditis* is said to be highly mosaic because (a) development is controlled by gradients of morphogens (b) part of the embryo fails to develop if a founder cell is destroyed (c) some individuals are self-fertilizing hermaphrodites (d) all development is controlled by maternal effect genes (e) programmed cell deaths never occur

- Which of the following illustrates the regulative nature of early mouse development? (a) the mouse embryo is free-living prior to implantation in the uterus (b) it is possible to produce a transgenic mouse (c) it is possible to produce a mouse in which a specific gene has been “knocked out” (d) genes related to *Drosophila* homeotic genes have been identified in mice (e) a chimeric mouse can be produced by fusing two mouse embryos
- Arabidopsis* is useful as a model organism for the study of plant development because (a) it is of great economic importance (b) it has large polytene chromosomes (c) many developmental mutants have been isolated (d) it contains a large amount of DNA per cell (e) it has a rigid developmental pattern
- The mating type switching system of yeast is an example of (a) nuclear equivalence (b) genomic rearrangement (c) gene amplification (d) cell totipotency (e) pattern formation

REVIEW QUESTIONS

- Development consists of four main processes: determination, differentiation of cells, pattern formation, and morphogenesis. Define each process and describe how they relate to one another.
- What lines of evidence support the concept of nuclear equivalence?
- What are the relative merits of *Drosophila*, *Caenorhabditis*, *Mus*, and *Arabidopsis* as model organisms for the study of development?
- What is the value of homeotic genes in developmental studies?
- Describe how transgenic organisms are useful in the study of gene regulation in development.
- Give some examples of genomic rearrangements that are known to occur as a part of some developmental processes.
- Under what conditions are examples of gene amplification seen?
- What are oncogenes, and what is their relationship to cellular genes involved in the control of normal growth and development?

YOU MAKE THE CONNECTION

- Why is an understanding of gene regulation in eukaryotes crucial to an understanding of developmental processes?
- Why do developmental biologists need to understand biological diversity?

Why is it necessary for scientists to study development in more than one type of organism?

Kit Chan came to the United States with a degree in biology and biochemistry from The Chinese University of Hong Kong. He completed his undergraduate studies during a time when there was much excitement about the prospects of genetic engineering. Kit was particularly fascinated by molecular biology. He went on to obtain a Ph.D. in molecular virology at Baylor College of Medicine in Houston and proceeded to become a laboratory scientist. After working in research science for several years, he attended Columbia University School of Law in New York City and now applies both his scientific and legal knowledge to patent law. In addition to his biotechnology patent practice of eight years, he teaches patent law, intellectual property law, and technology transfer at the City University of New York Law School.

How did you decide to become a lawyer?

After I finished my graduate studies, I began my postdoctoral work at Cold Spring Harbor Laboratory on Long Island. I was working in molecular oncology—how an oncogene is turned on and how that affects the cell, particularly the cell cycle. The oncogene I was working on, called *myc*, encodes a nuclear protein that regulates transcription. My project was to try to see how the protein is made and how it interacts with different cellular components. At that time there were constant discussions at Cold Spring Harbor Laboratory about the Human Genome Project and the legal ramifications of biotechnology. I did some

Biotechnology Patent Lawyer

K I T C H A N

research and discovered that I could apply my biology background to a career in law as a biotechnology patent lawyer.

How does your biology background help you in your law practice?

A biology background is useful in evaluating the prospects for obtaining a biotechnology patent. For example, if someone discovers a gene that is responsible for Alzheimer's disease, the patent application could include the DNA and RNA probes for this gene. The application might also include the protein that is encoded by the Alzheimer's disease gene and antibodies directed against the protein.

My biology background also enables me to determine the further ramifications of an invention. For instance, if someone wishes to patent a drug for the herpes virus, I know that the same drug might block the replication of other viruses as well. This helps me devise a patent application that covers other potential uses of the drug.

What does an inventor obtain by filing a patent?

The patent is a contract between the government and the applicant. For a definite period of time, an applicant obtains exclusive rights to his or her invention, and in exchange, the inventor provides full disclosure of the invention in the public domain. Currently, the patent expiration period is twenty years. This means that while the patent holder retains rights to the invention, other scientists can have access to the invention and may be able to build upon the original work.

What are some of the legal issues arising from the Human Genome Project and any new genetic technologies on the horizon?

In my law classes, I teach that there are often conflicting perspectives surrounding the potential uses of genetic information. These include the issues of individual privacy and possible discrimination, and the interests of the insurance industry. I have been active in the science and law reading

of legal position papers concerning these issues for the New York City Bar Association. The ethical position is that, for each individual, the genetic profile should be confidential. That sounds easy: Most of us feel that our medical records should be confidential; therefore, so should our genome information. On the other hand, the insurance companies' position is that if you carry, say, an alcoholism or a tobacco preference gene, why shouldn't you have to pay higher premiums than people who are not genetically predisposed to alcohol or smoking high risk factors?

Another debate is about the Employment Discrimination Act. If a company knows that statistically, you are more likely to die at the age of 48 because you are at high risk for cardiac disease based on your genetic profile, whereas I am more likely to live until age 90 based on mine, why shouldn't they hire me instead of hiring you?

The same kind of genome information can be an advantage. Right now, in terms of technology, we are working toward highly individualized medicine. The medication that you take and the medication that I take should be different. The reason is that we have distinct genetic make-ups, which could affect the effective dosage. When someone needs a combination therapy, we should be able to look at his or her genome map and say, "Oh, you have the alcohol dehydrogenase gene isoform 3 or you have LDL isoform 1," and then combine a beta blocker with the effective dosage. Then, you would not be likely to overdose.

Have you noticed a great many changes in the biotechnology patent laws recently?

The recent laws have made it easier and better for biotechnology patents. Five years ago it was a lot harder to get a patent issued. For example, if you were claiming an AIDS therapeutic composition, the Patent Office would require official FDA approval, involving a complete, double-blind study with a placebo and statistically significant results. This is an extremely costly and time-consuming process. Now the Patent Office is more receptive and understands the technology involved in the research and development phase, and appreciates that one purpose of the patent is to encourage the inventor to explore further the commercial significance of the invention. All in all, in my opinion, we are going in the right direction letting more patents be issued so as to encourage the industry. I feel it's very exciting these days.

CHAPTER 17

Introduction to Darwinian Evolution

Life is thought to have originated only once. The biological diversity represented by the millions of species currently living on our planet has evolved from a single ancestor during Earth's long history. Thus, organisms that are radically different, such as slime molds and crocodiles, are in fact distantly related to one another and are linked through numerous intermediate ancestors to a single, common ancestor. The British naturalist Charles Darwin (1809–1882), shown here at age 31, developed a remarkably simple, scientifically testable mechanism to explain this. He argued persuasively that all the species that exist today, as well as the countless extinct species that existed in the past, arose from earlier ones by a process of gradual divergence (separation), or evolution.

Evolution can be defined as the accumulation of heritable changes within populations over time. (**Heritable** traits are those that are genetically based and therefore are able to be passed to offspring. A **population** is a group of individuals of one species that live in the same geographical area at the same time.) Evolution does not refer to changes that occur in an individual within its lifetime, but to changes in the characteristics of populations over many generations. These changes may be so small that they are difficult to detect or so great that the population differs markedly from its ancestral population. Eventually, two populations may diverge to such a degree that we refer to them as different species. (The concept of species is developed extensively in Chapter 19. For now, a simple working definition is that a species comprises one or more populations of similar organisms that are capable of interbreeding with one another.)

The concept of evolution is the cornerstone of biology because it links all fields of the life sciences into a unified body of knowledge. Biologists attempt to understand both the remarkable variety as well as the fundamental similarities of organisms within the context of evolution. Thus, evolution allows biologists to compare common threads among organisms as seemingly different as bacteria, whales, lilies, and tapeworms. Evolution also has important practical applications. Agriculture, for example, must deal with the evolution of pesticide resistance in insects and other pests. Likewise, medicine must re-

(The Granger Collection, New York)

spond to the rapid evolutionary potential of disease-causing bacteria.

This chapter discusses Darwin and the scientific development of the theory of evolution by natural selection. It also presents several kinds of evidence that support evolution, including fossils, comparative anatomy, developmental biology, biogeography, molecular biology, and experimental evidence.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Discuss the historical development of the theory of evolution.
 2. Define evolution and explain the four premises of evolution by natural selection as proposed by Charles Darwin.
 3. Compare the synthetic theory of evolution with Darwin's original theory of evolution.
 4. Summarize the evidence for evolution obtained from the fossil record.
 5. Summarize the evidence for evolution derived from comparative anatomy.
 6. Define and give examples of homologous features, homoplastic features, and vestigial structures.
 7. Explain how developmental biology provides insights into the evolutionary process.
 8. Define biogeography and summarize how the distribution of organisms supports evolution.
 9. Explain how scientists make inferences about evolutionary relationships from the sequence of amino acids in proteins and the sequence of nucleotides in DNA.
 10. Give an example of how evolutionary hypotheses can be tested experimentally.
-

IDEAS ABOUT EVOLUTION ORIGINATED BEFORE DARWIN

Although Darwin is universally associated with evolution, ideas of evolution predate Darwin by centuries. Aristotle (384–322 B.C.) saw much evidence of natural affinities among organisms. This led him to arrange all of the organisms he knew in a “Scale of Nature” that extended from the exceedingly simple to the most complex. He visualized organisms as being imperfect but “moving toward a more perfect state.” This idea has been interpreted by some scientific historians as the forerunner of evolutionary theory, but Aristotle was vague on the nature of this “movement toward perfection” and certainly did not propose that the process of evolution was driven by natural selection. Furthermore, modern evolutionary theory now recognizes that evolution does not move toward more “perfect” states, nor even necessarily toward greater complexity.

Long before Darwin, fossils had been discovered embedded in rocks. Some of these corresponded to parts of familiar species, but others were strangely unlike any known species. Fossils were often found in unexpected contexts. Marine invertebrates (sea animals without backbones), for example, were sometimes discovered in rocks high on mountains. Leonardo da Vinci was among the first to correctly interpret these unusual finds as the remains of animals that had existed in previous ages but had become extinct.

The French naturalist Jean Baptiste de Lamarck (1744–1829) was the first scientist to propose that organisms undergo change over time as a result of some natural phenomenon rather than divine intervention. In his *Philosophie Zoologique*, published in 1809, Lamarck presented a possible explanation for how organisms evolved. Lamarck thought that all organisms were endowed with a vital force that drove them to change toward greater complexity over time. He also thought that organisms could pass traits acquired during their lifetimes to their offspring. For example, Lamarck suggested that the long neck of the giraffe developed when a short-necked ancestor stretched its neck to browse on the leaves of trees. Its offspring inherited the longer neck, which stretched still further as they ate.

This process, repeated over many generations, supposedly resulted in the long necks of modern giraffes.

The proposed mechanism for Lamarckian evolution was discredited when the basis of heredity was later discovered. It remained for Darwin to discover the mechanism of evolution by natural selection.

DARWIN'S VOYAGE WAS THE BASIS FOR HIS THEORY OF EVOLUTION

Darwin, the son of a prominent physician, was sent at the age of 15 to study medicine at the University of Edinburgh. Finding himself unsuited for medicine, he transferred to Cambridge University to study theology. During that time, he became the protégé of the Reverend John Henslow, who was a professor of botany. Henslow encouraged Darwin's interest in the natural world. Shortly after receiving his degree, Darwin embarked as a naturalist on the H.M.S. *Beagle*, which was taking a five-year exploratory cruise around the world to prepare navigation charts for the British Navy.

The *Beagle* left Plymouth, England, in 1831 and cruised along the east and west coasts of South America (Fig. 17–1). While other members of the crew mapped the coasts and harbors, Darwin spent many weeks ashore studying the animals, plants, fossils, and geological formations of both coastal and inland regions, areas that had not been extensively explored. He collected and catalogued thousands of plant and animal specimens and kept notes of his observations—information that would become essential in the development of his theory.

The *Beagle* spent almost two months at the Galapagos Islands, 965 kilometers (600 miles) west of Ecuador, where Darwin continued his observations and collections. He compared the animals and plants of the Galapagos with those of the South American mainland. He was particularly impressed by their similarities and wondered why the organisms of the Galapagos should resemble those from South America more than those from other islands in different parts of the world. More-

Figure 17–1 The voyage of H.M.S. *Beagle*. The five-year voyage began in Plymouth, England (gold star), in 1831. Darwin's observations of the Galapagos Islands were the basis for his theory of evolution by natural selection.

over, although there were similarities between Galapagos and South American species, there were also distinct differences. There were even recognizable differences in the reptiles and birds from one island to the next (Fig. 17–2). After he returned home, Darwin pondered these observations and attempted to develop a satisfactory explanation for the distribution of species among the islands.

Darwin drew on several lines of evidence when considering how species might have originated. Despite the work of

Lamarck, the general notion in the mid-1800s was that the Earth was too young for organisms to have changed significantly since they had first appeared. During the early 19th century, however, geologists advanced the idea that mountains, valleys, and other physical features of Earth's surface did not originate in their present forms, but developed slowly over long periods of time by the geological processes of volcanic activity, uplift, erosion, and glaciation. Darwin took *Principles of Geology*, published by geologist Charles Lyell in 1830, with

(a)

(b)

(c)

Figure 17–2 Three species of Galapagos finches. Darwin inferred that these birds are derived from a common ancestral population of seed-eating birds from South America. Variation in their beaks is the result of adaptation to different kinds of food. (a) The cactus finch (*Geospiza scandens*) feeds on the fleshy parts of cacti. (b) The large ground finch (*Geospiza magnirostris*) has an extremely heavy, nutcracker-type bill adapted for eating thick, hard-walled seeds. (c) The woodpecker finch (*Camarhynchus pallidus*) has insectivorous habits similar to those of woodpeckers but lacks the complex beak and tongue adaptations that permit woodpeckers to reach their prey. The adaptations of the woodpecker finch to this lifestyle are almost entirely behavioral—it digs insects out of bark and crevices using cactus spines, twigs, or even dead leaves. (a and b, Frans Lanting/Minden Pictures; c, Miguel Castro/Photo Researchers, Inc.)

Figure 17–3 Artificial selection in chickens. Shown is a chicken that was deliberately bred to resemble Big Bird on “Sesame Street.” Many show breeds exist that exhibit a great deal of variation. The chickens we eat are not a recognizable breed but are hybrids bred for their meat or egg production. (© Eric Sander)

him on his voyage and studied it carefully. Lyell provided an important concept for Darwin—that the slow pace of geological processes, which still occur today, indicated that the Earth was extremely old.

Other important evidence that influenced Darwin was the fact that breeders and farmers could develop many varieties of domesticated animals in just a few generations (Fig. 17–3). This was accomplished by choosing certain traits and breeding only individuals that exhibited the desired traits, a procedure known as **artificial selection**. Breeders, for example, had produced numerous dog varieties—bloodhounds, Dalmatians, Airedales, border collies, and Pekinese, to name a few—by artificial selection.

Many plant varieties were also produced by artificial selection. For example, cabbage, broccoli, brussels sprouts, cauliflower, collard greens, kale, and kohlrabi are distinct vegetable crops that are all members of the same species, *Brassica oleracea* (Fig. 17–4). All seven were produced by selective breed-

Figure 17–4 Artificial selection in *Brassica oleracea*. An enlarged terminal bud (the “head”) was selected in cabbage, flower clusters in broccoli and cauliflower, axillary buds in brussels sprouts, leaves in collards and kale, and stems in kohlrabi. (John Arnaldi)

ing of the colewort, or wild cabbage, a leafy plant native to Europe and Asia. Beginning more than 4000 years ago, some farmers artificially selected wild cabbage plants that formed overlapping leaves. Over time, these leaves became so prominent that the plants, which resembled modern-day cabbages, became recognized as separate and distinct from their wild cabbage ancestor. Other farmers selected different features of the wild cabbage, giving rise to the other modifications. For example, kohlrabi was produced by selection for an enlarged storage stem, and Brussels sprouts by selection for enlarged axillary buds. Thus, humans are responsible for the evolution of *Brassica oleracea* into seven distinct vegetable crops. Darwin was aware of artificial selection and thought that a similar selective process occurred in nature.

The ideas of Thomas Malthus (1766–1834), a British clergyman and economist, were another important influence on Darwin. Malthus noted in *An Essay on the Principle of Population as It Affects the Future Improvement of Society*, published in 1798, that population growth is not always desirable—a view contrary to the beliefs of his day. He observed that populations have the capacity to increase geometrically ($1 \rightarrow 2 \rightarrow 4 \rightarrow 8 \rightarrow 16$) and thus outstrip the food supply, which has the capacity to increase only arithmetically ($1 \rightarrow 2 \rightarrow 3 \rightarrow 4 \rightarrow 5$). In the case of humans, Malthus suggested that the conflict between population and food supply generates famine, disease, and war, which serve as inevitable brakes on population growth.

DARWIN PROPOSED THAT EVOLUTION OCCURS BY NATURAL SELECTION

Darwin's years of observing the habits of animals and plants had introduced him to the struggle for existence described by Malthus. It occurred to Darwin that in this struggle inherited variations favorable to survival would tend to be preserved, while unfavorable ones would be eliminated. The result would be **adaptation**—evolutionary modification that improves the chances of survival and reproductive success of the population—to the environment. Eventually, the accumulation of modifications might result in a new species. Time was the only thing required for new species to originate, and the geologists of the era, including Lyell, had supplied evidence that Earth was indeed old enough to provide an adequate period of time.

Darwin had at last obtained a workable mechanism of evolution, that of **natural selection**, in which better adapted organisms are more likely to survive and become the parents of the next generation. As a result of natural selection, the population changes over time; the frequency of favorable traits increases in successive generations while less favorable traits become scarce or disappear. Darwin spent the next 20 years formulating his arguments for natural selection, accumulating an immense body of evidence to support his theory, and corresponding with other scientists.

As Darwin was pondering his ideas, Alfred Russell Wallace (1823–1913), a British naturalist who was studying the plants and animals of the Malay Archipelago, was similarly struck by the diversity of species and the peculiarities of their distribution. He wrote a brief essay on this subject and sent it to Darwin, by then a world-renowned biologist, asking his opinion. Darwin recognized his own theory and realized that Wallace had independently arrived at the same conclusion—that evolution occurs by natural selection. Darwin's colleagues persuaded him to present Wallace's manuscript along with an

abstract of his own work, which he had prepared and circulated to a few friends several years earlier. Both papers were presented in July 1858 at a London meeting of the Linnaean Society. Darwin's monumental book, *The Origin of Species by Natural Selection; or, The Preservation of Favored Races in the Struggle for Life*, was published in 1859. Wallace's book, *Contributions to the Theory of Natural Selection*, was published in 1870, eight years after he returned from the Malay Archipelago.

Darwin's mechanism of evolution by natural selection consists of four observations about the natural world: overproduction, variation, limits on population growth, and differential reproductive success.

1. **Overproduction.** Each species has the capacity to produce more offspring than will survive to maturity. Through reproduction, natural populations may geometrically increase in number over time. For example, if each breeding pair of elephants produces six offspring during its 90-year life span, in 750 years a single pair of elephants will give rise to a population of 19 million! Yet elephants have not overrun the planet.
2. **Variation.** The individuals in a population exhibit variation. Each individual has a unique combination of traits, such as size, color, and ability to tolerate harsh environmental conditions. Some traits improve an individual's chances of survival and reproductive success, whereas others do not. It is important to remember that the variation necessary for evolution by natural selection must be heritable (Fig. 17–5). (Although Darwin recognized the importance to evolution of inherited variation, he did not know the mechanism of inheritance.)
3. **Limits on population growth,** or a struggle for existence. There is only so much food, water, light, growing space, and other resources available to a population, and, consequently, organisms compete with one another for these lim-

Figure 17–5 Genetic variation in emerald tree boas (*Corallus caninus*). These snakes were caught in a small section of forest in French Guiana. Many snake species exhibit considerable variation in their coloration and patterns. (J. Sauvanet/Peter Arnold, Inc.)

ited resources. Because there are more individuals than the environment can support, not all will survive to reproduce. Other limits on population growth include predators, disease organisms, and unfavorable weather conditions.

4. **Differential reproductive success.** Those individuals that possess the most favorable combination of characteristics (those that make individuals better adapted to their environment) are more likely to survive and reproduce. Because offspring tend to resemble their parents, the next generation obtains the parents' heritable traits. Successful reproduction is the key to natural selection: the best adapted individuals are those that reproduce most successfully, whereas less fit individuals die prematurely or produce fewer or inferior offspring.

Over time, enough changes may accumulate in geographically separated populations (often with slightly different environments) to produce new species. Darwin noted that the Galapagos finches appear to have evolved in this way. The different islands of the Galapagos kept the finches isolated from one another, thereby allowing them to diverge, or take separate evolutionary pathways, into separate species. The evolution of new species is considered in greater detail in Chapter 19.

THE SYNTHETIC THEORY OF EVOLUTION COMBINES DARWIN'S THEORY WITH GENETICS

One of the premises on which Darwin based his theory of evolution by natural selection is that individuals transmit traits to the next generation. However, Darwin was unable to explain *how* this occurs or *why* individuals vary within a population. Although he was a contemporary of Gregor Mendel (see Chapter 10), who elucidated the basic patterns of inheritance, Darwin was apparently not acquainted with Mendel's work, which was not recognized by the scientific community until the early part of the 20th century.

During the 1930s and 1940s, biologists combined the principles of genetics with Darwin's theory of natural selection to develop a unified explanation of evolution known as **neo-Darwinism** or, more commonly, the **synthetic theory of evolution**.¹ (*Synthesis* in this context refers to combining parts of several previous theories to form a unified whole.)

The synthetic theory of evolution is a conceptual breakthrough that explains Darwin's observation of variation among offspring in terms of **mutation**, or changes in DNA, such as nucleotide substitutions. That is, mutation provides the genetic variability on which natural selection acts during evolu-

tion. The synthetic theory of evolution, which emphasizes the genetics of *populations* (rather than individuals) as the central focus of evolution, has held up well since it was developed (see Chapter 18). It has dominated the thinking and research of biologists working in many areas, and has resulted in an enormous accumulation of scientific evidence to support evolution by natural selection. (See *Making the Connection: Tuberculosis, Bacterial Resistance to Antibiotics, and Evolution* for a discussion of a serious health issue that is related to natural selection in bacteria.)

Most biologists accept the basic principles of the synthetic theory of evolution but have recently scrutinized some of its aspects. For example, what is the role of chance in evolution? How rapidly do new species evolve? These questions have arisen in part from a reevaluation of the fossil record and in part from discoveries in molecular aspects of inheritance. Such critical analyses are an integral part of the scientific process because they stimulate additional observation and experimentation, along with reexamination of previous evidence. Science is an ongoing process, and information obtained in the future may require modifications to certain parts of the synthetic theory of evolution.

MANY TYPES OF SCIENTIFIC EVIDENCE SUPPORT EVOLUTION

A vast body of experimental evidence supports evolution, including observations from the fossil record, comparative anatomy, developmental biology, biogeography, and molecular biology. In addition, evolutionary hypotheses are increasingly being tested experimentally.

The fossil record provides strong evidence for evolution

Perhaps the most direct evidence for evolution comes from the discovery, identification, and interpretation of **fossils**, which are the remains or traces typically left in sedimentary rock by previous organisms. (The term *fossil* comes from the Latin word *fossilis*, meaning "something dug up.") The fossil record shows a progression from the earliest, single-celled organisms to the many single-celled and multicellular organisms living today. To date, paleontologists (scientists who study fossils) have described and named about 300,000 fossil species, and more are being discovered all the time.

Although most fossils are preserved in sedimentary rock, some more recent remains have been exceptionally well preserved in bogs, tar, amber (ancient tree resin), or ice (Fig. 17–6). For example, the remains of a woolly mammoth deep-frozen in Siberian ice for more than 25,000 years were so well preserved that part of its DNA could be analyzed.

Fossils provide a record of ancient organisms and some understanding of where and when they lived. Using fossils of organisms from different geological ages, the lines of descent

¹Some of the founders of the synthetic theory of evolution were biologists Theodosius Dobzhansky, Ronald Fisher, Julian Huxley, Ernst Mayr, George Gaylord Simpson, and G. Ledyard Stebbins, Jr.

Copley/Visuals Unlimited; e, Scott Berner/Visuals Unlimited)

MAKING THE CONNECTION

TUBERCULOSIS, BACTERIAL RESISTANCE TO ANTIBIOTICS, AND EVOLUTION

What is antibiotic-resistant tuberculosis, and how is it related to evolution? Beginning in the late 1980s, an alarming increase in the incidence of tuberculosis (TB) has been documented by the U. S. Centers for Disease Control and Prevention in Atlanta. In the thirty or so years before that time, the number of cases of TB had declined in the United States, largely as a result of treating TB with antibiotics, which are drugs intended to harm or kill bacteria and other microorganisms.

Many people are exposed to the bacteria that cause TB, but only people who are very young, very old, or weakened from some other disease usually exhibit symptoms. One of the reasons for the current outbreak of TB is the HIV virus (the virus that causes AIDS), which incapacitates the immune system. Patients who are infected with HIV and who formerly had symptom-free TB are at greater risk for deadly infections.

Tuberculosis exhibits a disturbing trend in which drug-resistant strains of the bacteria that cause TB have developed in the past decade. These strains are resistant to one or more antibiotics that traditionally were used to treat TB. Drug-resistant TB is deadly: as many as 80% of the people infected with multi-drug-resistant TB (MDR-TB) die within two months of diagnosis—even with medical care.

The development of bacterial resistance to antibiotics is an ex-

ample of evolution. Bacteria are continually evolving, even inside the bodies of human and animal hosts. When an antibiotic is used to treat a bacterial infection, a few bacteria may survive because they are genetically resistant to the antibiotic*, and they pass these genes to future generations. As a result, the bacterial population contains a larger percentage of antibiotic-resistant bacteria than before.

Drug resistance is usually found in patients who were previously treated for TB, and quite often human behavior is a factor in the development of drug resistance. A person infected with TB must take three to ten pills of antibiotics each day for at least six months. After the first week or two of treatment, the person usually feels better; many patients decide to quit taking their medication at this point. When this happens, the TB bacteria still lurking in their bodies—those with a resistance to the antibiotic formerly used—rally. The evolution of a strain of bacteria resistant to several drugs is a worst-case scenario. MDR-TB is extremely difficult to treat effectively and, as mentioned previously, is often fatal.

*Bacteria develop genetic resistance through mutations (see Chapters 11 and 12) and through acquiring new genes from plasmids (see Chapters 11 and 14, discussion of transformation) or viruses (see Chapter 23, discussion of transduction).

(evolutionary relationships) that gave rise to modern-day organisms can sometimes be inferred. In many instances, fossils provide direct evidence of the origin of new species from pre-existing species, including transitional forms.

For example, during the 1980s and 1990s, paleontologists have discovered several fossil intermediates in whale evolution (Fig. 17–7). Scientific evidence indicates that whales descended from a now-extinct group of four-legged terrestrial mammals called mesonychids. (The closest living relatives of whales and porpoises are hooved mammals such as antelopes, deer, and giraffes.) About 50 to 60 million years ago, some descendants of mesonychids had adapted to swimming in shallow seas. Fossils of *Ambulocetus natans*, a 50-million-year-old whale discovered in Pakistan, had many features of modern whales but also possessed hind limbs and feet. (Modern whales do not have hind limbs, although vestigial pelvic and hindlimb bones persist. Vestigial structures are discussed later in this chapter.) In addition to swimming, this ancient whale moved about on land, perhaps as sea lions do today. By 40 million years ago, the whale transition from land to ocean was almost complete. Egyptian fossils of *Dorudon atrox*, a 6-meter (18-foot) whale that lived at that time, indicate a streamlined body (like modern-day whales) along with a pair of reduced, 15-centimeter (6-inch) hind limbs too small to be used in locomotion.

The formation and preservation of a fossil require that an organism be buried under conditions that slow or prevent the decay process. This is most likely to occur if an organism's remains are covered quickly by a sediment of fine soil particles suspended in water. In this way remains of aquatic organisms may be trapped in bogs, mud flats, sand bars, or deltas. Remains of terrestrial organisms that lived on a flood plain may also be covered by water-borne sediments or, if the organism lived in an arid region, by wind-blown sand. Over time, the sediments harden to form sedimentary rock, and the organism's remains are usually replaced by minerals so that many details of its structure, even cellular details, remain.

The fossil record is not a random sample of past life, but instead is biased toward aquatic organisms and those living in the few terrestrial habitats conducive to fossil formation. Relatively few fossils of tropical rainforest organisms have been found, for example, because their remains decay extremely rapidly on the forest floor, before fossils can develop. Another reason for bias in the fossil record is that organisms with hard body parts such as bones and shells are more likely to form fossils than those with soft body parts.

Because of the nature of the scientific process, each fossil discovery represents a separate “test” of the theory of evolution. If any of the tests fail, the theory would have to be modified to fit the existing evidence. The discovery, for example,

Figure 17–7 Fossil intermediates in whale evolution. The now-extinct *Ambulocetus natans* was a transitional form between modern whale descendants and their terrestrial ancestors. *Ambulocetus* possessed a number of recognizable whale features and retained the hind limbs of its four-legged ancestors. The later *Dorudon atrox* was more streamlined and possessed tiny hind limbs that were nonfunctional. The exact relationships of *Ambulocetus* and *Dorudon* to other whales are uncertain; they may or may not have been direct ancestors of modern whales, as shown in the diagram. (Adapted from Gingerich and Uhen, University of Michigan Museum of Paleontology, and from Thewissen, Madar, and Hussain. See Recommended Readings for complete citations.)

of fossil remains of humans (*Homo sapiens*) in Precambrian rocks, which are more than 570 million years old, would falsify the theory of evolution as currently proposed. However, Precambrian rocks examined to date contain fossils of simple organisms, such as cyanobacteria, that are thought to have evolved early in the history of life. The earliest fossils of *Homo sapiens* with anatomically modern features do not appear in the fossil record until approximately 100,000 years ago (see Chapter 21).

Various methods can be used to determine the age of fossils

Because layers of sedimentary rock occur naturally in the sequence of their deposition, with the more recent layers on top

of the older, earlier ones (Fig. 17–8), most fossils are dated by their relative position in sedimentary rock. However, geological events occurring after the rocks were initially formed have occasionally changed the relationships of some rock layers. Geologists identify specific sedimentary rocks not only by their positions in layers but also by features such as mineral content and by the fossilized remains of certain organisms, known as **index fossils**, that characterize a specific layer over large geographical areas. Index fossils are fossils of organisms that existed for a relatively short geological time but were preserved as fossils in large numbers. With this information, geologists can arrange rock layers and the fossils they contain in chronological order and identify comparable layers in widely separated locations.

Radioactive isotopes, also called **radioisotopes**, present in

Figure 17-8 Layers characterize sedimentary rock. The younger layers overlie the older layers. The layers shown here were exposed when a road cut was made for a highway in Utah. (Tom Bean)

a rock provide a means to accurately measure its age (see Chapter 2). Radioisotopes emit invisible radiations. As a radioisotope emits radiation, its nucleus changes into the nucleus of a different element in a process known as **radioactive decay**. For example, the radioactive nucleus of uranium-235 decays over time into lead-207.

Each radioisotope has its own characteristic rate of decay. The period of time required for one half of the atoms of a radioisotope to change into a different atom is known as its **half-life** (Fig. 17-9). Radioisotopes differ significantly in their half-lives. For example, the half-life of iodine-132 is only 2.4 hours, whereas the half-life of uranium-235 is 704 million years. The half-life of a particular radioisotope is constant and does not vary with temperature, pressure, or any other environmental factor.

The age of a fossil is estimated by measuring the relative proportions of the original radioisotope and its decay product. For example, the half-life of potassium-40 is 1.3 billion years, meaning that in 1.3 billion years half of the radioactive potas-

Figure 17-9 Radioisotope decay. At time zero, the radioactive clock begins ticking. At this point a sample is composed entirely of the radioisotope. After one half-life, only 50% of the original radioisotope remains. During each succeeding half-life, one half of the remaining radioisotope is converted to decay product(s).

sium will have decayed into its decay product, argon-40. The radioactive clock begins ticking when the rock solidifies. The rock initially contains some potassium, but no argon. Because argon is a gas, it escapes from hot rock as soon as it forms, but when potassium decays in rock that has cooled and solidified, the argon accumulates in the crystalline structure of the rock. If the ratio of potassium-40 to argon-40 in the rock being tested is 1:1, the rock is 1.3 billion years old.

Several radioisotopes are commonly used to date fossils. These include potassium-40 (half-life 1.3 billion years), uranium-235 (half-life 704 million years), and carbon-14 (half-life 5730 years). Potassium-40, with its long half-life, can be used to date fossils that are many hundreds of millions of years old. Radioisotopes other than carbon-14 are used to date the *rock* in which fossils are found, whereas carbon-14 is used to date the *carbon remains* of anything that was once living, such as wood, bones, or shells. Whenever possible, the age of a fossil is independently verified using two or more different radioisotopes.

Carbon-14, which is continuously produced in the atmosphere from nitrogen-14 (by cosmic radiation), subsequently decays back to nitrogen-14. Because the formation and the decay of carbon-14 occur at constant rates, the ratio of carbon-14 to carbon-12 (the more abundant, stable isotope of carbon) is constant in the atmosphere. Since each organism absorbs carbon from the atmosphere,² its ratio of carbon-14 to carbon-12 is the same as the atmosphere. When an organism dies, however, it no longer absorbs carbon, and the proportion of carbon-14 in its remains declines as carbon-14 de-

²Organisms absorb carbon from the atmosphere either directly (by photosynthesis) or indirectly (by consuming photosynthetic organisms).

Figure 17-10 Homology in animals. The human arm, cat forelimb, whale flipper, and bat wing have a basic underlying similarity of structure because they are derived from a common ancestor.

cays to nitrogen-14. Because of its relatively short half-life, carbon-14 is useful for dating fossils that are 50,000 years old or less.

Comparative anatomy of related species demonstrates similarities in their structures

Comparing the structural details of features found in different but related organisms reveals a basic similarity. Such features that are derived from the same structure in a common ancestor are termed **homologous features**. For example, consider the limb bones of mammals. A human arm, a cat forelimb, a whale front flipper, and a bat wing, although quite different in appearance, have strikingly similar arrangements of bones, muscles, and nerves. Figure 17-10 shows a comparison of their skeletal structures. Each has a single bone (the humerus) in the part of the limb nearest the trunk of the body, followed by the two bones (radius and ulna) of the forearm, a group of bones (carpals) in the wrist, and a variable number of digits (metacarpals and phalanges). This similarity is particularly striking because arms, forelimbs, flippers, and wings are used in different ways for different functions, and there is no overriding mechanical reason for them to be so similar structurally. Similar arrangements of parts of the forelimb are evident in ancestral reptiles and amphibians and even in the first fishes that came out of water onto land hundreds of millions of years ago.

Leaves are one example of a homologous feature in plants. In many plant species, leaves have been modified for functions other than photosynthesis. A cactus spine and a pea tendril, although quite different in appearance, are homologous because both are modified leaves (Fig. 17-11). The spine protects the succulent stem tissue of the cactus, whereas the ten-

dril, which winds around a small object once it makes contact, helps support the climbing stem of the pea plant. Such basic structural similarities in organs used in different ways are precisely the expected outcome of a common evolutionary origin. The basic structure present in a common ancestor was modified in different ways for different functions as various descendants subsequently evolved.

Not all species with “similar” features have descended from a more recent common ancestor, however. Features that are not homologous but simply have similar functions in distantly related organisms are termed **homoplastic features**. For example, the wings of various distantly related flying animals, such as insects and birds, are homoplastic features that have evolved over time to meet the common function of flight, though they are different in more fundamental aspects. Bird wings are modified forelimbs supported by bones, whereas insect wings may have evolved from gill-like appendages present in the aquatic ancestors of insects. Spines, which are modified leaves, and thorns, which are modified stems, are an example of homoplasy in plants. Spines and thorns resemble one another superficially but are homoplastic features that evolved to solve the common need for protection from herbivores (Fig. 17-12).

Like homology, homoplasy offers crucial evidence of evolution. Homoplastic features are of evolutionary interest because they demonstrate that organisms with separate ancestries may adapt in similar ways to similar environmental demands. Such independent evolution of similar structures in distantly related organisms is known as **convergent evolution**. Armadillos, anteaters, and pangolins are an excellent example of convergent evolution (Fig. 17-13). They resemble one another in lifestyle and appearance—all have strong, sharp claws to dig open ant and termite mounds and elongated snouts with long, sticky tongues to catch these insects. Yet armadillos, anteaters, and pangolins evolved from three distantly related orders of

Figure 17-11 Homology in plants. (a) The spines of the fishhook cactus (*Ferocactus wislizenii*) are modified leaves, as are (b) the tendrils of the garden pea (*Pisum sativum*). Leaves of the garden pea are compound, and the terminal leaflets are modified into tendrils that are frequently branched.

mammals. (See Chapter 22 for further discussion of homology and homoplasy.)

Comparative anatomy reveals the existence of **vestigial structures**. Many organisms contain organs or parts of organs that are seemingly nonfunctional and degenerate, often undersized or lacking some essential part. Vestigial structures are

remnants of more developed structures that were present and functional in ancestral organisms. In the human body, more than 100 structures are considered vestigial, including the appendix, coccyx (fused tail bones), body hair, wisdom teeth, and the muscles that move our ears. Whales (see Fig. 17-7) and pythons have vestigial hindlimb bones; pigs have vestigial toes

Figure 17-12 Homoplasy. (a) A spine of Japanese barberry (*Berberis thunbergii*) is a modified leaf. (In this example, the spine is actually the midrib of the original leaf, which has been shed.) (b) Thorns of downy hawthorn (*Crataegus mollis*) are modified stems that develop from axillary buds.

(a)

(b)

(c)

Figure 17–13 Convergent evolution. Three distantly related mammals exhibit structural similarities as a result of convergent evolution. These species adapted independently to eat ants and termites in similar grassland/forest environments in different parts of the world. (a) The armadillo (*Oryzomys azer*) is native to central, southern, and eastern Africa. (b) A giant anteater (*Myrmecophaga tridactyla*) at a termite mound. The anteater is native to Latin America, from southern Mexico to northern Argentina. (c) The pangolin (*Manis crassicaudata*) is native to Africa and southern and southeastern Asia. (a, Kjell B. Sandved/Visuals Unlimited; b, Gunter Ziesler/Peter Arnold, Inc.; c, Mandal Ranjit/Photo Researchers, Inc.)

that do not touch the ground; wingless birds have vestigial wing bones; and many blind, burrowing or cave-dwelling animals have nonfunctioning, vestigial eyes.

The occasional presence of a vestigial structure is to be expected as a species adapts to a changing mode of life. Some structures become much less important for survival and may end up as vestiges. When a structure no longer confers a selective advantage, it usually becomes smaller and loses much or all of its function with the passage of time. Since the presence of the vestigial structure is usually not harmful to the organism, however, selective pressure for completely eliminating it is weak, and the vestigial structure can be found in many subsequent generations.

Vertebrates have retained some developmental features of their ancestors

All vertebrates have similar patterns of embryological development that indicate they share a common ancestor. The resemblance among embryos of different vertebrates is closer than the resemblance among adults. In fact, it is difficult to distinguish among the early embryos of a reptile, a bird, a pig, or a human (Fig. 17–14). Segmented muscles, gill pouches, a tubular heart without left and right sides, a system of arteries known as aortic arches in the gill region, and many other features are found in all vertebrate embryos. All of these structures are necessary and functional in the developing fish. The small segmented muscles of the fish embryo give rise to the segmented muscles used by the adult fish in swimming. The gill pouches break through to the surface as gill slits. The adult fish heart remains undivided because it pumps blood forward to the gills that develop in association with the aortic arches.

Since none of these embryonic features persists in the adults of reptiles, birds, or mammals, why are these fishlike structures present in their embryos? Evolution is a conserva-

tive process, and natural selection builds on what has come before rather than starting from scratch. Terrestrial vertebrates are thought to have evolved from fishlike ancestors; therefore, they share some of the early stages of development still found in fish today. The accumulation of genetic changes over time in these vertebrates has modified the basic body plan laid out in fish development.

The distribution of plants and animals supports evolution

The study of the past and present geographical distribution of organisms is called **biogeography**. Darwin was interested in biogeography and considered why the species found on ocean islands tend to resemble species of the nearest mainland, even if the environment is different, but not to resemble species on islands with similar environments in other parts of the world. Darwin studied the plants and animals of two sets of arid islands—the Cape Verde Islands, some 650 kilometers (about 400 miles) west of Dakar, Africa, and the Galapagos Islands, a comparable distance west of Ecuador, South America. On each group of islands, the plants and terrestrial animals were indigenous (native), but those of the Cape Verde Islands resembled African species and those of the Galapagos resembled South American species. The similarities of Galapagos species to South American species were particularly striking considering that the Galapagos Islands are dry and rocky and the nearest part of South America is humid and has a lush tropical rain forest. Darwin concluded that species from the neighboring continent migrated or were carried to the islands, where they subsequently adapted to the new environment and, in the process, evolved into new species.

If evolution was not a factor in the distribution of species, we would expect to find a given species everywhere that it could survive. However, the geographical distribution of organisms that actually exists makes sense in the context of evo-

Figure 17-14 Similarities in vertebrate embryological development. The early stages of embryonic development are almost identical in different vertebrate species. Numerous structural similarities are shared by the early stages, including the presence of gill pouches and a tail.

lution. For example, Australia, which has been a separate land mass for millions of years, has distinctive organisms. Australia has populations of egg-laying mammals (monotremes) and pouched mammals (marsupials) not found anywhere else. Two hundred million years ago, Australia and the other continents were joined together in a major land mass (see Chapter 19). Over the course of millions of years, the Australian continent gradually separated from the others. The monotremes and marsupials in Australia continued to thrive and diversify. The isolation of Australia also prevented placental mammals, which arose elsewhere at a later time, from competing with its monotremes and marsupials. In other areas of the world where placental mammals occurred, most monotremes and marsupials became extinct. (Biogeography is discussed further in Chapter 52.)

Molecular comparisons among organisms provide evidence for evolution

Evidence for evolutionary relationships is provided by similarities and differences in the biochemistry and molecular biology of various organisms. Indeed, lines of descent based solely on biochemical and molecular characters closely resemble lines of descent based on structural and fossil evidence. Molecular evidence for evolution includes the universal genetic code and the conserved sequences of amino acids in proteins and of nucleotides in DNA.

The genetic code is universal

Organisms owe their characteristics to the types of proteins that they possess, which in turn are determined by the sequence of nucleotides in their mRNA (as specified by the order of nucleotides in their DNA). Evidence that all life is related comes from the fact that all organisms use a genetic code that is virtually identical. Recall from Chapter 12 that the genetic code specifies a triplet (a sequence of three nucleotides in DNA) that codes for a particular codon (a sequence of three nucleotides in mRNA) that codes for a particular amino acid in a polypeptide chain. For example, “AAA” in DNA codes for “UUU” in mRNA, which codes for the amino acid phenylalanine in organisms as diverse as shrimp, humans, bacteria, and tulips. In fact, “AAA” codes for phenylalanine in *all* organisms examined to date.

The universality of the genetic code—no other code has been found in any organism—is compelling evidence that all organisms arose from a common ancestor. The genetic code has been maintained and transmitted through all branches of the evolutionary tree since its origin in some extremely early (and successful) organism.

Proteins contain a record of evolutionary change

Darwin’s theory that all species are related through descent with modification from the earliest organisms has been further

TABLE 17–1 Differences in Nucleotide Sequences in DNA as Evidence of Phylogenetic Relationships*

Species Pairs	Percent Divergence in a Selected DNA Sequence [†]
Human–chimpanzee	1.7
Human–gorilla	1.8
Human–orangutan	3.3
Human–gibbon	4.3
Human–rhesus monkey (Old World monkey)	7.0
Human–spider monkey (New World monkey)	10.8
Human–tarsier	24.6

[†]Noncoding sequences of β -globin genes.

supported by evidence from molecular biology. Investigations of the sequence of amino acids in proteins that play the same roles in many species have revealed both great similarities and certain specific differences.

Even organisms that are remotely related, such as humans, fruit flies, sunflowers, and yeasts, share some proteins, such as cytochrome *c*, which is part of the electron transport chain in aerobic respiration. To survive, all aerobic organisms need a respiratory protein with the same basic structure and function as the cytochrome *c* of their common ancestor. Consequently, not all of the amino acids that confer the structural and functional features of cytochrome *c* are free to change. Any mutations that changed the amino acid sequence at structurally important sites of the cytochrome *c* molecule would have been harmful, and natural selection would have prevented such mutations from being passed to future generations. However, in the course of the long, independent evolution of different organisms, mutations have resulted in the substitution of many amino acids at less important locations in the cytochrome *c* molecule. The greater the differences in the amino acid sequences of their cytochrome *c* molecules, the longer it is thought to have been since two organisms diverged.

DNA contains a record of evolutionary change

Because a protein's amino acid sequences are coded in DNA,³ the differences in amino acid sequences indirectly demonstrate

³Of course, not all DNA codes for proteins (witness introns and tRNA genes). However, DNA sequencing of non-protein-coding DNA is also useful in determining evolutionary relationships.

the nature and number of underlying DNA base-pair changes that must have occurred during evolution. Such molecular information is determined directly by **DNA sequencing**, in which the order of nucleotide bases in DNA is determined. Generally, the more closely species are thought to be related on the basis of other scientific evidence, the greater the percentage of nucleotide sequences that their DNA molecules have in common. By using the DNA sequence data in Table 17–1, for example, you can conclude that the closest living relative of humans is the chimpanzee (because its DNA has the lowest percentage differences in the sequence examined). Which of the primates in Table 17–1 is the most distantly related to humans?

A **phylogenetic tree**, a diagram showing lines of descent, can be derived from differences in a given DNA nucleotide sequence. Such a phylogenetic tree for selected primates is depicted in Figure 17–15. (See *Making the Connection: Molecular Clocks, Evolution, and Genetics* for a discussion of how DNA sequencing is used to estimate the time of divergence between two closely related species or taxonomic groups.)

Figure 17–15 Phylogenetic tree of selected primates. This diagram, which is based on the DNA sequence percentage differences given in Table 17–1, is compatible with fossil and structural evidence. Closely related organisms, such as chimpanzees and humans, show fewer differences in their nucleotide sequences. More distantly related organisms, such as spider monkeys and humans, show greater differences in their nucleotide sequences.

MAKING THE CONNECTION

MOLECULAR CLOCKS, EVOLUTION, AND GENETICS

Can biologists interested in studying evolutionary relationships make use of the fact that mutations in DNA nucleotide sequences have been occurring throughout the course of evolution? Within a given taxonomic group, mutations are assumed to have occurred at a fairly steady rate over millions of years. Thus, the more differences you find in the same sequences of DNA of one species compared with another, the more time must have elapsed since the two diverged from a common ancestor. (The *same* DNA sequence refers to the nucleotide codes for homologous sections of DNA in the species being compared.)

From the number of alterations in the same DNA sequence taken from different organisms, we can develop a **molecular clock** to estimate the time of divergence between two closely related species or higher taxonomic groups. The clock is calibrated by comparing the number of nucleotide changes with the dates of evolutionary branch points that are known from the fossil record.

Such molecular clocks can be used to complement geological estimates of the divergence of species or to assign tentative dates to evolutionary events that lack fossil evidence. Molecular clocks are also used, along with fossil evidence and structural data, to help reconstruct **phylogeny**, which is the evolutionary history of a group of related species (see Chapter 22). By assigning tentative dates to the divergence of species, molecular clocks show the relative order of branch points in phylogeny.

Molecular clocks must be developed and interpreted with care. The rates of mutation appear to vary among different genes and among distantly related taxonomic groups. Therefore, although some mutations occur at a fairly uniform rate for species that are closely related, a single molecular clock for all genes in all species cannot be established.

Evolutionary hypotheses can be tested experimentally

Increasingly, biologists are designing imaginative experiments, often in natural settings, to test evolutionary hypotheses. David Reznick from the University of California at Riverside and John Endler from James Cook University in Australia, for example, have studied evolution in guppy populations in Venezuela and Trinidad, a small island in the southern Caribbean.

Reznick and Endler observed that different streams have different kinds and numbers of fishes that prey on guppies. Predatory fish that prey on larger guppies are present at lower elevations in all streams; these areas of intense predation pressure are known as *high predation habitats*. Predators are often excluded from tributaries or upstream areas by rapids and waterfalls. The areas above such barriers are known as *low predation habitats* because they contain only one species of small predatory fish that occasionally eat smaller guppies.

Differences in predation are correlated with many differences in the guppies, including male coloration, behavior, and attributes known as *life history traits*, including age and size at sexual maturity, the number of offspring per litter, the size of the offspring, and the frequency of reproduction. For example, guppy adults are larger in streams at higher elevations and smaller in streams at lower elevations. Reznick and colleagues have studied these life history traits and considered the role that predators might have played in the evolution of differences in life histories.

Reznick and his colleagues paid particular attention to the differences in guppy size, hypothesizing that these differences are related to predator preferences. However, they first had to

rule out the possibility that some unknown environmental factor was responsible for the size differences. To determine this, they captured adult female guppies from high and low predation habitats in Trinidad and sent them to their laboratory. They exploited a convenient property of guppy reproductive biology, which is that adult females are virtually always pregnant. Because these females store sperm, each female was able to produce a series of litters when she was isolated in the laboratory. The offspring of each female were then mated to produce a second generation. All the guppies were reared in identical predator free laboratory environments.

The second generation of guppies from low predation environments grew into larger, later maturing adults. Conversely, the second generation from high predation environments grew into smaller adults that matured at an earlier age. It is assumed that any differences among guppy populations that persist after two generations in identical laboratory environments have a genetic basis. This experiment therefore demonstrated that differences in size between the two populations were inherited; that is, they were not caused by some nongenetic factor, such as the availability of food.

Genetic differences between the two guppy populations are of particular interest because ecologists had predicted before this study that higher mortality rates found in high predation habitats would select for earlier maturity and smaller size at maturity. These predicted life history differences are consistent with the genetic differences observed among these populations of guppies.

Do predators actually cause these differences to evolve? Reznick and colleagues tested this evolutionary hypothesis by conducting field experiments in Trinidad. Taking advantage of waterfalls that prevent upstream movement of guppies

Figure 17–16 Experimental evidence of natural selection in guppies. Male and female guppies from a stream in which the predators preferred large adult guppies as prey (*red bars*) were transferred to a stream in which the predators preferred juveniles and small adults. After 11 years, the descendants of these guppies (*blue bars*) were measurably larger in size, compared to their ancestors. (Data from Reznick et al, *Science*, Vol. 275, 28 March 1997.)

and/or guppy predators, they moved either guppies or guppy predators over such barriers. For example, guppies from a high predation habitat were introduced into a low predation habitat by moving them over a barrier waterfall, into a section of stream that was free of guppies and large predators. The only fish species that lived in this section of stream prior to the introduction was the predator that occasionally preyed on small guppies.

Eleven years later, they captured adult females from the introduction site (low predation habitat) and the control site

below the barrier waterfall (high predation habitat). They bred these females in their laboratory and compared the life histories of succeeding generations, as in the earlier study. The descendants of guppies introduced into the low predation habitat matured at an older age and larger size than the descendants of guppies collected from the control site below the waterfall (Fig. 17–16). They also produced fewer, but larger, offspring. The life histories of the introduced fish had therefore evolved to be similar to those of fish that are typically found in such low predation habitats. These and other studies have also demonstrated that the predators have played an active role in the evolution of other traits, such as average number of offspring produced during the lifetime of an individual female (fecundity), male coloration, and behavior.

Such experiments demonstrate that evolution is not only real, but that it is occurring now, driven by selective forces, such as predation, that can be experimentally manipulated. Darwin incorrectly assumed evolution is so gradual that humans cannot observe it. As Jonathan Weiner, author of *The Beak of the Finch: A Story of Evolution in Our Time*, puts it, “Darwin did not know the strength of his own theory. He vastly underestimated the power of natural selection. Its action is neither rare nor slow. It leads to evolution daily and hourly, all around us, and we can watch.”

SUMMARY WITH KEY TERMS

- I. **Evolution**, the genetic change in a **population** of organisms over time, is the unifying concept of biology.
- II. Charles Darwin and Alfred Wallace independently proposed the theory of evolution by **natural selection**, which is based on four observations:
 - A. **Overproduction**: Each species produces more offspring than will survive to maturity.
 - B. **Variation**: Genetic variation exists among the individuals in a population.
 - C. **Limits on population growth**: Organisms compete with one another for the resources needed for life, such as food, living space, water, light, and so on.
 - D. **Differential reproductive success**: The offspring with the most favorable combination of characteristics are most likely to survive and reproduce, passing those genetic characteristics to the next generation. Thus, natural selection results in **adaptations**, which are evolutionary modifications that improve the chances of survival and reproductive success in a particular environment.
- E. Over time, enough changes may accumulate in geographically separated populations (often with slightly different environments) to produce new species.
- III. The **synthetic theory of evolution**, or **neo-Darwinism**, combines Darwin's theory of evolution by natural selection with modern genetics to explain how species adapt to their environment.
 - A. **Mutation** provides the genetic variability that natural selection acts on during evolution.
 - B. The synthetic theory of evolution emphasizes the genetics of populations rather than of individuals.
- IV. The concept that evolution has occurred and is occurring is now well documented.
 - A. Direct evidence of evolution comes from **fossils**, the remains or traces of ancient organisms.
 - B. Evidence supporting evolution is derived from comparative anatomy.

1. **Homologous** features have basic structural similarities, even though the structures may be used in different ways, because they derive from the same structure in a common ancestor. Homologous features indicate evolutionary affinities among the organisms possessing them.
 2. **Homoplastic** features have similar functions in quite different, distantly related organisms. Homoplastic features demonstrate **convergent evolution**, in which organisms with separate ancestries adapt in similar ways to comparable environmental demands.
 3. **Vestigial structures** are nonfunctional or degenerate remnants of structures that were present and functional in ancestral organisms. Structures occasionally become vestigial as species adapt to different modes of life.
- C. Developmental biology provides evidence of evolution.
1. The embryos of different vertebrates are more similar than the adults.
 2. The accumulation of genetic changes since organisms **diverged**,

or took separate evolutionary pathways, has modified the pattern of development in more complex vertebrate embryos.

- D. **Biogeography**, the distribution of plants and animals, supports evolution. Areas that have been separated from the rest of the world for a long time have organisms that are unique to those areas.
- E. Molecular biology provides evidence of evolution.
1. The universality of the genetic code is compelling evidence that all life is related.
 2. The sequence of amino acids in common proteins reveals greater similarities in closely related species.
 3. A greater proportion of the nucleotide sequence in DNA is identical in closely related organisms.
- F. Experimental data provide evidence of evolution.
1. Reznick has studied the effects of predation intensity on the evolution of guppy populations in both the laboratory and nature.
 2. Such experiments are a powerful way for investigators to test the underlying processes of natural selection.

POST - TEST

1. Evolution is based on which of the following concepts? (a) organisms share a common origin (b) over time, organisms have diverged from a common ancestor (c) an animal's body parts can change over its lifetime, and these acquired changes can be passed to the next generation (d) a and b are correct (e) a, b, and c are correct
2. Jewish and Muslim men have been circumcised for many generations, yet this practice has had no effect on the penile foreskin of their offspring. This observation disproves evolution as envisioned by (a) Lamarck (b) Darwin (c) Wallace (d) a and c are correct (e) b and c are correct
3. Which of the following is *least* likely to have occurred after the first small population of finches reached the Galapagos Islands from the South American mainland? (a) after many generations, the finches became increasingly different from the original population (b) over time, the finches adapted to their new environment (c) after many generations, the finches were unchanged and unmodified in any way (d) the finches were unable to survive in their new home and died out
4. Which of the following is *not* part of Darwin's mechanism of evolution? (a) differential reproductive success (b) variation in a population (c) inheritance of acquired (nongenetic) traits (d) overproduction of offspring (e) struggle for existence
5. The fossil record (a) usually occurs in sedimentary rock (b) sometimes appears fragmentary (c) is relatively complete for tropical rainforest organisms but incomplete for aquatic organisms (d) a and b are correct (e) a, b, and c are correct
6. The molecular record found inside cells suggests that evolutionary changes are caused by an accumulation of (a) traits acquired through need (b) alterations in the order of nucleotides in DNA (c) characters acquired during an individual's lifetime (d) hormones (e) environmental changes
7. Darwin proposed _____ as the mechanism by which evolutionary change takes place. (a) natural selection (b) homoplasy (c) convergent evolution (d) mutation (e) homology
8. In _____, the selecting agent is the environment, whereas in _____, the selecting agent is humans. (a) natural selection; convergent evolution (b) mutation; artificial selection (c) homoplasy; homology (d) artificial selection; natural selection (e) natural selection; artificial selection
9. Structures that are similar in underlying form in different species due to a common evolutionary origin are called (a) homoplastic (b) homologous (c) vestigial (d) convergent (e) synthetic
10. Aardvarks, anteaters, and pangolins are similar in structure and form as a result of (a) homology (b) convergent evolution (c) biogeography (d) vestigial structures (e) artificial selection
11. The species of the Galapagos Islands (a) are similar to those on the Cape Verde Islands (b) are similar to those on the South American mainland (c) are identical to those on the Cape Verde Islands (d) are identical to those on the South American mainland (e) are similar to those on both the African and South American mainlands

REVIEW QUESTIONS

1. Explain briefly the concept of evolution by natural selection.
2. Why are only inherited variations important in the evolutionary process?
3. What part of Darwin's theory was he unable to explain? How does the synthetic theory of evolution explain this?
4. How do scientists date fossils? How do fossils provide evidence of evolution?
5. Distinguish among homologous features, homoplastic features, and vestigial structures. How does each provide evidence of evolution?
6. How does developmental biology provide evidence of a common ancestry for vertebrates as diverse as reptiles, birds, pigs, and humans?
7. Explain why there are many species of marsupials in Australia and only a few elsewhere.
8. What is indicated if the DNA from two species is found to be almost identical?
9. Explain how predator preference drives the evolution of guppies.

YOU MAKE THE CONNECTION

- Although most salamanders have four legs, a few species that live in shallow water lack hind limbs and have extremely tiny forelimbs (see *photograph*). Develop a hypothesis to explain how limbless salamanders came about according to Darwin's mechanism of evolution by natural selection. How could you test your hypothesis?
- What adaptations must an animal possess in order to swim in the ocean? Why are such genetically different organisms as porpoises, which are mammals, and sharks, which are fish, so similar in form?
- The human fetus grows a coat of fine hair, the lanugo, that is shed before or shortly after birth. Chimpanzee and other primate fetuses also grow coats of hair, but they are not shed. Explain these observations based on what you have learned in this chapter.
- Write a short paragraph explaining each of the following statements:
 - Natural selection chooses from among the individuals in a population those most suited to *current* environmental conditions. It does not guarantee survival under future conditions.
 - Individuals do not evolve, but populations do.
 - The organisms that exist today do so because their ancestors possessed traits that allowed them and their offspring to thrive.
 - At the molecular level, evolution takes place by the replacement of one nucleotide by another.
 - Evolution is said to have occurred within a population when measurable genetic changes are detected.

The narrow-striped dwarf siren (*Pseudobranchius striatus axanthus*). This aquatic salamander, which is native to Florida, resembles an eel. (Suzanne L. Collins and Joseph T. Collins/Photo Researchers, Inc.)

CHAPTER 18

Evolutionary Change in Populations

As we saw in Chapter 17, evolution occurs in populations, not individuals. Although natural selection results from differential survival and reproduction of individuals, individuals do not evolve during their lifetimes. Evolutionary change, which includes modifications in structure, physiology, ecology, and behavior, is inherited from one generation to the next. Although Darwin recognized that evolution occurs in populations, he did not understand how traits are passed to successive generations. One of the most significant advances in biology since Darwin's time has been the demonstration of the genetic basis of evolution.

Recall from Chapter 17 that a **population** consists of all the individuals of the same species that live in a particular place at the same time. Individuals within a population vary in many recognizable traits. A population of snails, for example, may vary in shell size, weight, or color. Some of this variation is due to the environment, and some is due to heredity. Evolution is concerned with heritable traits, that is, with genetic variation as represented by the number, frequency, and kinds of alleles in a population. For example, the photograph shows genetic variation in the shell patterns and colors in a snail species (*Cepaea nemoralis*), native to Scotland. Variation in shell color may have adaptive value in these snails, as some colors predominate in cooler environments, whereas other colors are more common in warmer habitats.

Each population possesses a **gene pool**, which is the total genetic material of all the individuals that make up that population and includes all the alleles for all the genes present in the population. Because diploid ($2n$) organisms possess a maximum of two different alleles at each genetic locus, a single individual typically has only a small fraction of the alleles present in a population's gene pool. The genetic variation that is evident among individuals in a given population indicates that each individual has a different combination of the alleles in the gene pool.

(G.I. Bernard/Animals Animals)

The evolution of populations is best understood in terms of allele frequencies. An **allele frequency** is the percentage of a specific allele of a given gene locus in the population. If the allele frequencies remain constant from generation to generation, the population is not undergoing evolutionary change, and it is said to be in **genetic equilibrium**. Changes in allele frequencies over successive generations, however, indicate that evolution has occurred.

In this chapter we contrast genetic equilibrium with evolutionary change and discuss the five factors responsible for evolutionary change: nonrandom mating, mutation, genetic drift, gene flow, and natural selection. We then consider genetic variation as the raw material for evolution.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Define population, allele frequency, genetic equilibrium, and microevolution.
2. Discuss the significance of the Hardy-Weinberg principle as it relates to evolution and list the five conditions required for genetic equilibrium.
3. Use the Hardy-Weinberg principle to solve problems involving populations at genetic equilibrium.
4. Discuss how each of the following alters allele frequencies in populations: nonrandom mating, mutation, genetic drift, gene flow, and natural selection.
5. Distinguish among stabilizing selection, directional selection, and disruptive selection, and give an example of each.
6. Describe the nature and extent of genetic variation, including genetic polymorphism, balanced polymorphism, neutral variation, and geographical variation.
7. Explain how the sickle cell allele illustrates heterozygote advantage.
8. Relate how frequency-dependent selection affects genetic variation.

THE HARDY-WEINBERG PRINCIPLE DESCRIBES GENETIC EQUILIBRIUM

Consider a trait determined by a single gene locus with two alleles, A and a , that follow simple Mendelian dominance. When you examine a hypothetical natural population of 1000 individuals, you observe that only 90 exhibit the recessive phenotype characteristic of the genotype aa . The remaining 910 individuals exhibit the dominant phenotype and are either AA or Aa . You might assume that, after many generations, genetic recombination during sexual reproduction would cause the dominant allele to become more common in the population. You might even assume that the recessive allele would eventually disappear altogether. However, your assumptions would be incorrect, as the frequencies of alleles and genotypes would not change from generation to generation unless influenced by outside factors that will be discussed shortly.

A population whose allele and genotype frequencies do not change from generation to generation is said to be at genetic equilibrium. The explanation for the stability of successive generations in populations at genetic equilibrium was provided independently by Godfrey Hardy, an English mathematician, and Wilhelm Weinberg, a German physician, in 1908. They pointed out that the expected frequencies of various genotypes in a population can be described mathematically. The resulting **Hardy-Weinberg principle** shows that in large populations the process of inheritance does not by itself cause changes in allele frequencies. It also explains why dominant alleles are not necessarily more common than recessive ones. The Hardy-Weinberg principle represents an ideal situation that probably never occurs in the natural world. However, it is useful because it provides a model to help us understand the real world. Knowledge of the Hardy-Weinberg principle is essential to understanding the mechanisms of evolutionary change in sexually reproducing populations.

We now expand our original example to illustrate the Hardy-Weinberg principle. The frequency of either allele, A or a , is described by a number that ranges from zero to one. An allele that is totally absent from the population has a frequency

of zero. If all the alleles of a given locus are the same in the population, then the frequency of that allele is one.

Because only two alleles, A and a , exist at the locus in our example, the sum of their frequencies must equal one. If we let p represent the frequency of the dominant (A) allele in the population, and q the frequency of the recessive (a) allele, then we can summarize their relationship with a simple binomial equation, $p + q = 1$. When we know the value of either p or q , we can calculate the value of the other: $p = 1 - q$ and $q = 1 - p$.

Because $p + q = 1$, then $(p + q)^2 = 1$. This binomial equation can be expanded to describe the relationship of the allele frequencies to the genotypes in the population. When it is expanded, we obtain the frequency of the offspring genotypes:

$$\begin{array}{ccccccc} p^2 & + & 2pq & + & q^2 & = & 1 \\ \text{Frequency of } AA & & \text{Frequency of } Aa & & \text{Frequency of } aa & & \text{All the individuals} \\ & & & & & & \text{in a population} \end{array}$$

From the fact that we had 90 homozygous recessive individuals in our population of 1000, we infer that the frequency of the aa genotype, q^2 , is 90/1000, or 0.09. Since q^2 equals 0.09, q is equal to the square root of 0.09, or 0.3. From the relationship between p and q , we conclude that $p = 1 - q = 1 - 0.3 = 0.7$.

Based on this information, we can calculate the frequency of homozygous dominant individuals (AA): $p^2 = 0.7 \times 0.7 = 0.49$ (Fig. 18–1). The frequency of heterozygous individuals, Aa , would be: $2pq = 2 \times 0.7 \times 0.3 = 0.42$. Thus, approximately 490 individuals are expected to be homozygous dominant, and 420 heterozygous. Note that the sum of homozygous dominant and heterozygous individuals equals 910, the number with which we began.

Any population in which the distribution of genotypes conforms to the relation $p^2 + 2pq + q^2 = 1$, whatever the absolute values for p and q may be, is at genetic equilibrium. *The Hardy-Weinberg principle of genetic equilibrium tells us what to expect when a sexually reproducing population is not evolving.* The proportion of alleles in successive generations will always be the same, provided the following five conditions are met:

Genotypes	AA	Aa	aa
Frequency of genotypes in population	0.49	0.42	0.09
Frequency of alleles in gametes	A = 0.49 + 0.21 = 0.7		a = 0.21 + 0.09 = 0.3

		$p = 0.7$	$q = 0.3$				
Allele frequencies in male gametes		<table><tr><td>AA</td><td>Aa</td></tr><tr><td>$p^2 = 0.7 \times 0.7 = 0.49$</td><td>$pq = 0.7 \times 0.3 = 0.21$</td></tr></table>	AA	Aa	$p^2 = 0.7 \times 0.7 = 0.49$	$pq = 0.7 \times 0.3 = 0.21$	
	AA	Aa					
$p^2 = 0.7 \times 0.7 = 0.49$	$pq = 0.7 \times 0.3 = 0.21$						
		<table><tr><td>Aa</td><td>aa</td></tr><tr><td>$pq = 0.7 \times 0.3 = 0.21$</td><td>$q^2 = 0.3 \times 0.3 = 0.09$</td></tr></table>	Aa	aa	$pq = 0.7 \times 0.3 = 0.21$	$q^2 = 0.3 \times 0.3 = 0.09$	
Aa	aa						
$pq = 0.7 \times 0.3 = 0.21$	$q^2 = 0.3 \times 0.3 = 0.09$						
		$p = 0.7$	$q = 0.3$				

(b)

(b)

Figure 18–1 The Hardy-Weinberg principle. (a) How to calculate the frequencies of the alleles *A* and *a* in the gametes. (b) When eggs and sperm containing *A* or *a* alleles unite randomly, the frequency of each of the possible genotypes (*AA*, *Aa*, *aa*) among the offspring is calculated by multiplying the frequencies of the alleles *A* and *a* in eggs and sperm.

- 1. Random mating.** In unrestricted random mating, each individual in a population has an equal chance of mating with any individual of the opposite sex. In our example, the individuals represented by the genotypes *AA*, *Aa*, and *aa* must mate with one another at random and must not select their mates on the basis of genotype.
- 2. No net mutations.** There must be no mutations that convert *A* into *a* or vice versa. That is, the frequencies of *A* and *a* in the population must not change due to mutations.
- 3. Large population size.** Allele frequencies in a small population are more likely to be changed by random fluctuations (that is, by genetic drift, discussed shortly) than are allele frequencies in a large population.
- 4. No migration.** There can be no exchange of genes with other populations that might have different allele frequencies. In other words, there can be no migration of individuals into or out of a population.

5. No natural selection. If natural selection is occurring, certain phenotypes (and their corresponding genotypes) are favored over others. Consequently, the allele frequencies will change, and the population will evolve.

The Hardy-Weinberg principle allows biologists to calculate allele frequencies in a given population if we know the genotype frequencies, and vice versa. These values can be used as a basis of comparison with a population's allele or genotype frequencies in succeeding generations. During that time, if the allele or genotype frequencies deviate from the values predicted by the Hardy-Weinberg principle, then the population is evolving. (You can test your understanding of the Hardy-Weinberg principle by solving the problems in the Review Questions at the end of this chapter.)

MICROEVOLUTION OCCURS WHEN A POPULATION'S ALLELE OR GENOTYPE FREQUENCIES CHANGE

Evolution represents a departure from the Hardy-Weinberg principle of genetic equilibrium, and the degree of departure between the observed allele or genotype frequencies and those expected by the Hardy-Weinberg principle indicates the amount of evolutionary change. This type of evolution—generation-to-generation changes in allele or genotype frequencies *within* a population—is sometimes referred to as **microevolution** because it involves relatively small or minor changes that occur, usually over a few generations. Changes in the allele frequencies of a population result from five microevolutionary processes: nonrandom mating, mutation, genetic drift, gene flow, and natural selection. When one or more of these processes is acting on a population, allele or genotype frequencies will change from one generation to the next.

NONRANDOM MATING CHANGES GENOTYPE FREQUENCIES

When individuals select mates on the basis of phenotype (thereby selecting the corresponding genotype), they can bring about evolutionary change in the population. Two examples of nonrandom mating are inbreeding and assortative mating.

In many populations, individuals mate more often with close neighbors than with more distant members of the population. As a result, neighbors tend to be more closely related—that is, genetically similar—to one another. The mating of genetically similar individuals that are more closely related than if they had been chosen at random from the entire population is known as **inbreeding**. Homozygosity increases with each successive generation of inbreeding. The most extreme example of inbreeding is self-fertilization, which is particularly common in plants.

Figure 18–2 Survivorship of inbred and noninbred mice. The mouse population was sampled six times during a 10-week period. Noninbred mice (red) had a higher survivorship than inbred mice (blue). (Adapted from Jiménez et al., *Science*, Vol. 266, 14 Oct. 1994.)

Inbreeding does not appear to be detrimental in some populations, but in others it causes **inbreeding depression**, in which inbred individuals have lower fitness than noninbred individuals. Inbreeding depression—as evidenced by fertility declines and high juvenile mortality—is thought to be caused by the expression of harmful recessive alleles as homozygosity increases with inbreeding.

Several studies in the 1990s have provided direct evidence of inbreeding depression in nature. For example, white-footed mice (*Peromyscus leucopus*) were taken from a field and used to develop both inbred and noninbred populations in the labo-

ratory. When these laboratory-bred populations were returned to nature, their survivorship was estimated from release-recapture data. The noninbred mice had a statistically significant higher rate of survivorship (Fig. 18–2).

Assortative mating, in which individuals select mates by their phenotypes, is another example of nonrandom mating. For example, biologists selected two phenotypes—high bristle number and low bristle number—in a fruit fly (*Drosophila melanogaster*) population. Although they made no effort to control mating, they observed that the flies preferentially mated with those of similar phenotypes, that is, females with high bristle number tended to mate with males with high bristle number, and females with low bristle number tended to mate with males with low bristle number. Assortative mating is also practiced in many human societies, in which men and women tend to marry individuals like themselves in such characters as height, race, or intelligence. Like inbreeding, assortative mating increases homozygosity at the expense of heterozygosity in the population, but it does not change the overall allele frequencies in the population. Because nonrandom mating changes genotype frequencies, however, it does cause populations to evolve.

MUTATION INCREASES VARIATION WITHIN A POPULATION

Variation is introduced into a population through **mutation**, which is an unpredictable change in DNA (Fig. 18–3). Mutations, which are the source of all new alleles, can result from (1) a change in the nucleotide base pairs of a gene, (2) a rearrangement of genes within chromosomes so that their interactions produce different effects, or (3) a change in the chro-

Figure 18–3 Fruit fly (*Drosophila melanogaster*) mutation. (a) A normal fly. (b) A mutant with vestigial wings. Because mutations are random changes in genetic material, most mutations are neutral or harmful to the organism. Yet for island-dwelling insects, fully developed wings might be more of a disadvantage than an advantage, permitting the insect to be too easily blown away from land. Perhaps for this reason, flies and other insects that live on small islands frequently have reduced wings or are entirely wingless. (a, b, Peter J. Bryant/Biological Photo Service)

mosomes. Mutations occur unpredictably and spontaneously. The rate of mutation appears to be relatively constant for a particular gene but may vary by several orders of magnitude among genes within a single species and among different species.

Not all mutations pass from one generation to the next. Those occurring in somatic (body) cells are not heritable. When an individual with such a mutation dies, the mutation is lost. Some mutations, however, occur in reproductive cells. These mutations may or may not overtly affect the offspring, because most of the DNA in a cell is “silent” and does not code for specific polypeptides or proteins that are responsible for physical characteristics. Even if a mutation occurs in the DNA that codes for a polypeptide, it may still have little effect on the structure or function of that polypeptide (we discuss such *neutral variation* later in the chapter). However, when the polypeptide is sufficiently altered to change its function, the mutation is usually harmful. By acting against seriously abnormal phenotypes, natural selection eliminates or reduces to low frequencies the most harmful mutations. Small mutations, even those with slightly harmful phenotypic effects, have a better chance of being incorporated into the population, where at some later time, under different environmental conditions, they may produce traits that are helpful or adaptive for the population.

Mutations do not determine the *direction* of evolutionary change. Consider a population living in an increasingly dry environment. A mutation producing a new allele that helps an individual adapt to dry conditions is no more likely to occur than one for adapting to wet conditions or one with no relationship to the changing environment. The production of new mutations simply increases the genetic variability that can be acted on by natural selection and, therefore, the potential for new adaptations.

Mutation by itself causes small deviations in allele frequencies from those predicted by the Hardy-Weinberg principle. Although allele frequencies may be changed by mutation, these changes are typically several orders of magnitude smaller than changes caused by other evolutionary forces, such as genetic drift. As an evolutionary force, mutation is usually negligible, but it is important as the ultimate source of variation.

IN GENETIC DRIFT RANDOM EVENTS CHANGE ALLELE FREQUENCIES

The size of a population has important effects on allele frequencies because random events, or chance, will tend to cause changes of relatively greater magnitude in a small population. If a population consists of only a few individuals, an allele present at a low frequency in the population could be completely lost purely by chance. Such an event would be most unlikely in a large population. For example, consider two populations, one with 10,000 individuals and one with 10 individuals. If

an uncommon recessive allele occurs at a frequency of 10%, or 0.1, then 1900 individuals in the large population possess the allele.¹ That same frequency, 0.1, in the smaller population means that only about 2 individuals possess the allele.² From this exercise, it is easy to see that there is a greater likelihood of losing the rare allele from the smaller population than from the larger one. Predators, for example, might happen to kill one or two individuals possessing the uncommon allele in the smaller population purely by chance.

The production of random evolutionary changes in small breeding populations is known as **genetic drift**. Genetic drift results in allele frequency changes in a population from one generation to another. One allele may be eliminated from the population by chance, regardless of whether that allele is beneficial, harmful, or of no particular advantage or disadvantage. Thus, genetic drift can decrease genetic variation *within* a population, although it tends to increase the genetic differences *among* different populations.

When genetic bottlenecks occur, genetic drift becomes a major evolutionary force

Because of fluctuations in the environment, such as depletion in food supply or an outbreak of disease, a population may periodically experience a rapid and marked decrease in the number of individuals. The population is said to go through a **genetic bottleneck** during which genetic drift can occur in the small population of survivors. As the population again increases in size, many allele frequencies may be quite different from those in the population preceding the decline.

Scientists hypothesize that genetic variation in the cheetah was considerably reduced by a genetic bottleneck that occurred at the end of the last Ice Age, some 10,000 years ago. At that time, cheetahs nearly became extinct, perhaps due to overhunting by humans. The few surviving cheetahs possessed greatly reduced genetic variability, and as a result, the cheetah population today is nearly genetically uniform or homogeneous (see *Making the Connection: Cheetahs, Genetics, and Ecology*).

The founder effect occurs when a few “founders” establish a new colony

When one or a few individuals from a large population establish, or found, a colony (as when a few birds separate from the rest of the flock and fly to a new area), they bring with them only a small fraction of the genetic variation present in the original population. As a result, the only alleles represented

¹ $2pq + q^2 = 2(0.9)(0.1) + (0.1)^2 = 0.18 + 0.01 = 0.19$; $0.19 \times 10,000 = 1900$

² $0.19 \times 10 = 1.9$

MAKING THE CONNECTION

CHEETAHS, GENETICS, AND ECOLOGY

Are cheetahs (*Acinonyx jubatus*) endangered because of their extreme genetic uniformity or because of loss of habitat? The outlook for the cheetah's long-term survival is far from certain. There are currently fewer than 10,000 cheetahs in sub-Saharan Africa and northern Iran. For many years, lack of genetic diversity and inbreeding depression were considered the primary factors responsible for the cheetah's plight.

Evidence of the extreme genetic uniformity in cheetahs was demonstrated in the 1980s when biologists discovered that unrelated cheetahs accepted skin grafts from one another. (Normally, only identical twins accept skin grafts so readily.) Geneticists hypothesized that inbreeding depression was responsible for problems with cheetahs in captive breeding programs. Compared to other large cats, cheetah males exhibit low sperm counts, many of their sperm have abnormalities, and cheetah females do not bear as many offspring. Also, many cheetah offspring have health problems and are more susceptible to disease.

Notwithstanding the cheetah's genetic uniformity, ecologists who study cheetahs in nature say that inbreeding depression is not impairing the cheetah's chance of breeding success. They have observed that the main cause of juvenile mortality is predation—most young cheetahs are killed by lions or hyenas, not by the consequences of defective genes. Moreover, ecologists say that male cheetahs have no difficulty siring offspring in nature, despite their low sperm counts and high rates of sperm abnormalities.

Ecologists would like the focus on saving the cheetah to switch from genetic to environmental factors, that is, from captive breeding in zoos to what ecologists perceive as the real threat to the cheetah's survival—loss of habitat. While geneticists agree that protection of habitat should be the main focus in attempts to save the

The endangered cheetah. The most specialized member of the cat family, the cheetah is the world's fastest animal and has been clocked at 110 kilometers per hour (70 mph) for short distances. Despite its speed, this fascinating animal is a somewhat timid predator that often gives up its prey to more aggressive animals such as lions, vultures, and hyenas. (Fritz Pölking/Visuals Unlimited)

cheetah (and *all* endangered species) from extinction, they also emphasize that lack of genetic diversity should remain an important consideration in conservation strategies to save the cheetah.

among their descendants will be those few that the colonizers happened to possess. Typically, the allele frequencies in the newly founded population are very different from those of the parent population. The genetic drift that results when a small number of individuals from a large population colonize a new area is called the **founder effect**.

The founder effect has been observed in populations of wild plants on islands off the Pacific coast of Canada. The Canadian mainland has several wild species of small, weedy annuals in the daisy family. These plants produce wind-dispersed seeds with fluffy parachutes similar to dandelion fruits. The seeds of mainland populations range in size from small to large, as do the fluffy parachutes. Sampling of these plants on 240 islands off the Canadian coast over a 10-year period revealed that the youngest island populations produced signifi-

cantly smaller seeds than mainland populations. (Ages of island populations were easy to estimate because new colonizations occurred frequently.) This observation illustrates both the founder effect (only small seeds with large parachutes remain aloft to be blown by the wind to the nearby islands) and rapid evolutionary change by natural selection.

The Finnish people may also illustrate the founder effect (Fig. 18–4). Geneticists who sampled DNA from Finns and from the European population at large found that Finns exhibit considerably less genetic variation than other Europeans. This evidence supports the hypothesis that Finns are descended from a small group of people who settled in what is now Finland some 4000 years ago and, because of the geography and climate, remained separate from other European societies for centuries.

Figure 18–4 Finns and the founder effect. The Finnish people are thought to have descended from a small founding population that remained separate from the rest of Europe for centuries. (Courtesy of Embassy of Finland/MattiTirri)

GENE FLOW GENERALLY INCREASES VARIATION WITHIN A POPULATION

Members of a species tend to be distributed in local populations that are genetically isolated to some degree from other populations. For example, the bullfrogs of one pond form a population separated from those in an adjacent pond. Some exchanges occur by migration between ponds, but the frogs in one pond are much more likely to mate with those in the same pond. Members of most species tend to be distributed in such local populations. Because each population is isolated to some extent from other populations of the species, they can have distinct genetic traits and gene pools.

The migration of breeding individuals between populations causes a corresponding movement of alleles, or **gene flow**, that can have significant evolutionary consequences. As alleles flow from one population to another, they usually increase the amount of genetic variability within the recipient population. If sufficient gene flow occurs between two populations, they become more similar genetically. Because gene flow has a tendency to reduce the amount of variation between two populations, it tends to counteract the effects of natural selection and genetic drift, both of which often cause populations to become increasingly distinct.

If migration by members of a population is considerable, and if populations differ in their allele frequencies, then significant genetic changes can result. For example, by 10,000 years ago modern humans occupied all of Earth's major land areas except a few islands. Because the population density was low, the small, isolated human populations underwent random genetic drift and natural selection. More recently (during the

past 300 years or so), major migrations have caused an increase in gene flow, significantly altering allele frequencies within previously isolated human populations.

NATURAL SELECTION CHANGES ALLELE FREQUENCIES IN A WAY THAT INCREASES ADAPTATION

Natural selection is the mechanism of evolution first proposed by Darwin in which members of a population that possess more successful adaptations to the environment are more likely to survive and reproduce (see Chapter 17). Over successive generations, the proportion of favorable alleles increases in the population. In contrast to other microevolutionary processes (nonrandom mating, mutation, genetic drift, and gene flow), natural selection leads to adaptive evolutionary change. As a result, a population becomes better adapted to its environment. Natural selection not only explains why organisms are well adapted to the environments in which they live, but also helps to account for the remarkable diversity of life. Natural selection enables populations to change, thereby adapting to different environments and different ways of life.

Natural selection is the differential reproduction of individuals with different traits, or phenotypes (and therefore different genotypes), in response to the environment. Natural selection preserves individuals with favorable phenotypes and eliminates those with unfavorable phenotypes. Individuals that are able to survive and produce fertile offspring have a selective advantage.

The mechanism of natural selection does not cause the development of a “perfect” organism. Rather, it weeds out those individuals whose phenotypes are less adapted to environmental challenges, while allowing better adapted individuals to survive and pass their alleles to their offspring. By reducing the frequency of alleles that result in the expression of less favorable traits, the probability that favorable alleles responsible for an adaptation will come together in the offspring is increased.

Natural selection operates on an organism's phenotype

Natural selection does not act directly on an organism's genotype. Instead, it acts on the phenotype, which is, at least in part, an expression of the genotype. Natural selection acts on the heritable component of the phenotype, which represents an interaction of all the alleles in the organism's genotype. It is rare that a single gene has complete control over a single phenotypic trait, such as Mendel originally observed in garden peas. Much more common is the interaction of several genes

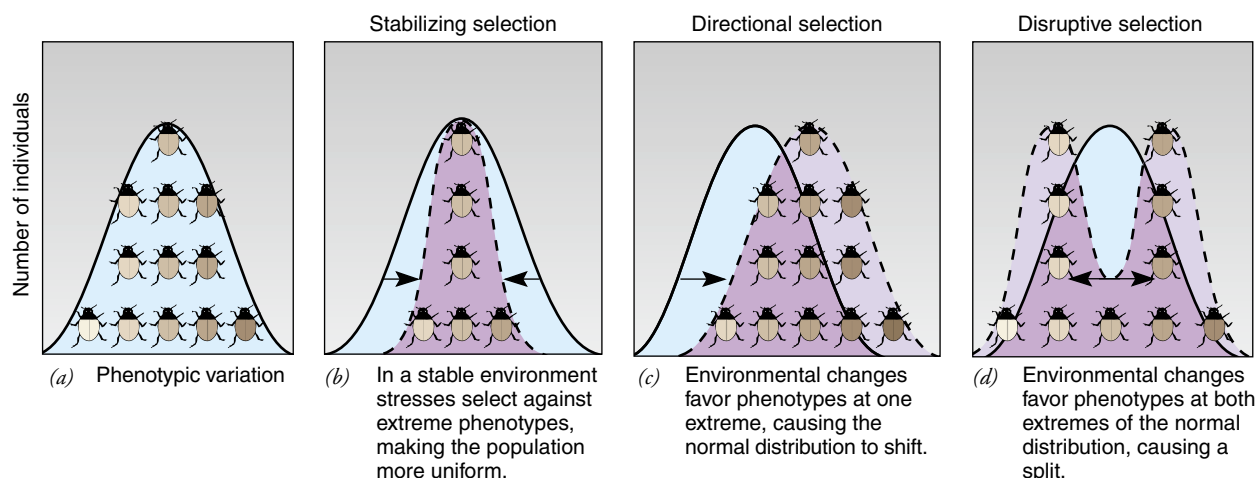

Figure 18–5 Modes of selection. (a) A trait that is under polygenic control (in this example, wing colors in a hypothetical population of beetles) exhibits a normal distribution of phenotypes in the absence of selection. (b) As a result of stabilizing selection, variation about the mean is reduced. (c) Directional selection shifts the curve in one direction. (d) Disruptive selection results in two or more peaks.

for the expression of a single trait (see Chapter 10). Many plant and animal characteristics are under this type of polygenic control.

When traits (human height, for example) are under polygenic control, a range of phenotypes occurs, with most of the population located in the median range and fewer at either extreme. This is a normal distribution or standard bell curve (Fig. 18–5a; see also Fig. 10–22). Three kinds of selection occur that cause changes in the normal distribution of phenotypes in a population: stabilizing, directional, and disruptive selection. Although we consider each process separately, their influences generally overlap in nature.

Stabilizing selection favors intermediate phenotypes

The process of natural selection associated with a population that is well adapted to its environment is known as **stabilizing selection**. Most populations are probably under the influence of stabilizing forces most of the time. Stabilizing selection selects against phenotypic extremes. In other words, individuals with an average, or intermediate, phenotype are favored.

One of the most widely studied cases of stabilizing selection involves human birth weight, which is under polygenic control and is also influenced by environmental factors. Extensive data from hospitals have shown that infants born with intermediate weights are more likely to survive (Fig. 18–6). Infants at either extreme (too small or too large) have higher rates of mortality. When newborn infants are too small, their body systems are immature, and when they are too large, they have difficult deliveries because they cannot pass as easily

through the cervix and vagina. Stabilizing selection operates to reduce the variability in birth weight so that it is close to the weight with the minimum mortality rate.

Because stabilizing selection tends to decrease variation by favoring individuals near the mean of the normal distribution

Figure 18–6 Stabilizing selection. Infants with very low or very high birth weights have higher death rates. The blue line indicates the percentage of infants born at each weight; the red line indicates percentage of deaths at each birth weight.

at the expense of those at either extreme, the bell curve narrows (Fig. 18–5*b*). Although stabilizing selection decreases the amount of variation in a population, variation is rarely eliminated by this process because other microevolutionary processes act against a decrease in variation. For example, mutation is slowly but continually adding to the genetic variation within a population.

Directional selection favors one phenotype over another

If an environment changes over time, **directional selection** may favor phenotypes at one of the extremes of the normal distribution (Fig. 18–5*c*). Over successive generations, one phenotype gradually replaces another. So, for example, if greater size is advantageous in a new environment, larger individuals will become increasingly common in the population. Directional selection can only occur, however, if alleles favored under the new circumstances are already present in the population.

Darwin's Galapagos finches provide an excellent example of directional selection. Since the 1970s, Peter and Rosemary Grant of Princeton University have studied the Galapagos finches, including a meticulous analysis of their eating habits and beak sizes during an extended drought that was followed by a flood on one of the islands (Fig. 18–7). During the drought, the number of insects and small seeds declined, and large, heavy seeds became the finches' primary food source. Many finches died during this time, and most of the survivors were larger birds whose beaks were larger and deeper. In a few generations, these larger birds became more common in the population. Following the flood, however, smaller seeds became the primary food source, and smaller finches with average-sized beaks were favored. In this example, natural selection is directional: during the drought, natural selection operated in favor of the larger phenotype, whereas following the flood, selection occurred in the opposite direction, favoring the smaller phenotype. The peppered moth population studied in England (see Chapter 1) and the guppy populations studied in Venezuela and Trinidad (see Chapter 17) are other examples of directional selection.

Disruptive selection favors phenotypic extremes

Sometimes extreme changes in the environment may favor two or more different phenotypes at the expense of the mean. That is, more than one phenotype may be favored in the new environment. **Disruptive selection** is a special type of directional selection in which there is a trend in several directions rather than just one (Fig. 18–5*d*). It results in a divergence, or splitting apart, of distinct groups of individuals within a population. Disruptive selection selects against the average, or intermediate, phenotype.

Figure 18–7 Directional selection. The beaks of Galapagos finches are highly variable, and biologists observed that different phenotypes were favored in different climate conditions. (a) Larger birds with large, deep beaks were favored during a period of extended drought when the main available food was large, heavy seeds. (b) Smaller finches with average-sized beaks were favored when the rains returned and the birds' primary food source was smaller seeds.

Limited food supply during a severe drought caused a population of finches on another island in the Galapagos to experience disruptive selection. The finch population initially exhibited a variety of beak sizes and shapes. Because the only food available during the drought was wood-boring insects and seeds from cactus fruits, natural selection favored birds with beaks suitable for obtaining these types of food. Finches with longer beaks survived because they could open cactus fruits, and those with wider beaks survived because they could strip off tree bark to expose insects. However, finches with intermediate beaks were unable to use either food source efficiently and consequently had a low survival rate.

Natural selection can induce change in the types and frequencies of alleles in populations only if there is preexisting inherited variation. Genetic variation is the raw material for evolutionary change, as it provides the diversity on which natural selection can act. Without genetic variation, evolution cannot occur. We now examine the genetic basis for variation that is acted on by natural selection.

GENETIC VARIATION IS NECESSARY FOR NATURAL SELECTION

Populations contain abundant genetic variation that was originally introduced by mutation. Sexual reproduction, with its associated crossing-over, independent assortment of chromosomes during meiosis, and random union of gametes, also contributes to genetic variation. The sexual process allows the variability introduced by mutation to be combined in new ways, which may be expressed as new phenotypes.

The effect of recombination can be surprisingly great. Recall from Chapter 10 that nine different genotypes are generated in a dihybrid cross ($AaBb \times AaBb$) involving only two loci, each with only two alleles.³ If we were dealing with five different unlinked loci, each with six alleles, the number of different genotypes possible would be 4,084,101!⁴ Because most organisms possess thousands of loci, the number of possible allele combinations is staggering. Some of the combinations may be adaptively superior and favored by natural selection.

Genetic polymorphism exists in genes and the proteins for which they code

One way of evaluating genetic variation in a population is to examine **genetic polymorphism**, which is the presence in a population of two or more alleles for a given locus. Genetic polymorphism is extensive in populations, although many of the alleles are present at low frequencies. Much of genetic polymorphism is not evident because it does not produce distinct phenotypes.

One way that biologists estimate the total amount of genetic polymorphism in populations is by comparing the different forms of a particular protein. Each form consists of a slightly different amino acid sequence that is coded for by a different allele. For example, tissue extracts containing a particular enzyme may be analyzed by gel electrophoresis (see Chapter 14) for different individuals. In gel electrophoresis, the enzymes are placed in slots on a gel, and an electric current is applied that causes each enzyme to migrate across the gel. Slight variations in amino acid sequences in the different forms of a particular enzyme cause each to migrate at a different rate, which can be detected using special stains or radioactive labels. Table 18–1 shows the degree of polymorphism in selected plant and animal groups based on gel elec-

TABLE 18 – 1 Genetic Polymorphism of Selected Enzymes within Plant and Animal Species		
Organism	Number of Species Examined	Percentage of Enzymes Studied that are Polymorphic
Plants		
Gymnosperms	55	70.9
Flowering plants (monocots)	111	59.2
Flowering plants (dicots)	329	44.8
Invertebrates		
Marine snails	5	17.5
Land snails	5	43.7
Insects	23	32.9
Vertebrates		
Fishes	51	15.2
Amphibians	13	26.9
Reptiles	17	21.9
Birds	7	15.0
Mammals	46	14.7
Plant data adapted from Hamrick and Godt, 1990. Animal data adapted from Hartl, 1980, and Hedrick, 1983.		

trophoresis of several enzymes. Note that genetic polymorphism tends to be greater in plants than in animals.

Determining the sequence of nucleotides in DNA from individuals in a population provides a *direct* estimate of genetic polymorphism. One method of DNA sequencing is described in Figure 14–9. DNA sequencing of specific genes in an increasing number of organisms, including humans, indicates that genetic polymorphism in most populations is extensive.

Balanced polymorphism can exist for long periods of time

Balanced polymorphism is a special type of genetic polymorphism in which two or more alleles persist in a population over many generations as a result of natural selection. Heterozygote advantage and frequency-dependent selection are mechanisms that preserve balanced polymorphism.

³The nine genotypes that result from $AaBb \times AaBb$ are $AABB$, $AABb$, $AAbb$, $AaBB$, $AaBb$, $Aabb$, $aaBB$, $aaBb$, and $aabb$.
⁴There are 21 different ways that six alleles can combine in diploid individuals. Because there are five different genes, each with six alleles, the total number of different genotypes possible is 21^5 , or 4,084,101.

Genetic variation may be maintained by heterozygote advantage

We have seen that natural selection often causes unfavorable alleles to be eliminated from a population while favorable alleles are retained. However, natural selection sometimes helps to maintain genetic diversity, including alleles that are unfavorable in the homozygous state, in a population. This happens, for example, when the heterozygote, Aa , has a higher degree of **fitness**—that is, is better able to make a genetic contribution to subsequent generations—than either homozygote, AA or aa . This phenomenon, known as **heterozygote advantage**, is demonstrated in humans by the selective advantage of heterozygous carriers of the sickle cell allele.

The mutant allele (s) for sickle cell anemia produces an altered hemoglobin that deforms or sickles the red blood cells, making them more likely to form dangerous blockages in capillaries and to be destroyed in the liver, spleen, or bone marrow (see Chapter 15). Individuals who are homozygous for the sickle cell allele (ss) usually die at an early age if medical treatment is not available.

Heterozygous individuals carry alleles for both normal (S) and sickle cell hemoglobin. The heterozygous condition (Ss) causes an individual to be more resistant to a type of severe malaria (falciparum malaria) than those individuals who are homozygous for the normal hemoglobin allele (SS). In a heterozygous individual, each allele produces its own specific kind of hemoglobin, and the red blood cells contain the two kinds in roughly equivalent amounts. Such cells do not ordinarily sickle as readily as cells containing only the s allele, and the red blood cells containing the abnormal hemoglobin are more resistant to infection by the malaria-causing parasite, which lives in red blood cells, than are the red blood cells containing only normal hemoglobin.

Each of the two types of homozygous individuals is at a disadvantage. Those homozygous for the sickle cell allele are likely to die of sickle cell anemia, whereas those homozygous for the normal allele may suffer or die of malaria. The heterozygote is therefore more fit than either homozygote. In parts of Africa, the Middle East, and southern Asia where falciparum malaria is prevalent, heterozygous individuals survive in greater numbers than either homozygote (Fig. 18–8). The s allele is maintained at a high frequency in the population even though the homozygous recessive condition is almost always lethal.

What happens to the frequency of s alleles in Africans and others who possess it when they migrate to the United States and other nonmalarial countries? As might be expected, the frequency of the s allele gradually declines in such populations because it confers a selective disadvantage by causing sickle cell anemia in homozygous individuals but no longer confers a selective advantage by preventing malaria in heterozygous individuals. The s allele never disappears from the population, however, because it is “hidden” from selection in heterozygous individuals and because it is frequently reintroduced into the

Figure 18–8 Heterozygote advantage. The distribution of sickle cell anemia (bars) is compared with the distribution of falciparum malaria (dark tan region). The correlation strongly suggests that the resistance of heterozygous individuals to malaria has served to balance the harmful effects of sickle cell anemia.

African American population by gene flow from the African population.

Genetic variation may be maintained by frequency-dependent selection

Thus far in our discussion of natural selection, we have assumed that the fitness of particular phenotypes (and their corresponding genotypes) is independent of their frequency in the population. There are, however, cases of **frequency-dependent selection**, in which the fitness of a particular phenotype depends on how frequently it appears in the population. Often, a phenotype has a greater selective value when it is rare than when it is common in the population. Such phenotypes lose their selective advantage as they become more common.

Frequency-dependent selection often acts to maintain genetic variation in populations of prey species. In this case, the predator catches and consumes the more common phenotype, but may ignore the rarer phenotypes. Consequently, the less common phenotype makes a greater relative contribution to the next generation. Frequency-dependent selection has been demonstrated with aquatic insects called water boatmen (Fig. 18–9), which have three distinct color phenotypes. When all three phenotypes are present at equal frequencies, fish are more likely to consume the most obvious (i.e., least camouflaged) form. However, in populations where one phenotype is present in greater numbers than the other two, the most abundant form is preferentially eaten by fish, regardless of its color. Thus, frequency-dependent selection acts to decrease the frequency of the more common phenotypes (and their genotypes) and increase the frequency of the less common types.

Figure 18–9 Frequency-dependent selection. Water boatmen are aquatic insects that swim in ponds and streams by using their middle and hind legs as oars. These insects occur in three color forms (only one is shown). Frequency-dependent selection operates to maintain all three phenotypes within a given population. (Stephen Dalton/Photo Researchers, Inc.)

The extent of neutral variation in organisms is difficult to determine. It is relatively easy to demonstrate that an allele is beneficial or harmful, provided that its effect is observable. But the variation in alleles that involves only slight differences in the proteins they code for may or may not be neutral. These alleles may be influencing the organism in subtle ways that are difficult to measure or assess. Also, an allele that is neutral in one environment may be beneficial or harmful in another.

Populations in different geographical areas often exhibit genetic variation

In addition to the genetic variation among individuals within a population, genetic differences often exist among different populations within the same species, a phenomenon known as *geographical variation*. One type of geographical variation is a **cline**, which is a gradual geographical change in a species' phenotype and genotype frequencies. A cline exhibits variation in the expression of such traits as color, size, shape, physiology, or behavior through a series of geographically separate populations. Clines are common among species with continuous ranges over large geographical areas. For example, the body sizes of many widely distributed birds and mammals increase gradually as the latitude increases, presumably because larger animals are better able to withstand the colder temperatures of winter.

The common yarrow (*Achillea millefolium*), a wildflower that grows in a variety of North American habitats from lowlands to mountain highlands, exhibits clinal variation in height in response to different climates at different altitudes. Although substantial variation exists among individuals within each population, individuals in populations at higher altitudes are, on average, shorter than those at lower altitudes. The genetic basis of these clinal differences can be experimentally demonstrated by growing a series of populations from different geographical areas in the same environment (Fig. 18–10). Despite being exposed to identical environmental conditions, each experimental population exhibits the traits characteristic of the altitude from which it was collected.

Neutral variation may give no selective advantage or disadvantage

Some of the genetic variation observed in a population may confer no apparent selective advantage or disadvantage in a particular environment. For example, random changes in DNA that do not alter protein structure usually do not affect the phenotype. Variation that does not alter the ability of an individual to survive and reproduce and is, therefore, not adaptive is called **neutral variation**.

Figure 18-10 Clinal variation in yarrow (*Achillea millefolium*). Seeds from widely dispersed populations in the Sierra Nevada of California and Nevada were collected and grown in a uniform environment, revealing genetic differences in height that were related to the altitude where the plants were collected.

SUMMARY WITH KEY TERMS

- I. Each population possesses a **gene pool**, which includes all the alleles for all of the genes present in the population. An **allele frequency** is the percentage of a specific allele of a given gene locus in the population.
 - A. If the allele frequencies remain constant from generation to generation, the population is not undergoing evolutionary change and is said to be at **genetic equilibrium**.
 - B. If the allele frequencies change over successive generations, the population is undergoing **microevolution**.
- II. The **Hardy-Weinberg principle** states that in a population at genetic equilibrium, allele and genotype frequencies do not change from generation to generation.
- III. Allele frequencies may be changed by nonrandom mating, mutation, genetic drift, gene flow, and natural selection.
 - A. In nonrandom mating, individuals select mates on the basis of genotype (or phenotype).
 1. **Inbreeding** is the mating of genetically similar individuals that are more closely related than if they had been chosen at random from the entire population.
 2. In **assortative mating** individuals select mates by their phenotypes.
 - B. New alleles originate as **mutations**.
 - C. **Genetic drift** is a random change in the allele frequencies of a small population. The changes caused by genetic drift are usually not adaptive.
 - D. The migration of individuals between populations causes a corresponding movement of alleles, or **gene flow**, that can cause changes in allele frequencies.
- E. Changes in allele frequencies that lead to adaptation are caused by **natural selection**.
 1. Natural selection operates on an organism's phenotype.
 2. Natural selection can change the genetic composition of a population in a favorable direction for a particular environment.
 - a. **Stabilizing selection** favors the mean at the expense of phenotypic extremes.
 - b. **Directional selection** favors one phenotypic extreme over another, causing a shift in the phenotypic mean.
 - c. **Disruptive selection** favors two or more phenotypic extremes.
- IV. Most populations have abundant genetic variability.
 - A. **Genetic polymorphism** is the presence in a population of two or more alleles for a given locus.
 - B. **Heterozygote advantage** occurs when the heterozygote exhibits greater fitness than either homozygote. Both dominant and recessive alleles are maintained in the population.
 - C. In **frequency-dependent selection**, a genotype's selective value varies with its frequency of occurrence.
 - D. Genetic variation that confers no detectable selective advantage is called **neutral variation**.
 - E. Geographical variation is genetic variation that exists among different populations within the same species. A **cline** is a gradual geographical change in a species' phenotype and genotype frequencies.

POST-TEST

1. The genetic description of an individual is its genotype, whereas the genetic description of a population is its (a) phenotype (b) gene pool (c) genetic drift (d) founder effect (e) changes in allele frequencies
2. If a population's allele frequencies remain constant from generation to generation (a) the population is undergoing evolutionary change (b) the population is said to be at genetic equilibrium (c) microevolution has taken place (d) directional selection is occurring, but only for a few generations (e) genetic drift is a significant evolutionary force
3. Comparing the different forms of a particular protein in a population provides biologists with an estimate of (a) genetic drift (b) genetic polymorphism (c) gene flow (d) heterozygote advantage (e) frequency-dependent selection
4. The continued presence of the allele that causes sickle cell anemia in areas where malaria is prevalent demonstrates which of the following phenomena? (a) genetic polymorphism (b) frequency-dependent selection (c) heterozygote advantage (d) genetic drift (e) population bottleneck
5. Frequency-dependent selection often acts to maintain _____ in a population. (a) assortative mating (b) genetic drift (c) gene flow (d) genetic variation (e) stabilizing selection
6. According to the Hardy-Weinberg principle (a) allele frequencies are not dependent on dominance or recessiveness but remain essentially unchanged from generation to generation (b) the sum of allele frequencies for a given locus is always greater than 1 (c) if a locus has a single allele, its frequency must be 0 (d) allele frequencies change from generation to generation (e) the process of inheritance, by itself, causes changes in allele frequencies
7. What is the correct equation for the Hardy-Weinberg principle? (a) $p^2 + pq + 2q^2 = 1$ (b) $p^2 + 2pq + 2q^2 = 1$ (c) $2p^2 + 2pq + 2q^2 = 1$ (d) $p^2 + pq + q^2 = 1$ (e) $p^2 + 2pq + q^2 = 1$
8. The Hardy-Weinberg principle is applicable provided (a) population size is small (b) migration only occurs at the beginning of the breeding season (c) mutations occur at a constant rate (d) matings occur exclusively between individuals of the same genotype (e) natural selection does not occur
9. Which of the following is *not* an evolutionary agent that causes change in allele frequencies? (a) mutation (b) natural selection (c) genetic drift (d) random mating (e) gene flow from migration
10. Mutation (a) leads to adaptive evolutionary change (b) adds to the genetic variation of a population (c) is the result of genetic drift (d) almost always benefits the organism (e) a and b are correct
11. Which of the following is *not* true of natural selection? (a) Natural selection acts to preserve favorable traits and eliminate unfavorable traits. (b) The offspring of individuals that are better adapted to the environment will make up a larger proportion of the next generation. (c) Natural selection directs the course of evolution by preserving the traits acquired during an individual's lifetime. (d) Natural selection acts on a population's genetic variability, which arises through mutation. (e) Natural selection may result in changes in allele frequencies in a population.
12. In _____, individuals with a phenotype near the phenotypic mean of the population are favored over those with phenotypic extremes. (a) microevolution (b) stabilizing selection (c) directional selection (d) disruptive selection (e) genetic equilibrium

REVIEW QUESTIONS

1. In a human population of 1000, 840 are tongue rollers (TT or Tt), and 160 are non-tongue rollers (tt). What is the frequency of the dominant allele (T) in the population?
2. In a population at genetic equilibrium, the frequency of allele A is 0.5. What is the frequency of the homozygous dominant genotype (AA)? What is the frequency of the heterozygous genotype (Aa)?
3. If 96% of the garden peas in a population at genetic equilibrium are tall (TT or Tt), what is the frequency of the dominant allele (T)?
4. If 16% of the individuals in a population at genetic equilibrium are recessive (aa), what is the frequency of the recessive allele in the population? What is the frequency of the dominant allele?
5. A biologist catches 1600 moths using special insect traps. Of this population, 64 exhibit the recessive phenotype (bb), and 1536 the dominant phenotype (BB or Bb). Assuming that this is a random sample of the wild population, is the population at genetic equilibrium?
6. The genotype frequencies of a population are determined to be 0.6 AA , 0.0 Aa (there are no heterozygotes), and 0.4 aa . Its allele frequencies are $p = 0.6$ and $q = 0.4$. Is this population at genetic equilibrium? Why or why not?
7. The chemical phenylthiocarbamide (PTC) tastes bitter to most people but is tasteless to others. About 30% of Americans are PTC nontasters (tt), and 70% are PTC tasters (TT or Tt). Assuming the population is at genetic equilibrium, estimate the frequency of the nontaster (t) and taster (T) alleles.
8. If a population of 2000 is at genetic equilibrium but contains only 180 individuals with the recessive phenotype (rr), what is the expected frequency of the recessive allele (r) nine generations later?
9. If the genotype frequencies in a population not at genetic equilibrium are 0.36 TT , 0.48 Tt , and 0.16 tt , what are the allele frequencies of T and t ?
10. If the genotype frequencies in a population at not genetic equilibrium are 0.64 TT , 0.32 Tt , and 0.04 tt , what are the allele frequencies of T and t ?
11. The frequency of the allele A in a population at genetic equilibrium is 0.7. What is the expected frequency of the Aa genotype?

Answers to these Review Questions are included in the Appendix with the Post-Test answers.

YOU MAKE THE CONNECTION

1. Why are mutations almost always neutral or harmful?
2. Explain this apparent paradox: We discuss evolution in terms of *genotype*

fitness (the selective advantage that a particular genotype confers on an individual), yet natural selection acts on an organism's *phenotype*.

CHAPTER 19

Speciation and Macroevolution

Thus far in our study of evolution, we have examined natural selection and how populations evolve (Chapters 17 and 18). We now focus our attention on how species and higher taxa (for example, new classes)¹ evolve. We do not know exactly how many species exist, but biologists estimate there may be something on the order of 13 to 14 million different species. About 1.75 million species have been scientifically named and described. These include 250,000 plant species, 42,000 vertebrate animals, and some 750,000 insects. The concept of distinct kinds of organisms, known as **species** (from Latin, meaning “kind”) is not new. However, every definition of species has some sort of limitation. Linnaeus, the 18th century biologist who is considered the founder of modern taxonomy, classified plants into separate species based on structural differences (see Chapter 22). This method, known as the *morphological species concept*, is still used to help characterize species, but structure alone is not adequate to explain what constitutes a species. For example, dogs come in a wide variety of sizes and shapes, yet all dogs are clearly the same kind of organism and are classified as members of the same species.

Population genetics did much to clarify the concept of species. According to the **biological species concept**, first expressed by Ernst Mayr in 1940, a species consists of groups of populations whose members are capable of interbreeding in nature to produce fertile offspring and do not interbreed with, that is, are reproductively isolated from, members of different species. In other words, each species has a gene pool that is isolated from that of other species, and each is restricted by reproductive barriers from interbreeding with other species.

One of the problems with the biological species concept is that it applies only to sexually reproducing organisms. Organisms that reproduce asexually do not interbreed, so we cannot think of them in terms of reproductive isolation. These organisms and extinct organisms are classified on the basis of structural and biochemical characteristics. Another potential problem with the biological species concept is that organisms assigned to different species may successfully interbreed if

(Gary Retherford/Photo Researchers, Inc.)

brought into the artificial environment and caging of a wildlife ranch, circus, zoo, greenhouse, aquarium, or laboratory. The photo shows a “zebrass,” a sterile hybrid between a zebra and a donkey that retains features of both parental species. Although such matings may occur under artificial conditions (such as the wildlife ranch in Texas where this cross took place), zebras and donkeys do not interbreed in the wild.

This chapter discusses reproductive barriers that isolate species from one another, the possible evolutionary mechanisms that explain how the millions of species that live today or lived in the past originated from ancestral species, and the rates of evolutionary change. We then examine macroevolution, which is large-scale phenotypic changes (such as the appearance of wings with feathers during the evolution of birds from reptiles) that permit the evolution of taxonomic groups higher than the species level—new genera, families, orders, classes, and even phyla.

¹The taxonomic categories (taxa) above the level of species are artificial constructs used by humans to indicate degrees of relatedness among organisms. Thus, closely related species are grouped into the same genus (pl., *genera*), similar genera into the same family, similar families into the same order, similar orders into the same class, and similar classes into the same phylum.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Define a species and explain the limitations of the biological species concept.

2. Explain the significance of reproductive isolating mechanisms and distinguish among the different prezygotic and postzygotic barriers.

3. Explain the mechanism of allopatric speciation and give an example.

4. Explain the mechanisms of sympatric speciation and give both plant and animal examples.

5. Take either side in a debate on the pace of evolution by representing the opposing views of gradualism and punctuated equilibrium.
6. Define macroevolution and distinguish among microevolution, speciation, and macroevolution.

7. Discuss macroevolution in the context of novel features, including preadaptations, allometric growth, and paedomorphosis.

8. Discuss the macroevolutionary significance of adaptive radiation and extinction.

9. Explain how the course of evolution was affected by continental drift.

SPECIES ARE REPRODUCTIVELY ISOLATED IN VARIOUS WAYS

A number of **reproductive isolating mechanisms** prevent interbreeding between two different species whose ranges overlap. These mechanisms preserve the genetic integrity of each species because gene flow between species is prevented. Most species have two or more mechanisms that block a chance occurrence of individuals from two different species overcoming a single reproductive isolating mechanism. Most work before fertilization occurs (prezygotic), whereas others work after fertilization has taken place (postzygotic) (Table 19–1).

Prezygotic barriers interfere with fertilization

Prezygotic barriers are reproductive isolating mechanisms that prevent fertilization from taking place. Because male and female gametes never come into contact, an interspecific zygote (fertilized egg formed by the union of an egg from one species and a sperm from another species) is never produced. Prezygotic barriers include temporal isolation, behavioral isolation, mechanical isolation, and gametic isolation.

Sometimes genetic exchange between two groups is prevented because they reproduce at different times of the day, season, or year. Such examples demonstrate **temporal isolation**. For example, two very similar species of fruit flies, *Drosophila pseudoobscura* and *D. persimilis*, have ranges that overlap to a great extent, but they do not interbreed. *Drosophila pseudoobscura* is sexually active only in the afternoon and *D. persimilis* only in the morning. Similarly, two frog species have overlapping ranges in eastern Canada and the United States. The wood frog (*Rana sylvatica*) usually mates in late March or early April, when the water temperature is about 7.2°C (45°F), whereas the northern leopard frog (*R. pipiens*) usually mates in mid-April, when the water temperature is 12.8°C (55°F) (Fig. 19–1).

Many animal species exchange a distinctive series of signals before mating. Such courtship behaviors illustrate **behavioral isolation** (also known as **sexual isolation**). Bowerbirds, for example, exhibit species-specific courtship patterns. The male satin bowerbird of Australia constructs an elaborate bower of twigs, adding decorative blue parrot feathers and white flowers at the entrance (Fig. 19–2). When a female approaches the bower, the male dances about her, holding a particularly eye-catching decoration in his beak. While dancing, he sings a

TABLE 19 – 1 Reproductive Isolating Mechanisms	
Mechanism	How It Works
Prezygotic Barriers	Prevent fertilization
Temporal isolation	Similar species reproduce at different times
Behavioral isolation	Similar species have distinctive courtship behaviors
Mechanical isolation	Similar species have structural differences in their reproductive organs
Gametic isolation	Gametes of similar species are chemically incompatible
Postzygotic barriers	Reduce viability or fertility of hybrid
Hybrid inviability	Interspecific hybrid dies at early stage of embryonic development
Hybrid sterility	Interspecific hybrid survives to adulthood but is unable to reproduce successfully
Hybrid breakdown	Offspring of interspecific hybrid are unable to reproduce successfully

Figure 19-1 Temporal isolation in wood and leopard frogs. (a) The wood frog (*Rana sylvatica*) mates in early spring, often before the ice has completely melted in the ponds. (b) The leopard frog (*R. pipiens*) typically mates a few weeks later. (c) Graph of peak mating activity in wood and leopard frogs. In nature, wood and leopard frogs do not interbreed, although they have done so in the laboratory. (a, L. & D. Klein/Photo Researchers, Inc.; b, Rod Planck/Photo Researchers, Inc.)

courtship song that consists of a variety of sounds, including buzzes and laughlike hoots. These specific courtship behaviors keep similar bird species reproductively isolated from the satin bowerbird. If a male and female of two different species begin courtship, it stops when one member does not recognize or respond to the signals of the other. Another example of behavioral isolation involves the wood frogs and northern leopard frogs (just discussed as an example of temporal isolation). Males of these two species have very specific vocalizations to attract females of their species for breeding. These vocalizations reinforce the reproductive isolation of these species.

Sometimes members of different species court and even attempt copulation, but the incompatible structures of their

genital organs prevent successful mating. Structural differences that inhibit mating between species produce **mechanical isolation**. For example, many flowering plant species have physical differences in their flower parts that help them maintain their reproductive isolation from one another. In such plants, the flower parts are adapted for specific insect pollinators. Two species of sage, for example, have overlapping ranges in southern California. Black sage (*Salvia mellifera*), which is pollinated by small bees, has a floral structure different from that of white sage (*S. apiana*), which is pollinated by large carpenter bees (Fig. 19-3). Interestingly, black and white sage are also prevented from mating by a temporal barrier; black sage flowers in early spring, and white sage flowers in late spring and early summer. Presumably, mechanical isolation prevents insects from cross-pollinating the two species should they happen to flower at the same time.

If mating has taken place between two species, their gametes may still not combine. Molecular and chemical differences between species cause **gametic isolation**, in which the egg and sperm of different species are incompatible. In aquatic animals that release their eggs and sperm into the surrounding water simultaneously, interspecific fertilization is extremely rare (Fig. 19-4). The surface of the egg contains specific proteins that bind only to complementary molecules on the surface of sperm cells of the same species (see Chapter 49). A similar type of molecular recognition often occurs between pollen grains and the stigma (receptive surface of the female part of the flower) so that pollen does not germinate on the stigma of a different plant species.

Postzygotic barriers prevent gene flow when fertilization occurs

Fertilization sometimes occurs between gametes of two different species despite the existence of prezygotic barriers. When this happens, **postzygotic barriers** that increase the likelihood of reproductive failure come into play. Generally, the embryo of an interspecific hybrid spontaneously aborts. Embryonic development is a complex process requiring the precise inter-

Figure 19-2 Behavioral isolation in bowerbirds. Each bowerbird species has highly specialized courtship patterns that prevent its mating with another species. The male satin bowerbird (shown) constructs an enclosed place, or bower, of twigs to attract a female. Note the flowers and blue decorations that he has arranged at the entrance to his bower. (Patti Murray)

Figure 19-3 Mechanical isolation in black and white sage. Differences in floral structures between black and white sage allow them to be pollinated by different insects. Because the two species exploit different pollinators, they cannot interbreed. (a) The petal of the black sage functions as a landing platform for small bees. Larger bees cannot fit on this platform. (b) The larger landing platform and longer stamens of white sage allow pollination by larger California carpenter bees (a different species). If smaller bees land on white sage, their bodies do not brush against the stamens. (The upper part of the white sage flower has been removed.)

action and coordination of many genes. Apparently the genes from parents belonging to different species do not interact properly in regulating the mechanisms for normal development. In this case, reproductive isolation occurs by **hybrid inviability**. For example, nearly all the hybrids die in the embryonic stage when the eggs of a bullfrog are fertilized artificially with sperm from a leopard frog. Similarly, in crosses between different species of irises, the embryos die before reaching maturity.

If an interspecific hybrid does live, it may not be able to reproduce. There are several reasons for this. Hybrid animals may exhibit courtship behaviors incompatible with those of either parental species and, as a result, they will not mate. More often, **hybrid sterility** occurs when problems during meiosis cause the gametes of an interspecific hybrid to be abnormal. Hybrid sterility is particularly common if the two parental species have different chromosome numbers. For example, a mule is the offspring of a female horse ($2n = 64$) and a male donkey ($2n = 62$) (Fig. 19-5). This type of union almost always results in sterile offspring ($2n = 63$) because chromosomal synapsis (the pairing of homologous chromosomes during meiosis) and segregation cannot occur properly.

Occasionally, a fertile interspecific F_1 hybrid develops that produces a second generation (F_2) from a cross between two

Figure 19-4 Gametic isolation in sponges. A basket sponge (*Xestospongia nutz*) releases a cloud of gametes into the water. If one of these gametes encounters a gamete of a different species biochemical differences will prevent their union. (Marty Snyderman/Visuals Unlimited)

F_1 hybrids or a backcross between an F_1 hybrid and one of the parental species. The F_2 hybrid may exhibit **hybrid breakdown**, the inability of a hybrid to reproduce due to some defect. For example, hybrid breakdown in the F_2 generation of a cross between two sunflower species was 80%. In other words, 80% of the F_2 generation were defective in some way and could not reproduce successfully. Hybrid breakdown can also occur in the F_3 and later generations.

Figure 19-5 Hybrid sterility in mules. Mules are interspecific hybrids formed by mating a female horse with a male donkey. Although the mule (center) exhibits valuable characteristics of each of its parents, it is sterile. (John Eastcott/Yva Momatiuk/Animals Animals)

REPRODUCTIVE ISOLATION IS THE KEY TO SPECIATION

We are now ready to consider how entirely new species may arise from previously existing ones. The evolution of a new species, known as **speciation**, occurs when a population be-

comes reproductively isolated from other members of the species. Over time the gene pools of the two separated populations begin to diverge in genetic composition. When a population is sufficiently different from its ancestral species that no genetic exchange can occur between them, we say that speciation has occurred. Such a situation is thought to arise in two ways, through allopatric and sympatric speciation.

(a) Allopatric speciation

(b) Sympatric speciation (in plants)

Figure 19-6 Comparison of allopatric and sympatric speciation. (a) Allopatric speciation. (b) Sympatric speciation in plants. (The role of sympatric speciation in animal evolution is unclear.)

Long physical isolation and different selective pressures result in allopatric speciation

Speciation that occurs when one population becomes geographically separated from the rest of the species and subsequently evolves by natural selection and/or genetic drift is known as **allopatric speciation** (from the Greek *allo*, “different,” and *patri*, “native land”). Allopatric speciation is thought to be the most common method of speciation, and the evolution of new animal species has been almost exclusively by allopatric speciation (Fig. 19–6*a*).

The geographical isolation required for allopatric speciation may occur in several ways. Earth’s surface is in a constant state of change. Such change includes rivers shifting their courses; glaciers migrating; mountain ranges forming; land bridges developing that separate previously united aquatic populations; and large lakes diminishing into several smaller, geographically separated pools.

What might be an imposing geographical barrier to one species may be of no consequence to another. Birds and cattails, for example, do not become isolated when a lake subsides into smaller pools; birds can easily fly from one pool to another, and cattails disperse their pollen and fruits by air currents. Fish, on the other hand, are usually unable to cross the land barriers between the pools and so become reproductively isolated. In the Death Valley region of California and Nevada, large interconnected lakes formed during wetter climates of the last Ice Age. These lakes were populated by one or several species of pupfish. Over time, the climate became drier, and the large lakes dried up, leaving isolated pools. Presumably, each pool contained a small population of pupfish that gradually diverged from the common ancestral species by genetic

Figure 19–7 Allopatric speciation of pupfish (*Cyprinodon*). Shown is one of the more than 20 pupfish species that apparently evolved when larger lakes in southern Nevada dried up about 10,000 years ago, leaving behind small, isolated desert pools fed by springs. The pupfish’s short, stubby body is characteristic of fish that live in springs; fish that live in larger bodies of water are more streamlined. (Steinhart Aquarium, Tom McHugh/Photo Researchers, Inc.)

drift and natural selection. Today, there are more than 20 species of pupfish, and many, such as the Devil’s Hole pupfish (*Cyprinodon diabolis*) and the Owens pupfish (*C. radiosus*), are restricted to one or two isolated springs (Fig. 19–7).

Allopatric speciation also occurs when a small population migrates and colonizes a new area away from the range of the original species. This colony is geographically isolated from its parental species, and the small microevolutionary changes that accumulate in the isolated gene pool over many generations may eventually be sufficient to form a new species. Because islands provide the geographical isolation required for allopatric speciation, they offer excellent opportunities to study this mechanism. The Galapagos Islands and the Hawaiian Islands, for example, probably were originally colonized by a few individuals of a few species. The hundreds of unique species presently found on each island presumably descended from these original colonizers (Fig. 19–8).

Speciation is more likely to occur if the original isolated population is small. Recall that genetic drift, including the

Figure 19–8 Allopatric speciation of the Hawaiian goose (the nene). Nene (pronounced “nay-nay,” *Branta sandvicensis*) are geese found only on volcanic mountains on the geographically isolated islands of Hawaii and Maui, which are some 4200 kilometers (2600 miles) from the nearest continent. Compared to other geese, the feet of Hawaiian geese are not completely webbed, their toenails are longer and stronger, and their foot pads are thicker; these adaptations enable Hawaiian geese to walk easily on lava flows. Nene are thought to have evolved from a small population of geese that originated in North America. (M.J. Rauzon/VIREO)

(a)

(b)

Figure 19–9 Allopatric speciation in progress. Some scientists consider the Kaibab squirrel (a) and the Abert squirrel (b) as distinct populations of the same species (*Sciurus aberti*). Because the Kaibab and Abert squirrels are reproductively isolated from each other, however, some scientists have classified the Kaibab squirrel as a different species (*S. kaibabensis*). (a, Tom and Pat Leeson; b, Kent and Donna Dannen)

founder effect, is more consequential in small populations (see Chapter 18). Genetic drift tends to result in rapid changes in allele frequencies in the small, isolated population. The divergence caused by genetic drift is further accentuated by the different selective pressures of the new environment to which the population is exposed.

The Kaibab squirrel is an example of allopatric speciation in progress

About ten thousand years ago, when the American Southwest was less arid, the forests in the area supported a tree squirrel with conspicuous tufts of hair sprouting from its ears. A small tree squirrel population living on the Kaibab Plateau of the Grand Canyon became geographically isolated when the climate changed, causing areas to the north, west, and east to become desert. Just a few miles to the south lived the rest of the squirrels, known as Abert squirrels, but the two groups were separated by the Grand Canyon. With changes over time in both its appearance and its ecology, the Kaibab squirrel is on its way to becoming a new species.

During its many years of geographical isolation, the small population of Kaibab squirrels has diverged from the widely distributed Abert squirrels in a number of ways. Perhaps most evident are changes in fur color. The Kaibab squirrel now has a white tail and a black belly, in contrast to the gray tail and white belly of the Abert squirrel (Fig. 19–9). It is not clear why these striking changes arose in Kaibab squirrels.

Porto Santo rabbits may be an example of extremely rapid allopatric speciation

Allopatric speciation has the potential to occur quite rapidly. Early in the 15th century, a small population of rabbits was released on Porto Santo, a small island off the coast of Portugal. Because there were no other rabbits or competitors and no predators on the island, the rabbits thrived. By the 19th century, these rabbits were markedly different from their

European ancestors. They were only half as large (weighing slightly more than 500 grams, or 1.1 pounds), with a different color pattern and a more nocturnal lifestyle. Most significantly, attempts to mate Porto Santo rabbits with mainland European rabbits failed. Many biologists concluded that, within 400 years, an extremely short time in evolutionary history, a new species of rabbit had evolved.

Not all biologists agree that the Porto Santo rabbit is a new species. The objection stems from a more recent breeding experiment and is based on biologists' lack of a consensus about the definition of a species. In the experiment, newborn Porto Santo rabbits were raised by foster mothers of the wild Mediterranean rabbit. When they reached adulthood, these Porto Santo rabbits mated successfully with Mediterranean rabbits to produce healthy, fertile offspring. To some biologists, this experiment clearly demonstrated that Porto Santo rabbits are not a separate species but instead are an example of speciation in progress, much like the Kaibab squirrels just discussed. Other biologists think the Porto Santo rabbit is a separate species because it does not interbreed with other rabbits under natural conditions. They point out that the breeding experiment was successful only after the baby Porto Santo rabbits were raised under artificial conditions that probably modified their natural behavior.

Two populations diverge in the same physical location by sympatric speciation

Although geographical isolation is an important factor in many cases of evolution, it may not be an absolute requirement. In **sympatric speciation** (from the Greek *sym*, “together,” and *patri*, “native land”), a new species develops within the same geographical region as the parental species (Fig. 19–6b). The divergence of two gene pools in the same geographical range is especially common in plants. The role of sympatric speciation in animal evolution, however, is unclear and, until recently, has been difficult to demonstrate in nature.

How does sympatric speciation occur in plants? As discussed earlier, the union of two gametes from different species rarely forms viable offspring; if offspring are produced, they are usually sterile. Before gametes form, meiosis occurs to reduce the chromosome number (see Chapter 9). For the chromosomes to be parceled correctly into the gametes, homologous chromosome pairs must come together (a process called *synapsis*) during prophase I. This cannot usually occur in interspecific hybrid offspring because the chromosomes are not homologous. However, if the chromosome number doubles *before* meiosis, then pairing of homologous chromosomes can take place. While not a common occurrence, this spontaneous doubling of chromosomes has been documented in a variety of plants and a few animals. It produces nuclei with multiple sets of chromosomes.

Polyploidy, the possession of more than two sets of chromosomes, is a major factor in plant evolution. When polyploidy occurs in conjunction with **hybridization** (sexual reproduction between individuals from different species), it is known as **allopolyploidy**. Allopolyploidy can produce a fertile interspecific hybrid because the polyploid condition provides the homologous chromosome pairs necessary for synapsis during meiosis. As a result, gametes may be viable (Fig. 19–10). An allopolyploid, that is, an interspecific hybrid produced by allopolyploidy, can reproduce with itself (self-fertilize) or with a similar individual. However, allopolyploids are reproductively isolated from both parents because their gametes have a different number of chromosomes than those of either parent.

If a population of allopolyploids (that is, a new species) becomes established, selective pressures cause one of three outcomes. One, the new species may be unable to compete successfully against species that are already established, and so it becomes extinct. Two, the allopolyploid individuals may assume a new role in the environment and so coexist with both parental species. Three, the new species may successfully compete with either or both of its parental species. If it has a combination of traits that confers greater fitness than one or both parental species for all or part of the original range of the parent(s), the hybrid species may replace the parent(s).

Although allopolyploidy is extremely rare in animals, it is considered a significant factor in the evolution of flowering plant species. As many as 80% of all flowering plant species are thought to be polyploids, and most of these are allopolyploids (see *Making the Connection: Polyploidy, Guard Cells, and Angiosperm Evolution* in Chapter 27). Moreover, allopolyploidy provides a mechanism for extremely rapid speciation. A single generation is all that is needed to form a new, reproductively isolated species. Allopolyploidy may explain the rapid appearance of many flowering plant species in the fossil record and their remarkable diversity (about 235,000 species) today.

The kew primrose (*Primula kewensis*) is an example of sympatric speciation that was documented at the Royal Botanic Gardens at Kew, England, in 1898 (Fig. 19–11). The interspecific hybrid of two primrose species, *P. floribunda* ($2n =$

Figure 19–10 Sympatric speciation by allopolyploidy in plants. When two species (designated the P generation) successfully interbreed, the interspecific hybrid offspring (the F₁ generation) are almost always sterile (*bottom left*). If the chromosomes double prior to the onset of meiosis, proper synapsis and segregation of the chromosomes can occur, and viable gametes can form (*bottom right*). (Unduplicated chromosomes are shown for clarity.)

18) and *P. verticillata* ($2n = 18$), *P. kewensis* had a chromosome number of 18 but was sterile. Then, at three different times, it was reported to have spontaneously formed a fertile branch, which was an allopolyploid ($2n = 36$) that produced viable seeds of *P. kewensis*.

The mechanism of sympatric speciation has been experimentally verified for many plant species. One example is a

Figure 19-11 Sympatric speciation of a primrose. An allopolyploid primrose, *Primula kewensis*, arose in 1898 as an allopolyploid derived from the interspecific hybridization of *P. floribunda* and *P. verticillata*. Today *P. kewensis* is a popular houseplant. (The specific epithet *kewensis* was assigned in recognition of the species' place of origin, the Royal Botanic Gardens at Kew, England.)

group of species, collectively called hemp nettles, that occurs in temperate parts of Europe and Asia. One hemp nettle, *Galeopsis tetrahit* ($2n = 32$), is a naturally occurring allopolyploid thought to have formed by the hybridization of two species, *G. pubescens* ($2n = 16$) and *G. speciosa* ($2n = 16$). This process occurred in nature but was experimentally reproduced. *Galeopsis pubescens* and *G. speciosa* were crossed to produce F_1 hybrids, most of which were sterile. Nevertheless, both F_2 and F_3 generations were produced. The F_3 generation included a polyploid plant with $2n = 32$ that self-fertilized to yield fertile F_4 offspring that could not mate with either of the parental species. These allopolyploid plants had the same appearance and chromosome number as the naturally occurring *G. tetrahit*. When the experimentally produced plants were crossed with the naturally occurring *G. tetrahit*, a fertile F_1 generation was formed. Thus, the experiment duplicated the speciation process that occurred in nature.

Changing food preferences can cause sympatric speciation in animals

Biologists have observed the occurrence of sympatric speciation in animals, but its significance—how often it occurs and

under what conditions—is still actively debated. Many examples involve parasitic insects and rely on genetic mechanisms other than polyploidy. For example, in the 1860s in the Hudson River Valley of New York, a population of fruit flies (*Rhagoletis pomonella*) parasitic on the small, red fruits of native hawthorn trees was documented to have switched to a new host, domestic apples, which had been introduced from Europe. Although the sister populations (hawthorn maggots and apple maggots) continue to occupy the same geographical area, no gene flow occurs between them because they eat, mate, and lay their eggs on different hosts. In other words, because the hawthorn and apple maggots are reproductively isolated from each other, they have effectively become separate species. Most entomologists, however, still recognize hawthorn and apple maggots as a single species.

In situations like this, it is thought that a mutation arises in an individual and spreads through a small group of insects by sexual reproduction. The mutation reproductively isolates the insects from the rest of the population by allowing them a different ecological opportunity—in this case, to parasitize a different host species. Additional mutations may occur that cause the sister populations to diverge even further. In 1988 biologists reported that hawthorn and apple maggots have genetic differences in three chromosomal regions and identified genetic markers associated with changes in the timing of fly development. Both hawthorn and apple larvae (maggots) tunnel out of the fruit before winter, drop to the ground, and burrow into the soil. However, hawthorn maggots emerge from the ground as adults later in the summer than apple maggots, a difference that further contributes to their reproductive isolation.

Biologists have studied the speciation of colorful fishes known as cichlids (pronounced “sik-lids”) in several East African lakes. The different species of cichlids in a given lake have remarkably different eating habits. Some graze on algae; some consume dead organic material at the bottom of the lake; and others are predatory and eat plankton (microscopic aquatic organisms), insect larvae, and other cichlid species. Their food preferences are related to size (smaller cichlids consume plankton, for example), which in turn is related to mating preference (small, plankton-eating cichlids mate only with other small, plankton-eating cichlids). Recent DNA sequence data indicate that the cichlid species within each lake are more closely related to one another than they are to fishes in nearby lakes or rivers. These molecular data suggest that cichlid species evolved sympatrically rather than by repeated colonizations by fish populations in nearby rivers.

How rapidly did sympatric speciation occur in cichlids? In 1996 scientists published seismic and drill core data that suggest that the 500 endemic (that is, found nowhere else) cichlid species in Lake Victoria evolved in a remarkably short time—less than 12,400 years. This inference is based on evidence that Lake Victoria dried up completely during the late Pleistocene (about 12,400 years ago) when much of north and equatorial Africa was arid. It appears that the cichlids evolved

Explaining the Rapid Loss of Cichlid Diversity in Lake Victoria

HYPOTHESIS: Cichlids are disappearing from Lake Victoria because of changes in their habitat.

METHOD: Take field measurements in 22 different locations in Lake Victoria. Verify these field observations with laboratory experiments.

RESULTS: Increasing turbidity of Lake Victoria's water is preventing females of cichlid species from choosing mates of their own species, which they do based on color variations among the males of different species. As a result, females are interbreeding with males of other species, and the number of cichlid species declines as the distinctive gene pools of different species are merging.

CONCLUSION: Cichlid diversity will continue to decline unless effective measures are taken to reduce pollution in Lake Victoria immediately.

The hundreds of small, colorful cichlid species that diversified in Lake Victoria have always intrigued evolutionary biologists. However, many of these species are rapidly disappearing, and about half of the 500 species that biologists estimate lived in Lake Victoria in 1978 are now extinct. The Nile perch, a voracious predator that was deliberately introduced into the lake in 1960 to stimulate the local fishing economy and whose population exploded during the 1980s, has been blamed for the extinction of most of the cichlid species that have disappeared.

Biologists from the University of Leiden in the Netherlands observed, however, that species were also disappearing in habitats of the lake where the Nile perch is known to have little or no impact. Ole Seehausen and his colleagues measured environmental features at 22 localities with such habitats and found strong correlations between bright and diverse male colors, the number of species, and clear, well lit water, that is, the better the light in a given part of the lake, the more colorful the males and the greater the number of species present at a specific site.* Each species has its own distinct male coloration, which is used by females of that species to choose mates—an example of sexual isolation (discussed earlier in the chapter). In clear water, members of each species do not interbreed with members of other species. (**Sexual selection**, which is choosing a mate based on its color or some other characteristic, is discussed in Chapter 50.)

*Seehausen, O., J.J.M. van Alphen, and F. Witte, "Cichlid Fish Diversity Threatened by Eutrophication That Curbs Sexual Selection." *Science*, Vol. 277, 19 Sept. 1997.

As nearby forests have been cut, soil erosion has made the water of Lake Victoria more turbid (cloudy). Agricultural practices in the area have also contributed fertilizer as well as sediment pollution. Water transparency in deep lake water has decreased from an average of 6.8 meters in the 1920s to 2.2 meters in the 1990s, whereas water transparency in shallow areas along the shoreline has decreased from 3 meters to 1.5 meters in the past decade.

Seehausen demonstrated that as the water became more turbid from pollution, light could not penetrate as effectively, and the spectrum of visible colors became narrower. He hypothesized that, as a result, females could not distinguish males of their own species from males of closely related species. As discussed in the chapter, cichlids are young species, having evolved during the past 12,000 years. Their relative youth means that these species may not have yet evolved additional reproductive isolating mechanisms other than mate preference based on color. It also means that closely related species can be expected to interbreed without loss of fertility. With increasing turbidity, males lost their bright colors because they were no longer favored by sexual selection, and females have mated with males of other species, producing fertile, healthy offspring. Thus, males are losing their bright colors, and many species are being replaced by one or a few hybrids.

This hypothesis was verified in laboratory experiments. When aquaria were well lit, females of two closely related cichlid species (one blue, the other one red) consistently chose mates of their own species over those of the other species. When biologists blocked the light to simulate the turbid conditions in parts of Lake Victoria, however, females often chose males of the other species.

after the climate became wetter and Lake Victoria refilled. If future scientific experiments substantiate this conclusion, it means that the evolution of Lake Victoria's cichlids is the fastest known for such a large number of vertebrate species. (See *On the Cutting Edge: Explaining the Rapid Loss of Cichlid Diversity in Lake Victoria* for a discussion of how human activities have altered the evolutionary mechanism that maintains cichlid diversity.)

Reproductive isolation breaks down in hybrid zones

When two populations have significantly diverged as a result of geographical separation, there is no easy way to determine if the speciation process is complete (recall the controversy about whether Porto Santo rabbits are a separate species or a geographical race). If such populations, subspecies, or species

come into contact, they may hybridize where they meet, forming a **hybrid zone**, or area of overlap in which interbreeding occurs. Hybrid zones are typically narrow, presumably because the hybrids are not well adapted for either parental environment, and the hybrid population is typically very small compared to the parental populations.

On the Great Plains of North America, red-shafted and yellow-shafted flickers (a type of woodpecker) meet and interbreed. The red-shafted flicker, named for its red underwings and tail, is found in the western part of North America from the Great Plains to the Pacific Ocean. The yellow-shafted flicker, which has yellow underwings and tail, ranges east of the Rockies. Hybrid flickers, which form a stable hybrid zone from Texas to southern Alaska, are varied in appearance, although many have orange-colored underwings and tails.

Biologists are not in agreement about whether the red-shafted and yellow-shafted flickers are separate species or geographical races (that is, subspecies; see Chapter 22). According to the biological species concept, if red-shafted and yellow-shafted flickers are two species, they should maintain their reproductive isolation. On the other hand, the flicker hybrid zone has not expanded, that is, the two types of flickers have maintained their distinctiveness and have not rejoined into a single, freely interbreeding population.

The study of hybrid zones has made important contributions to what is known about speciation. As in other fields of science, disagreements and differences of opinion are an important part of the scientific process because they stimulate new ideas, hypotheses, and experimental tests that expand our base of scientific knowledge.

EVOLUTIONARY CHANGE CAN OCCUR RAPIDLY OR GRADUALLY

Does the fossil record provide clues about how rapidly new species arise? Biologists have long recognized that the fossil record lacks many transitional forms; the starting points (ancestral species) and the end points (new species) are present, but the intermediate stages in the evolution from one species to another are often “missing.” This observation has traditionally been explained by the incompleteness of the fossil record. Biologists have attempted to fill in the missing parts, much as a writer might fill in the middle of a novel when the beginning and end are already there.

Two different models, punctuated equilibrium and gradualism, have been developed to explain evolution as observed in the fossil record (Fig. 19–12). The **punctuated equilibrium** model was proposed by paleontologists who question whether the fossil record really is as incomplete as it initially appeared. First advanced by Stephen Jay Gould and Niles Eldredge in 1972, the punctuated equilibrium model suggests that the fossil record accurately reflects evolution as it actually occurs in the history of a species, with long periods of **stasis**

(no evolutionary change) punctuated, or interrupted, by short periods of rapid speciation that are perhaps triggered by changes in the environment. Thus, speciation normally proceeds in “spurts.” These relatively short periods of active evolution (for example, one hundred thousand years) are followed by long periods (for example, two million years) of stability.

With punctuated equilibrium, speciation can occur in a relatively short period of time. Keep in mind, however, that a “short” amount of time for speciation may be thousands of years. Such a span is short when compared with the several million years of a species’ existence. Biologists who support the idea of punctuated equilibrium emphasize that sympatric speciation and even allopatric speciation can occur in such relatively short periods. Punctuated equilibrium accounts for the abrupt appearance of a new species in the fossil record, with little or no evidence of intermediate forms. That is, proponents think that few transitional forms appear in the fossil record because few transitional forms occurred during speciation.

In contrast, the traditional view of evolution espouses the **gradualism** model, in which evolution proceeds continuously over long periods of time. Gradualism is rarely observed in the fossil record because the record is incomplete. (Recall from Chapter 17 that the conditions required for fossil formation are quite precise. The vast majority of organisms decompose when they die, leaving no trace of their existence.) Occasionally, a complete fossil record of transitional forms is discovered and cited as a strong case for gradualism. The gradualism model maintains that populations slowly diverge from one another by the gradual accumulation of adaptive characteristics within each population. These adaptive characteristics accumulate as a result of different selective pressures encountered in different environments.

The abundant fossil evidence of long periods with no change in a species has been used to argue against the gradualism model of evolution. Gradualists, however, maintain that any periods of stasis evident in the fossil record are the result of stabilizing selection (see Chapter 18). They also emphasize that stasis in fossils is deceptive because fossils do not reveal all aspects of evolution. While fossils display changes in external structure and skeletal structure, genetic changes in physiology, internal structure, and behavior—all of which also represent evolution—are not evident. Gradualists recognize rapid evolution only when strong directional selection occurs.

Thus, while biologists agree that natural selection is the primary mechanism for evolution, they may disagree as to the timing, or pace, of evolution during a given species’ existence. Many biologists embrace both models to explain the fossil record and contend that the pace of evolution may be abrupt in certain instances and gradual in others, and that neither punctuated equilibrium nor gradualism exclusively characterize the complex changes associated with evolution. Other biologists do not view the distinction between punctuated equilibrium and gradualism as real. They suggest that genetic changes occur gradually and at a roughly constant pace and

Figure 19-12 Gradualism and punctuated equilibrium. (a) In gradualism a slow, steady change in species occurs over time. (b) In punctuated equilibrium, long periods of stasis are interrupted by short periods of rapid speciation.

that the majority of these mutations do not affect speciation. When the mutations that *do* affect speciation occur, they are dramatic and produce a pattern consistent with the punctuated equilibrium model.

MACROEVOLUTION INVOLVES MAJOR EVOLUTIONARY EVENTS

Macroevolution refers to dramatic changes that occur over long time spans in evolution. One concern of macroevolution is to explain evolutionary novelties, which are large phenotypic changes such as the appearance of wings with feathers during the evolution of birds from reptiles. These phenotypic changes are so great that the new species possessing them are assigned to different genera or higher taxonomic categories. Studies of macroevolution also attempt to discover and explain major changes in species diversity through time, such as occur during adaptive radiation, when many species appear, and mass extinction, when many species disappear. Thus, evolutionary novelties, adaptive radiation, and mass extinction are important aspects of macroevolution.

Evolutionary novelties originate through modifications of preexisting structures

New designs arise from structures already in existence. A change in the basic pattern of an organism can produce something unique, such as wings on insects, flowers on plants, and feathers on birds. Usually these evolutionary novelties are variations of some preexisting structures, called **preadaptations**, that originally fulfilled one role, but were subsequently modified in a way that was adaptive for a different role. Feathers, which evolved from reptilian scales and may have originally provided thermal insulation in primitive birds, represent a preadaptation for flight. That is, with gradual modification, feathers evolved to function in flight as well as to fulfill their original thermoregulatory role. Similarly, the mammalian middle ear bones originated from modified jaw bones of reptiles.

How do such evolutionary novelties originate? Many are probably due to changes during development, which is the orderly sequence of events that occur as an organism grows and matures. Regulatory genes may exert control over hundreds of other genes (see Chapter 16), and very slight genetic changes in regulatory genes could ultimately cause major structural changes in the organism.

Figure 19–13 Allometric growth in humans. Different stages in the growth of a human are drawn the same size to demonstrate varied rates of growth for different parts of the body. For example, as humans develop, their legs grow more rapidly than their heads.

For example, during development, most organisms exhibit **allometric growth**, varied rates of growth for different parts of the body. The size of the head in human newborns is large in proportion to the rest of the body. As a human grows and matures, its torso, hands, and legs grow more rapidly than the head (Fig. 19–13). Allometric growth is found in many organisms, including the male fiddler crab with its single, oversized claw, and the ocean sunfish with its enlarged tail (Fig. 19–14). If growth rates are altered even slightly, drastic changes in the shape of an organism may result, changes that may or

may not be adaptive. For example, allometric growth may help explain the extremely small and relatively useless forelegs of the dinosaur *Tyrannosaurus rex* as compared to its ancestors.

Sometimes novel evolutionary changes occur when a species undergoes changes in the *timing* of development in comparison to its ancestor. Consider, for example, the changes that would occur if juvenile characteristics were retained in the adult stage, a phenomenon known as **paedomorphosis**. Adults of some salamander species have gills, a feature found only in the larval (immature) stages of other salamanders. Retention

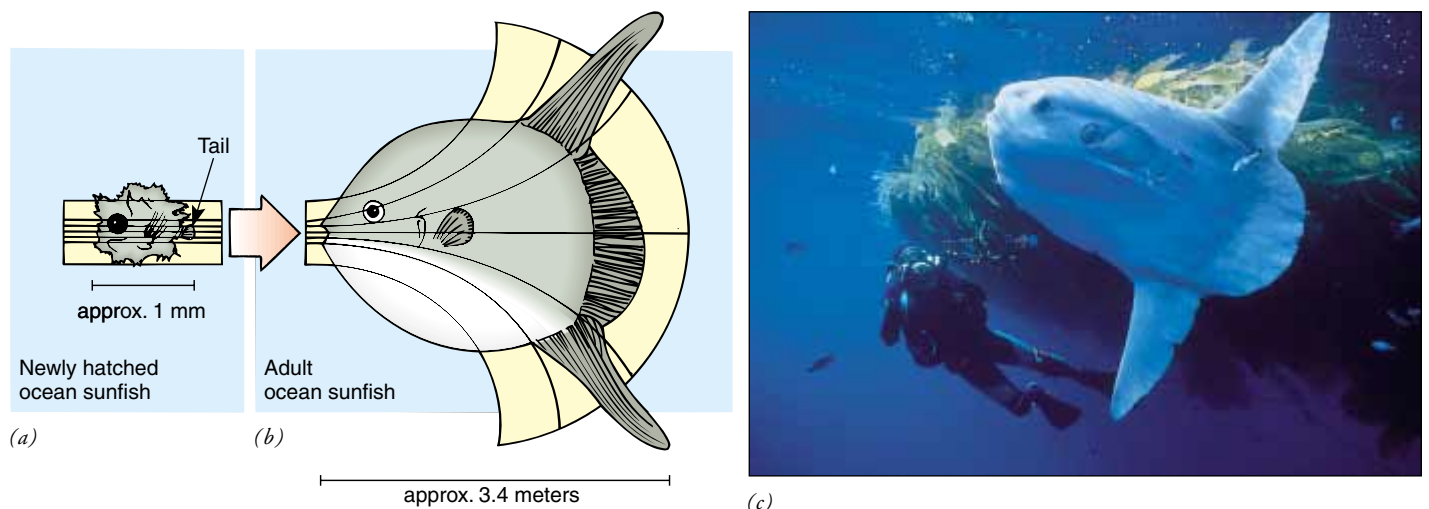

Figure 19–14 Allometric growth in the ocean sunfish. The tail end of an ocean sunfish grows faster than the head end, resulting in the unique shape of the adult. (a) A newly hatched ocean sunfish, only one mm long, has an extremely small tail. (b) This allometric transformation can be visualized by drawing rectangular coordinate lines through a picture of the juvenile fish and then changing the coordinate lines mathematically. (c) An ocean sunfish, also known as a mola, swims off the coast of southern California. The adult ocean sunfish is 3.4 meters (11 feet) long and weighs one metric ton (2206 pounds). (Richard Herrmann)

Figure 19–15 Pedomorphosis in a salamander. An adult axolotl salamander (*Ambystoma mexicanum*) retains the juvenile characteristic of external gills. This evolutionary novelty allows the axolotl to remain permanently aquatic and to reproduce without developing typical adult characteristics. (Jane Burton/Bruce Coleman, Inc.)

of gills throughout life obviously alters the salamander's behavioral and ecological characteristics (Fig. 19–15). Perhaps such salamanders succeeded because they had a selective advantage over “normal” adult salamanders, that is, by remaining aquatic, they did not have to compete for food with the terrestrial adult forms of related species. The gilled forms also escaped the typical predators of terrestrial salamanders (although they had other predators in their aquatic environment).

Adaptive radiation is the diversification of an ancestral species into many species

Adaptive radiation is the evolutionary diversification of many related species from one or a few ancestral species in a relatively short period of time. The concept of adaptive zones was developed to help explain why adaptive radiations take place. **Adaptive zones** are new ecological opportunities that were not exploited by an ancestral organism. At the species level, an adaptive zone is essentially identical to one or more similar *ecological niches* (the functional roles of species within a community; see Chapter 52). Examples of adaptive zones include nocturnal flying to catch small insects, grazing on grass while migrating across a savanna, and swimming at the ocean's surface to filter out plankton. When many adaptive zones are empty, as was the case of Lake Victoria when it refilled some 12,000 years ago (discussed earlier in the chapter), available

species such as the cichlids are able to rapidly diversify and exploit them.

Because islands have fewer species than do mainland areas of similar size, latitude, and topography, vacant adaptive zones are more common on islands than on continents. Consider the Hawaiian honeycreepers, a group of related birds found on the Hawaiian Islands. When the honeycreeper ancestors reached Hawaii, few other birds were present. The succeeding generations of honeycreepers quickly diversified into many new species and, in the process, occupied the many available adaptive zones that are normally occupied by finches, honey-eaters, creepers, and woodpeckers on the mainland. The diversity of their bills, like those of Galapagos finches (see Chapter 17), is a particularly good illustration of adaptive radiation (Fig. 19–16). Some honeycreeper bills are curved to extract nectar out of tubular flowers, for example, whereas others are short and thickened for ripping away bark in search of insects.

Another example of vacant adaptive zones involves the Hawaiian silverswords, 28 species of closely related plants found only on the Hawaiian Islands. When the silversword ancestor, a California plant related to daisies, reached the Hawaiian Islands, many diverse environments, such as exposed lava flows, dry woodlands, moist forests, and bogs, were present. The succeeding generations of silverswords quickly diversified, occupying the many adaptive zones available to them. The diversity in their leaves, which changed during the course of natural selection to enable different populations to adapt to various levels of light and moisture, is a particularly good illustration of adaptive radiation (Fig. 19–17). Leaves of silverswords that are adapted to shady moist forests are large, for example, whereas those of silverswords living in exposed dry areas are small. The leaves of silverswords living on exposed volcanic slopes are covered with dense silvery hairs that may reflect some of the intense ultraviolet radiation off the plant.

Adaptive radiation appears to be more common during periods of major environmental change, but it is difficult to determine if these changes actually induce adaptive radiation. It is possible that major environmental change indirectly affects adaptive radiation by increasing the rate of extinction. Extinction produces empty adaptive zones, which provide new opportunities for those species that remain. Mammals, for example, had existed as small nocturnal insectivores (insect eaters) for millions of years before undergoing adaptive radiation leading to the modern mammalian orders. This radiation was presumably triggered by the extinction of the dinosaurs. Mammals diversified and exploited a variety of adaptive zones relatively soon after the dinosaurs' demise. Flying bats, running gazelles, burrowing moles, and swimming whales all originated from the small, insect-eating, ancestral mammals.

The appearance of novel features is usually associated with major periods of adaptive radiation. For example, shells and skeletons may have been the evolutionary novelties responsible for a period of adaptive radiation at the beginning of the Paleozoic era (see Chapter 20), in which most animal phyla, living and extinct, appeared. Care must be taken in interpret-

Figure 19-17 Adaptive radiation in the Hawaiian silverswords. The silversword ancestor was a California plant similar to the daisy. (a) A silversword species (*Argyroxiphium sandwicense*) found only in Haleakala National Park on the island of Maui. (b) Leaf shapes of the 28 Hawaiian silverswords, all at a scale of $\times 0.25$. Leaf color, which varies considerably among the species, is not shown. (a, H. Gordon Morris, University of Tennessee; b, "Plant Speciation and the Founder Principle" by G.L. Stebbins, from Genetics, Speciation, and the Founder Principle, edited by Luther V. Giddings, Anderson et al. Copyright 1989 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.)

ing a cause-and-effect relationship between the appearance of a novel feature and adaptive radiation, however. It is tempting to take a simplistic approach and state, for example, that the evolution of the flower facilitated the adaptive radiation of thousands of species of flowering plants. It is true that the flowering plants diversified after the evolution of the flower, which may have presented a more competitive method of sexual reproduction because it permitted pollination by insects and other animals. However, adaptive radiation in the flowering plants may instead be a consequence of other adaptations that evolved. (Chapter 27 discusses other flowering plant adaptations as well as their highly successful mode of reproduction.)

Extinction is an important aspect of evolution

Extinction, the end of a lineage, occurs when the last individual of a species dies. The loss is permanent, for once a species is extinct it can never reappear. Extinctions have occurred continually since the origin of life; by one estimate, only one species is alive today for every 2000 that have become extinct. Extinction is the eventual fate of all species, in the same way that death is the eventual fate of all individual organisms.

Although extinction has a negative short-term impact on biological diversity, it can facilitate evolution over a period of

thousands to millions of years. As mentioned previously, when species become extinct, their adaptive zones become vacant. Consequently, those organisms still living are presented with new opportunities for speciation and can diverge to fill the unoccupied niches. In other words, the extinct species are eventually replaced by new species.

During the long history of life, extinction appears to have occurred at two different rates. The continuous, low-level extinction of species is sometimes called **background extinction**. In contrast, five or possibly six times during Earth's history, **mass extinctions** of numerous species and higher taxa have taken place in both terrestrial and marine environments. The most recent mass extinction, which occurred about 65 million years ago, killed off the dinosaurs (Fig. 19–18). The time span over which a mass extinction occurred may have lasted several million years, but that is relatively short compared with the 3.5 billion years or so of Earth's history of life. Each period of mass extinction has been followed by a period of adaptive radiation of some of the surviving groups.

The causes of past episodes of mass extinction are not well understood. Both environmental and biological factors seem to have been involved. Major changes in climate could have adversely affected those plants and animals that lacked the genetic flexibility to adapt. Marine organisms, in particular, are adapted to a steady, unchanging climate. If Earth's tempera-

Figure 19–18 Mass extinction of the archosaurs. At the end of the Cretaceous period, approximately 65 million years ago, a mass extinction of many organisms, including the dinosaurs, occurred. Most of the archosaurs (one of five main groups of reptiles) became extinct. The only lines to survive were crocodiles and birds, both of which are archosauran descendants.

ture were to increase or decrease by just a few degrees overall, many marine species would probably perish.

It is also possible that past mass extinctions were due to changes in the environment induced by catastrophes. If a large comet or small asteroid collided with Earth, for example, the dust ejected into the atmosphere on impact could have blocked much of the sunlight. In addition to disrupting the food chain by killing many plants (and therefore terrestrial animals), this event would have lowered Earth's temperature, leading to the death of many marine organisms. Evidence that the extinction of dinosaurs was caused by an extraterrestrial object's collision with Earth continues to accumulate (see Chapter 20).

Biological factors also trigger extinction. Competition among species may lead to the extinction of those species that cannot compete effectively. The human species, in particular, has had a profound impact on the rate of extinction. The habitats of many animal and plant species have been altered or destroyed by humans, and habitat destruction can result in a species' extinction. The U. N. Global Biodiversity Assessment, released in late 1995 and based on the work of about 1500 scientists from around the world, estimates that more than 31,000 plant and animal species are currently threatened with extinction. As many as one-fifth of all species may become extinct within the next 30 years. The Center for Plant Conser-

vation, for example, estimates that about 4000 native plant species are of conservation concern in the United States; this number represents about 20% of U. S. plant species. Some biologists think that we have entered the greatest mass extinction episode in Earth's history. (Extinction is discussed further in Chapter 55.)

Earth's geological history is related to macroevolution and biogeography

In 1915 the German scientist Alfred Wegener, who had noted a correspondence between the geographical shapes of South America and Africa, proposed that all the land masses had at one time been joined into one huge supercontinent, which he called Pangaea (Fig. 19–19*a*). He further suggested that Pangaea had subsequently broken apart and that the various land masses had separated in a process known as **continental drift**. Wegener did not know of any mechanism that could have caused continental drift, and so his idea, although debated initially, was largely ignored.

In the 1960s, scientific evidence accumulated that provided the explanation for continental drift. Earth's crust is composed of seven large plates (plus a few smaller ones) that float on the mantle, which is the mostly solid² layer of Earth lying beneath the crust and above the core. The land masses are situated on some of these plates. As the plates move, the continents change their relative positions (Fig. 19–19*b, c, d, and e*). The movement of the crustal plates is termed **plate tectonics**.

Any area where two plates meet is a site of intense geological activity. Earthquakes and volcanoes are common in such a region. Both San Francisco, noted for its earthquakes, and the Mount Saint Helens volcano are situated where two plates meet. If land masses lie on the edges of two adjacent plates, mountains may form. The Himalayas formed when the plate carrying India rammed into the plate carrying Asia. When two plates grind together, one of them is sometimes buried under the other in a process known as subduction. When two plates move apart, a ridge of lava forms between them. The Atlantic Ocean is getting larger because of the expanding zone of lava along the mid-Atlantic ridge, where two plates are separating.

Knowledge that the continents were at one time connected and have since drifted apart is useful in explaining the geographical distribution of plants and animals, or **biogeography** (Fig. 19–20). Likewise, continental drift has played a major role in the evolution of different organisms. When Pangaea originally formed during the late Permian period, it brought together terrestrial species that had evolved separately from one another, leading to competition and some extinctions. Marine life was adversely affected, in part because, with the continents

Figure 19–20 The distribution of four fossils on five continents. These biogeographical data suggest that the continents were once joined. (Adapted from Colbert)

joined as one large mass, less coastline existed. (Because coastal areas are shallower, they contain high concentrations of marine species.) Pangaea separated into several land masses approximately 180 million years ago. As the continents began to drift apart, populations became geographically isolated in different environmental conditions and began to diverge along separate evolutionary pathways. As a result, the plants, animals, and other organisms of previously connected continents, South America and Africa for example, differ. Continental drift also caused gradual changes in ocean and atmospheric currents that have profoundly influenced the biogeography and evolution of organisms.

IS MICROEVOLUTION RELATED TO SPECIATION AND MACROEVOLUTION?

The concepts presented in Chapters 17 and 18 represent the **synthetic theory of evolution**, in which mutation provides the genetic variation on which natural selection acts. The syn-

²Most of the rock in the upper portion of the mantle is solid, although one or two percent is melted. Because of its higher temperature, the solid rock of the mantle is more plastic than the solid rock of the lithosphere above it.

thetic theory of evolution combines Darwin's theory with important aspects of genetics. All aspects of the synthetic theory of evolution have been tested and verified at the population and subspecies levels. Many biologists contend that microevolutionary processes (natural selection, mutation, genetic drift, and gene flow) account for the genetic variation within species and for the origin of new species. These biologists also think that macroevolution can be explained by microevolutionary processes.

The synthetic theory of evolution as it relates to speciation and macroevolution is supported by a considerable body of data from many fields. Consider, for example, the evolution of amphibians from fish, which was a major macroevolutionary event in the history of vertebrates. Study of the few known fossil intermediates has demonstrated that the transition from aquatic fish to terrestrial amphibian occurred as evolutionary novelties, such as changes in the limbs and skull roof, were added as a succession of small changes over a period of nine

to fourteen million years. This time scale is sufficient to have allowed natural selection and other microevolutionary processes to have produced the novel characters.

Although few biologists doubt the role of natural selection and microevolution in generating specific adaptations, some question the *extent* of microevolution's role in the overall pattern of life's history. These biologists ask whether speciation and macroevolution have been dominated by microevolutionary processes or by external, chance events (an impact by an asteroid, for example). Chance events do not "care" about adaptive superiority but instead lead to the random extinction or survival of species. In the case of an asteroid impact, for example, those species that survive may do so because they were "lucky" enough to be in a protected environment at the time of impact. If chance events have been the overriding factor during life's history, then microevolution cannot be the exclusive explanation for the biological diversity we have today.

SUMMARY WITH KEY TERMS

- I. According to the **biological species concept**, a **species** consists of groups of populations whose members freely interbreed in nature to produce fertile offspring, and do not freely interbreed with members of different species.
- II. **Reproductive isolating mechanisms** restrict the gene flow between species.
 - A. **Prezygotic barriers** are reproductive isolating mechanisms that prevent fertilization from taking place.
 1. **Temporal isolation** occurs when two species reproduce at different times of the day, season, or year.
 2. In **behavioral isolation**, distinctive courtship behaviors prevent mating between species.
 3. **Mechanical isolation** is due to incompatible structural differences in the reproductive organs of similar species.
 4. In **gametic isolation**, gametes from different species are incompatible due to molecular and chemical differences.
 - B. **Postzygotic barriers** are reproductive isolating mechanisms that prevent gene flow after fertilization has taken place.
 1. **Hybrid inviability** is the death of interspecific embryos during development.
 2. **Hybrid sterility** prevents interspecific hybrids that survive to adulthood from reproducing successfully.
 3. **Hybrid breakdown** prevents the offspring of hybrids that survive to adulthood and successfully reproduce from reproducing beyond one or a few generations.
- III. **Speciation** is the evolution of a new species from an ancestral population.
 - A. **Allopatric speciation** occurs when one population becomes geographically isolated from the rest of the species and subsequently diverges.
 - B. **Sympatric speciation** does not require geographical isolation.
 1. Sympatric speciation in plants results almost exclusively from **allopolyploidy**, in which a **polyploid** individual (one with more than two sets of chromosomes) is derived from two species.
 2. Sympatric speciation occurs in animals, but how often it occurs and under what conditions remain to be determined. Sympatric speciation in animals relies on genetic mechanisms other than polyploidy.
- C. A **hybrid zone** is an area in which two related populations, subspecies, or species meet and interbreed. Hybrid zones are typically narrow, presumably because the hybrids are not well adapted for either parental environment.
- IV. The pace of evolution is currently being debated.
 - A. According to the **punctuated equilibrium** model, evolution of species proceeds in spurts. Short periods of active speciation intersperse long periods of stasis.
 - B. According to the **gradualism** model, populations slowly diverge from one another by the accumulation of adaptive characteristics within a population.
- V. **Macroevolution** refers to dramatic evolutionary changes that occur over long time spans.
 - A. Macroevolution includes the appearance of evolutionary novelties, which are phenotypic changes so great that the new species possessing them are assigned to different genera or higher taxonomic categories.
 1. Evolutionary novelties may be due to changes during development. Slight genetic changes in regulatory genes, for example, could ultimately cause major structural changes in the organism.
 2. Evolutionary novelties may originate from **preadaptations**, structures that originally fulfilled one role but changed in a way that was adaptive for a different role.
 3. Changes in **allometric growth**, varied rates of growth for different parts of the body, result in overall changes in the shape of an organism.
 4. **Paedomorphosis**, the retention of juvenile characteristics in the adult, can occur due to changes in the timing of development.
 - B. **Adaptive radiation** is the process of diversification of an ancestral species into many new species.
 - C. **Extinction** is the death of a species. When species become extinct, the **adaptive zones** that they occupied become vacant, allowing other species to evolve and fill them.

POST-TEST

1. Two populations belong to the same species if (a) their members freely interbreed in nature (b) individuals from the two populations produce fertile offspring (c) their members do not interbreed with individuals of different species (d) a and c are correct (e) a, b, and c are correct
2. A prezygotic barrier prevents (a) the union of egg and sperm (b) reproductive success by an interspecific hybrid (c) the development of the zygote into an embryo (d) allopolyploidy from occurring (e) changes in allometric growth
3. The reproductive isolating mechanism in which two closely related species live in the same geographical area but reproduce at different times is (a) temporal isolation (b) behavioral isolation (c) mechanical isolation (d) gametic isolation (e) hybrid inviability
4. Interspecific hybrids, if they live, are (a) always sterile (b) always fertile (c) usually sterile (d) usually fertile (e) never sterile
5. The first step leading to allopatric speciation is (a) hybrid inviability (b) hybrid breakdown (c) adaptive radiation (d) geographical isolation (e) paedomorphosis
6. Sympatric speciation (a) is most common in animals (b) does not require geographical isolation (c) accounts for the evolution of the Hawaiian nene (d) involves the accumulation of gradual genetic changes (e) always takes thousands of years
7. Which of the following evolutionary processes is associated with allopolyploidy? (a) gradualism (b) allometric growth (c) sympatric speciation (d) mass extinction (e) preadaptation
8. According to punctuated equilibrium model (a) populations slowly diverge from one another (b) evolution of species occurs in spurts interspersed with long periods of stasis (c) evolutionary novelties originate from preadaptations (d) reproductive isolating mechanisms restrict the gene flow between species (e) the fossil record, being incomplete, does not accurately reflect evolution as it actually occurred
9. The evolutionary conversion of reptilian scales into a bird's feathers is an example of (a) allometric growth (b) paedomorphosis (c) gradualism (d) hybrid breakdown (e) preadaptation
10. Adaptive radiation is common following a period of mass extinction, probably because (a) the survivors of a mass extinction are remarkably well adapted to their environment (b) the unchanging environment following a mass extinction drives the evolutionary process (c) many adaptive zones are empty (d) many ecological niches are filled (e) the environment induces changes in the timing of development for many species
11. Adaptive radiations do not appear to have ever occurred (a) on isolated islands (b) in birds such as honeycreepers (c) in fishes such as cichlids (d) in environments with many existing species

REVIEW QUESTIONS

1. Compare the biological species concept with the morphological species concept.
2. Give an example of each of the following: (a) temporal isolation; (b) behavioral isolation; (c) mechanical isolation; (d) gametic isolation.
3. Describe the three types of postzygotic barriers and give an example of each.
4. Identify at least five geographical barriers that might lead to allopatric speciation.
5. Explain how hybridization and polyploidy can cause a new plant species to form in as little as one generation.
6. If you were in a debate and had to support the gradualism model, what would you say? How would you support the punctuated equilibrium model? Are these two ideas mutually exclusive?
7. Why are evolutionary novelties a concern of scientists studying macroevolution?
8. Give an example of each of the following: (a) preadaptation; (b) allometric growth; (c) paedomorphosis.
9. What roles do extinction and adaptive radiation play in macroevolution?
10. How does continental drift occur?
11. Explain why fossils of *Mesosaurus*, an extinct reptile that could not swim across open water, are found in the southern parts of both Africa and South America.

YOU MAKE THE CONNECTION

1. Why is allopatric speciation more likely to occur if the original isolated population is small?
2. Using the definition of the biological species concept given in the chapter introduction, is the Porto Santo rabbit an example of a speciation event that occurred in historical times, or is it an example of speciation in progress? Explain your answer.
3. Based on what you have learned in the chapter, hypothesize what the common ancestor of the more than 20 species of desert pupfish looked like. (*Hint:* the ancestral species lived in one or more large lakes.) How could you test your hypothesis?
4. Could hawthorn and apple maggots be considered an example of assortative mating (discussed in Chapter 18)? Explain your answer.
5. Since extinction is a natural process, should humans be concerned about the current mass extinctions that we are causing? Why or why not?

CHAPTER 20

The Origin and Evolutionary History of Life

The preceding three chapters were concerned with the evolution of organisms, but we have not yet dealt with what many regard as the fundamental question of biological evolution: how did life begin? Biologists generally accept the hypothesis that life developed from nonliving matter, but exactly how this process, called **chemical evolution**, occurred is not certain. Chemical evolution probably involved several stages. Current models suggest that small organic molecules first formed spontaneously and accumulated over time. These molecules may have been able to accumulate rather than being broken down (as occurs today) because conditions were different. The two factors presently responsible for breaking down organic molecules—free oxygen and living organisms—were absent from early Earth.

Large organic macromolecules such as proteins and nucleic acids could have then assembled from the smaller molecules. The macromolecules interacted with one another, combining into more complicated structures that could eventually metabolize and replicate. Natural selection favored macromolecular assemblages with cell-like structures. Their descendants eventually became the first true cells. After the first cells originated, they diverged over several billion years into the rich biological diversity that characterizes our planet today. Photosynthesis, aerobic respiration, and eukaryotic cell structure represent several major advances that developed during the evolutionary history of life.

Geological evidence, in particular the fossil record, provides us with much of what is known about the history of life, such as what kinds of organisms existed and where and when they lived. Certain organisms appear in the fossil record, then disappear and are replaced by others. Initially, unicellular prokaryotes predominated, followed by unicellular eukaryotes. The first multicellular eukaryotes—soft-bodied animals that did not leave many fossils—appeared in the ocean approximately 630 million years ago. Shelled animals and many other marine invertebrates (animals without backbones) appeared next, as exemplified by the trilobites in the photograph. Trilobites were members of a large group of primitive aquatic arthropods that lived during the Paleozoic era. Marine invertebrates were followed by the first vertebrates. The first fishes

(William E. Ferguson)

with jaws appeared and diversified; some of these gave rise to amphibians, which also spread and diversified. About 300 million years ago, amphibians gave rise to reptiles, which diversified and populated the land. Reptiles in turn gave rise independently to birds and to mammals. Plants underwent a comparable evolutionary history and diversification.

In this chapter we survey life over a vast span of time, starting some 3.8 billion years ago when our planet was relatively young. We examine proposed models about how life began and trace life's long evolutionary history from its beginnings to the present.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Describe the conditions that are thought to have existed on early Earth.
2. Contrast various hypotheses about life's origins.
3. Outline the major steps hypothesized to have occurred in the origin of cells.
4. Explain how the evolution of photosynthetic autotrophs affected both the atmosphere and other organisms.
5. Describe the endosymbiont theory and summarize the evidence supporting it.
6. List the geological eras in chronological order and give approximate dates for each.
7. Briefly describe the distinguishing organisms and major biological events of Precambrian time and of the Paleozoic, Mesozoic, and Cenozoic eras.

EARLY EARTH PROVIDED THE CONDITIONS FOR CHEMICAL EVOLUTION

Many biologists speculate that life originated only once and that life's beginnings occurred under environmental conditions quite different from those of today. We must therefore examine the conditions of early Earth to understand the origin of life. Although we will never be certain about the exact conditions that existed when life arose, scientific evidence from a number of sources provides us with valuable clues that help us formulate plausible scenarios.

Astrophysicists and geologists have determined that Earth is approximately 4.6 billion years old. The atmosphere of early Earth apparently included carbon dioxide (CO_2), water vapor (H_2O), carbon monoxide (CO), hydrogen (H_2), and nitrogen (N_2). It may also have contained some ammonia (NH_3), hydrogen sulfide (H_2S), and methane (CH_4), although these reduced molecules may have been rapidly broken down by ul-

traviolet radiation from the sun. The early atmosphere probably contained little or no free oxygen (O_2).

Four requirements must have existed for the chemical evolution of life: little or no free oxygen, a source of energy, the availability of chemical building blocks, and time. First, life could have begun only in the absence of free oxygen. Oxygen is quite reactive and would have oxidized the organic molecules that are necessary building blocks in the origin of life. Earth's early atmosphere was probably strongly reducing, which means that any free oxygen would have reacted with other elements to form oxides. Thus, oxygen would have been tied up in compounds.

The origin of life would also have required energy to do the work of building biological molecules from simple inorganic chemicals. Early Earth was a place of high energy with violent thunderstorms, widespread volcanic activity, bombardment from meteorites and other extraterrestrial objects, and intense radiation, including ultraviolet radiation from the sun (Fig. 20–1). The young sun probably produced more ul-

Figure 20–1 Conditions on early Earth. The strongly reducing atmosphere lacked oxygen; volcanoes erupted, spewing gases that contributed to the atmosphere; and violent thunderstorms produced torrential rainfall that eroded the land. Meteorites and other extraterrestrial objects continually bombarded Earth, causing cataclysmic changes in the crust, ocean, and atmosphere. (Courtesy of Reader's Digest Books. Drawing by H.K. Wimmer)

traviolet radiation than it does today, and the ancient Earth had no protective ozone layer to filter it.

A third requirement would have been the presence of the chemical building blocks needed for chemical evolution. These included water, dissolved inorganic minerals (present as ions), and the gases present in the early atmosphere. A final requirement for the origin of life was time for molecules to accumulate and react with one another. Earth is approximately 4.6 billion years old, and the earliest traces of life are approximately 3.8 billion years old; therefore, life had a maximum of 800 million years to get started.

Organic molecules formed on primitive Earth

Because organic molecules are the building materials for organisms, it is reasonable to first consider how they might have originated. The concept that simple organic molecules such as sugars, nucleotide bases, and amino acids could form spontaneously from simpler raw materials was first advanced in the 1920s by two scientists working independently: A. I. Oparin, a Russian biochemist, and J. B. S. Haldane, a Scottish physiologist and geneticist.

Their hypothesis was tested in the 1950s by American biochemists Stanley Miller and Harold Urey, who designed a closed apparatus that simulated conditions that presumably existed on early Earth (Fig. 20–2). They exposed an atmosphere rich in H_2 , CH_4 , H_2O , and NH_3 to an electrical discharge that simulated lightning. Their analysis of the chemicals produced in a week revealed that amino acids and other organic molecules had formed. Although more recent data suggest that Earth's early atmosphere was not rich in methane or ammonia, similar experiments using different combinations of gases have produced a wide variety of organic molecules that are important in contemporary organisms. These include all 20 amino acids, several sugars, lipids, the nucleotide bases of RNA and DNA, and ATP (when phosphate is present). Thus, before life began, its chemical building blocks may have been accumulating as a necessary step in chemical evolution.

Oparin envisioned that the organic molecules would, over vast spans of time, accumulate in the shallow seas to form a “sea of organic soup.” Under such conditions, he envisioned smaller organic molecules (monomers) combining to form larger ones (polymers). Evidence gathered since Oparin's time indicates that organic polymers may have formed and accumulated on rock or clay surfaces rather than in the primordial seas. Clay, which consists of microscopic particles of weathered rock, is particularly intriguing as a possible site for early polymerizations because it binds organic monomers and contains zinc and iron ions that might have served as catalysts. Laboratory experiments have confirmed that organic polymers form spontaneously from monomers on hot rock or clay surfaces.

In a different scenario of chemical evolution, early polymerizations leading to the origin of life may have occurred in

Figure 20–2 Testing a hypothesis about chemical evolution.

Diagram of the apparatus that Miller and Urey used to simulate the reducing atmosphere of early Earth. An electrical spark was produced in the upper right flask to simulate lightning. The gases present in the flask reacted together, forming a number of simple organic compounds that accumulated in the trap at the bottom.

cracks in the deep-ocean floor where hot water and minerals such as metal sulfides spew forth. Such **hydrothermal vents** would have been better protected than Earth's surface from the catastrophic effects of meteorite bombardment. Today these hot springs produce precursors of biological molecules and of energy-rich “food,” including hydrogen sulfide and methane.

After the first polymers formed, could they have assembled spontaneously into more complex structures? Scientists have synthesized several different **protobionts**, which are assemblages of abiotically produced (that is, not produced by organisms) organic polymers. They have been able to recover protobionts that resemble living cells in several ways, thus providing clues as to how aggregations of complex nonliving molecules took that “giant leap” and became living cells. These protobionts exhibit many functional and structural attributes of living cells. They often divide in half (binary fission) after they have sufficiently “grown.” Protobionts maintain an internal chemical environment that is different from the external environment (homeostasis), and some of them show the

Figure 20–3 Microspheres. These tiny protobionts exhibit some of the properties of life. (Steven Brooke and Richard LeDuc)

beginnings of metabolism (catalytic activity). They are highly organized, considering their relatively simple composition.

Microspheres are a type of protobiont formed by adding water to abiotically formed polypeptides (Fig. 20–3). Some microspheres demonstrate excitability: they produce an electrical potential across their surfaces, reminiscent of electrochemical gradients in cells. Microspheres can also absorb materials from their surroundings (selective permeability) and respond to changes in osmotic pressure as though they were enveloped by membranes, even though they contain no lipid.

THE FIRST CELLS PROBABLY ASSEMBLED FROM ORGANIC MOLECULES

The study of protobionts allows us to appreciate that relatively simple “pre-cells” can exhibit some of the properties of contemporary life. However, it is a major step (or several steps) to go from simple molecular aggregates such as protobionts to living cells. Although much has been learned about how organic molecules may have formed on primitive Earth, the problem of how pre-cells evolved into living cells remains to be solved.

It is not known exactly when life first appeared on Earth. **Microfossils** (ancient remains of microscopic life) indicate that cells were thriving 3.5 billion years ago, and nonfossil evidence published in 1996 indicates that life existed even earlier, at least 3.8 billion years ago. (The significance of this older date is discussed in *Making the Connection: The Earliest Date for Life and Speculations about How Life Arose*.)

The earliest cells were prokaryotic. Australian and South African rocks have yielded microscopic fossils of prokaryotic cells 3.1 to 3.5 billion years old. **Stromatolites**, another type of fossil evidence of the earliest cells, are rocklike columns composed of many minute layers of prokaryotic cells, usually

(a)

(b)

Figure 20–4 Stromatolites. (a) Living stromatolites at Hamlin Pool in Western Australia are composed of mats of cyanobacteria and minerals like calcium carbonate and are several thousand years old. (b) Cutaway view of a fossil stromatolite showing the layers of cyanobacteria and sediments that accumulated over time. This stromatolite, also from Western Australia, is about 3.5 billion years old. (a, Fred Bavendam/Peter Arnold, Inc.; b, Biological Photo Service)

cyanobacteria (Fig. 20–4). Over time, sediment collects around the cells and mineralizes. Meanwhile, a new layer of living cells grows over the older, dead cells. Fossil stromatolite reefs are found in a number of places in the world, including Great Slave Lake in Canada and the Gunflint Iron Formations along Lake Superior in the United States. Some fossil stromatolites are extremely ancient. One group in Western Australia, for example, is several billion years old. Living stromatolite reefs are still found, for example, in hot springs and in warm, shallow pools of fresh and salt water.

We have said that the origin of cells from macromolecular assemblages was a major step in the origin of life. Actually,

MAKING THE CONNECTION

THE EARLIEST DATE FOR LIFE AND SPECULATIONS ABOUT HOW LIFE AROSE

Why is it significant that Earth's earliest life may have existed 3.8 billion years ago? When American, Australian, and British scientists reported in 1996 that they had evidence of life some 300 million years earlier than the earliest established date of 3.5 billion years, the announcement generated a great deal of attention in the popular press as well as in scientific circles.

A new instrument called an ion microprobe was employed to determine carbon isotope ratios in some of Earth's oldest rocks, which were collected from Akilia Island off the southwestern coast of Greenland. Analysis of these rocks revealed carbon traces of the remains of ancient organisms. The lack of actual fossils in the rocks is the result of metamorphosis; the intense heat and pressure to which the rock was subjected would have destroyed all fossil traces. The new method of analysis appears to be reliable, and assuming the earlier date for life withstands future scientific scrutiny, it has significance as to when life arose and possibly where it arose.

To understand the significance of the new date, we must consider the early history of the solar system, when Earth was pelted by a hail of comets, asteroids, and meteorites—many as large as 100 kilometers (161 miles) in diameter. This barrage began soon

after Earth formed and gradually tapered off about 3.9 billion years ago. Scientists have long assumed that it would have been impossible for life to have begun during the bombardment. Each impact raised Earth's temperature, which did not begin to cool until the bombardment diminished. If the new date is correct and life was already thriving 3.8 billion years ago, then it had only about 100 million years in which to begin, a vanishingly short time in evolutionary terms.

Scientists are trying to understand the significance of the 100-million-year window for chemical evolution. Some speculate that life may have begun during the bombardment but somehow survived—perhaps in hydrothermal ocean vents (mentioned in the text). Other scientists have revived an old idea known as **panspermia**, which suggests that life did not originate on Earth, but began elsewhere in the galaxy—and drifted through space to Earth. If life originated elsewhere and was then introduced to Earth, more time is gained for the origin of life. However, if panspermia accounts for the origin of life on Earth, we still must elucidate a satisfactory explanation for the origin of life; the problem is simply transferred to another planet!

the evolution of cells probably occurred in a series of small steps. One of the most significant parts of that process would have been the evolution of molecular reproduction.

A crucial step in the origin of cells was molecular reproduction

In living cells, genetic information is stored in the nucleic acid DNA, which is transcribed into the message in RNA, which in turn is translated into the proper amino acid sequence in proteins. All three macromolecules in the DNA → RNA → protein sequence contain precise information, but only DNA and RNA are capable of self-replication, although only in the presence of the proper enzymes. Because both RNA and DNA can form spontaneously on clay in much the same way that other organic polymers do, the question becomes which molecule, DNA or RNA, first appeared in the prebiotic world.

Some scientists have suggested that RNA was the first informational molecule to evolve in the progression toward a self-sustaining, self-reproducing cell and that proteins and DNA came along later. According to the proposed model of the **RNA world**, the chemistry of prebiotic Earth gave rise to self-replicating RNA molecules that functioned as both enzyme and substrates for their own replication. We represent the replication as a circular arrow:

One of the surprising features of RNA is that it often has catalytic properties; such enzymatic RNAs are called **ribozymes**. In contemporary cells, ribozymes help catalyze the synthesis of RNA and process precursors into rRNA, tRNA, and mRNA (see Chapter 12). Before the evolution of true cells, ribozymes may have catalyzed their own replication in the clays, shallow rock pools, or hydrothermal vents where life originated. When RNA strands are added to a test tube containing RNA nucleotides but no enzymes, the nucleotides combine to form short RNA molecules. The rate of this reaction is increased if zinc is added as a catalyst. (Recall that zinc is bound to clay.)

In the RNA world, ribozymes (catalytic RNAs) initially catalyzed protein synthesis; only later did protein enzymes catalyze RNA synthesis.

Interestingly, RNA can direct protein synthesis by catalyzing peptide bond formation. Some single-stranded RNA molecules fold back on themselves as a result of interactions among the nucleotides composing the RNA strand. Sometimes the conformation (shape) of the folded RNA molecule is such that it weakly binds to an amino acid. If amino acids are held close together by RNA molecules, they may bond together, forming a polypeptide.

We have considered how the evolution of informational molecules may have given rise to DNA and later to proteins. If a self-replicating RNA capable of coding for proteins ap-

peared before DNA, how did DNA, the universal molecule of heredity, become involved in translation? Perhaps RNA made double-stranded copies of itself that eventually evolved into DNA.

The incorporation of DNA into the information transfer system would have been advantageous because the double helix conformation of DNA is more stable (that is, less reactive) than the single-stranded conformation of RNA. Such stability in a molecule that stores genetic information would have provided a decided advantage in the prebiotic world (as it does today).

In the DNA/RNA/protein world, then, DNA became the information storage molecule, RNA remained involved in protein synthesis, and protein enzymes catalyzed most cellular reactions, including DNA replication, RNA synthesis, and protein synthesis.

RNA is still a necessary component of the information transfer system because DNA is not catalytic. Thus natural selection at the molecular level favored the DNA \rightarrow RNA \rightarrow protein information sequence. Once DNA was incorporated into this sequence, RNA molecules assumed their present role as an intermediary in the transfer of genetic information.

Several additional steps had to occur before a true living cell could evolve from macromolecular aggregations. For example, the genetic code must have arisen extremely early in the prebiotic world because all organisms possess it, but how did it originate? Also, how did a plasma membrane of lipid and protein come to envelop the pre-cell assemblages, thereby permitting the accumulation of some molecules and the exclusion of others?

The first cells were probably heterotrophs, not autotrophs

The earliest cells probably obtained the organic molecules they needed from the environment, rather than synthesizing them. These primitive **heterotrophs** probably consumed many types of organic molecules that had spontaneously formed—sugars, nucleotides, and amino acids, to name a few. By fermenting these organic compounds, they obtained the energy needed to support life. Fermentation is, of course, an anaerobic process (that is, performed in the absence of oxygen), and the first cells were almost certainly **anaerobes**.

When the supply of spontaneously generated organic molecules was gradually depleted, only certain organisms could survive. Mutations had probably already occurred that permitted some cells to obtain energy directly from sunlight, perhaps by using sunlight to make ATP. These cells, which did not require the energy-rich organic compounds that were now

in short supply in the environment, had a distinct selective advantage.

Photosynthesis requires not only light energy but also a source of electrons, which are used to reduce CO_2 when organic molecules such as glucose are synthesized (see Chapter 8). Most likely, the first photosynthetic **autotrophs** (organisms that produce their own food from simple raw materials) used the energy of sunlight to split hydrogen-rich molecules such as H_2S , releasing elemental sulfur (not oxygen) in the process. Indeed, the green sulfur bacteria and the purple sulfur bacteria still use H_2S as a hydrogen source for photosynthesis.¹

The first photosynthetic autotrophs to obtain hydrogen by splitting water were the cyanobacteria. Water was quite abundant on early Earth, as it is today, and the selective advantage that splitting water bestowed on them allowed the cyanobacteria to thrive. In the process of splitting water, oxygen was released as a gas (O_2). Initially, the oxygen released from photosynthesis oxidized minerals in the ocean and in Earth's crust, and, as a result, oxygen did not begin to accumulate in the atmosphere for a long period of time. Eventually, however, oxygen began to accumulate in the ocean and the atmosphere.

The timing of the events just described can be estimated on the basis of geological and fossil evidence. Fossils from that period, which include rocks that contain traces of chlorophyll, as well as the fossil stromatolites discussed previously, indicate that the first photosynthetic organisms appeared approximately 3.1 to 3.5 billion years ago. This evidence suggests that heterotrophic forms existed even earlier.

Aerobes appeared after oxygen increased in the atmosphere

By two billion years ago, the cyanobacteria had produced sufficient oxygen to begin significantly changing the composition of the atmosphere. The increase in atmospheric oxygen had a profound effect on life. Obligate anaerobes (those organisms that cannot use oxygen for cellular respiration) were poisoned by the oxygen, and many species undoubtedly perished. Some anaerobes, however, survived in environments where oxygen does not penetrate; others developed ways to neutralize the oxygen so that it could not harm them. Some organisms, called **aerobes**, developed a respiratory pathway that *used* the oxygen to extract more energy from food and convert it to ATP energy. Aerobic respiration was joined to the existing anaerobic process of glycolysis.

The evolution of organisms that could use oxygen in their metabolism had several consequences. Organisms that respire aerobically gain much more energy from a single molecule of glucose than anaerobes gain by fermentation. As a result, the newly evolved aerobic organisms were more efficient and more competitive than anaerobes. Coupled with the poisonous na-

¹A third group of bacteria, the purple nonsulfur bacteria, uses other organic molecules or hydrogen gas as a hydrogen source.

ture of oxygen to anaerobes, the efficiency of aerobes forced anaerobes into relatively minor roles. Today the vast majority of organisms, including plants, animals, and most fungi, protists, and prokaryotes, use aerobic respiration, while only a few bacteria and even fewer protists and fungi are anaerobic.

The evolution of aerobic respiration had a stabilizing effect on both oxygen and carbon dioxide in the biosphere. Photosynthetic organisms used carbon dioxide as a source of carbon for the synthesis of organic compounds. This raw material would have been depleted from the atmosphere in a relatively short time without the advent of aerobic respiration, which releases carbon dioxide as a waste product from the complete breakdown of organic molecules. Carbon thus started cycling in the biosphere, moving from the nonliving physical environment, to photosynthetic organisms, to heterotrophs that ate the plants (see Chapter 53). Carbon was released back into the physical environment as carbon dioxide by aerobic respiration, and the carbon cycle continued. In a similar manner, oxygen was produced by photosynthesis and used during aerobic respiration.

Another significant consequence of photosynthesis occurred in the upper atmosphere, where molecular oxygen reacted to form **ozone**, O_3 (Fig. 20–5). A layer of ozone eventually blanketed Earth, preventing much of the sun's ultraviolet radiation from penetrating to the surface. With the ozone layer's protection from the mutagenic effect of ultraviolet radiation, organisms were able to live closer to the surface in aquatic environments and eventually to move onto land. Because the energy in ultraviolet radiation was necessary to form organic molecules, however, their abiotic synthesis decreased.

Eukaryotic cells descended from prokaryotic cells

Eukaryotes appeared in the fossil record 1.9 to 2.1 billion years ago. They arose from prokaryotes. Recall from Chapter 4 that prokaryotic cells lack nuclear envelopes as well as other membranous organelles such as mitochondria and chloroplasts. How did eukaryotic cells arise from prokaryotes?

The **endosymbiont theory**, advanced by Lynn Margulis, declares that organelles such as mitochondria and chloroplasts may each have originated from mutually advantageous symbiotic relationships between two prokaryotic organisms (Fig. 20–6). Chloroplasts apparently evolved from photosynthetic bacteria (perhaps cyanobacteria) that lived inside larger heterotrophic cells, while mitochondria presumably evolved from aerobic bacteria (perhaps purple bacteria) that lived inside larger anaerobic cells. Thus, early eukaryotic cells were composed of formerly free-living prokaryotes.

How did these bacteria come to be **endosymbionts**, which are organisms that live symbiotically inside a host cell? They may have originally been ingested, but not digested, by a host cell. Once so incorporated, they could have survived and reproduced along with the host cell so that future generations of the host also contained endosymbionts. The two organisms developed a mutualistic relationship in which each contributed

Figure 20–5 How ozone forms. Ozone (O_3) forms in the upper atmosphere when ultraviolet radiation from the sun breaks the double bonds of oxygen molecules.

something to the other. Eventually the endosymbiont lost the ability to exist outside its host, and the host cell lost the ability to survive without its endosymbionts. This theory stipulates that each of these partners brought to the relationship something the other lacked. For example, mitochondria provided the ability to carry out the aerobic respiration lacking in the original anaerobic host cell; chloroplasts provided the ability to use a simple carbon source (carbon dioxide) to produce needed organic molecules. The host cell provided a safe habitat and raw materials or nutrients.

Figure 20–6 The endosymbiont theory. Chloroplasts and mitochondria of eukaryotic cells are thought to have originated from various bacteria that lived as endosymbionts inside other cells.

The principal evidence in favor of the endosymbiont theory is that mitochondria and chloroplasts possess some (although not all) of their own genetic material and translational components. They have their own DNA (as a circular molecule similar to that of prokaryotes; see Chapter 23) and their own ribosomes (which resemble prokaryotic rather than eukaryotic ribosomes). Mitochondria and chloroplasts also possess some of the machinery for protein synthesis, including tRNA molecules, and are able to conduct protein synthesis on a limited scale independent of the nucleus. Furthermore, it is possible to poison mitochondria and chloroplasts with an antibiotic that affects prokaryotic but not eukaryotic cells. As discussed in Chapter 4, mitochondria and chloroplasts are enveloped by double membranes. The outer membrane apparently developed from the invagination of the host cell's plasma membrane, while the inner membrane is derived from the endosymbiont's plasma membrane.

A number of endosymbiotic relationships exist today. Many corals have algae living as endosymbionts within their cells (see *Making the Connection: Coral Reefs, Interdependence of Organisms, and Environmental Issues* in Chapter 28). In the gut of the termite lives a protozoon (*Myxotricha paradoxa*) that in turn has several different endosymbionts, including spiro-

chete bacteria that are attached to the protozoon and function as whiplike flagella, allowing it to move.

The endosymbiont theory does not completely explain the evolution of eukaryotic cells from prokaryotes. It does not explain, for example, how the genetic material in the nucleus came to be surrounded by a membranous envelope. A few biologists reject the endosymbiont theory and subscribe to the **autogenous model**, in which eukaryotes arose from prokaryotes by the proliferation of internal membranes to form cellular compartments; these internal membranes were derived from the prokaryotic plasma membrane. Regardless of how eukaryotic cells evolved, their advent set the stage for further evolutionary developments.

THE FOSSIL RECORD PROVIDES US WITH CLUES TO THE HISTORY OF LIFE

The sequence of biological, climate, and geological events that make up the history of life is recorded in rocks and fossils. The sediments of Earth's crust consist of five major rock strata (layers), each subdivided into minor strata, lying one on top of

the other. Very few places on Earth are covered by all layers, but the strata that are present typically occur in the correct order, with younger rocks on top of older ones. These sheets of rock were formed by the accumulation of mud and sand at the bottoms of the ocean, seas, and lakes. Each layer contains certain characteristic fossils that serve to identify deposits made at approximately the same time in different parts of the world.

Geologists divide Earth's 4.6-billion-year history into units of time based on major geological, climate, and biological events. Relatively little is known about Earth from its beginnings approximately 4.6 billion years ago up to 570 million years ago, a period known informally as **Precambrian time**. The fossil record of ancient organisms is abundant beginning about 570 million years ago. This most recent time, from 570 million years ago to the present, is divided into three **eras** based primarily on organisms that were characteristic of each era (Table 20–1). Eras are subdivided into **periods**, which in turn are composed of **epochs**.

Evidence of living cells is found in Precambrian deposits

Signs of Precambrian life date back to about 3.8 billion years ago. Not much physical evidence is available to us because the rocks of Precambrian time, being extremely ancient, are deeply buried in most parts of the world. Precambrian rocks are exposed in a few places, including the bottom of the Grand Canyon and along the shores of Lake Superior. More than 400 Precambrian rock formations have revealed microfossils.

During Precambrian time, widespread volcanic activity and giant upheavals raised mountains, and the heat, pressure, and churning associated with these movements probably destroyed most of whatever fossils may have been formed. Some evidence of life still remains as traces of graphite or pure carbon, which may be the transformed remains of primitive life. These remains are especially abundant in what were the ocean and seas of that time. Additionally, fossils resembling cyanobacteria have been recovered from several Precambrian formations. The fossils found in later (more recent) Precambrian rocks show unambiguous examples of some major groups of bacteria, fungi, protists (including multicellular algae), and animals.

One rich source of Precambrian fossil deposits is the Ediacaran Hills (pronounced “ee-dee-ack’a-ran”) in South Australia. **Ediacaran fossils**, the oldest known fossils of multicellular animals, are from very late in Precambrian time—from 600 to 570 million years ago. Biologists have not yet resolved the phylogenetic affinities of the simple, soft-bodied animals found there and at other Precambrian sites around the world. Some of these animals appear to be early examples of jellyfish, soft corals, segmented worms, mollusks, and soft-bodied arthropods, whereas others show no resemblance to any other known fossil or living organism (Fig. 20–7). If this interpretation is correct, then at least some of the Ediacaran animals were ancestral to animals that followed. Other biologists who have studied the fossils, however, think that the Ediacaran an-

imals have a body plan that is different from all known animal phyla. If this interpretation is correct, then these animals probably went extinct by the end of the Precambrian and, therefore, would not be directly related to modern animals.

A considerable diversity of organisms evolved during the Paleozoic era

The **Paleozoic era** began approximately 570 million years ago and lasted approximately 222 million years. It is divided into six periods: Cambrian, Ordovician, Silurian, Devonian, Carboniferous, and Permian.

The oldest subdivision of the Paleozoic era, the Cambrian period, is represented by rocks rich in fossils. Evolution was in such high gear, with the sudden appearance of many new animal groups, that this period has been nicknamed the **Cambrian explosion**. Fossils of all of the contemporary animal phyla are present, along with many bizarre, extinct phyla, in marine sediments. The sea floor was covered with sponges, corals, sea lilies, sea stars, snails, clamlike bivalves, primitive squidlike cephalopods, lamp shells (brachiopods), trilobites (see chapter opening photograph; also see Fig. 29–12), at least one primitive chordate, and other marine animals. Burrowing, grazing, and predatory animals all became established in the marine environment. Scientists have not determined the factor or factors responsible for the Cambrian explosion, which has been unmatched in the evolutionary history of life. There is, however, some evidence that oxygen concentrations, which had continued to gradually increase in the atmosphere, passed some critical environmental threshold (10% of present-day oxygen, or higher) late in Precambrian time. Scientists who

Figure 20–7 A Precambrian fossil. The organism, from the Ediacaran Hills of South Australia, lived in shallow marine waters. It is unlike any known modern organism. (William E. Ferguson)

TABLE 20-1 Some Important Biological Events in Geological Time

	Time	Era	Period	Epoch	Geological/Climatic Conditions
Million Years before Present	10,000 years ago to present	Cenozoic	Quaternary	Holocene	End of last Ice Age; warmer climate; higher sea levels as glaciers melt
	2			Pleistocene	Multiple ice ages; glaciers in Northern Hemisphere
	5		Tertiary	Pliocene	Uplift and mountain-building; volcanoes; climate much cooler; North and South America join at Isthmus of Panama
	25			Miocene	Mountains form; climate drier and cooler
	38			Oligocene	Rise of Alps and Himalayas; most land low; volcanic activity in Rockies; climate cool and dry
	55			Eocene	Climate warmer
	65			Paleocene	Continental seas disappear; climate mild to cool and wet
	144	Mesozoic	Cretaceous		Continents separate; most continents low; large inland seas and swamps; climate warm
	213		Jurassic		Continents low; inland seas; mountains form; continental drift begins; climate mild
	248		Triassic		Many mountains form; widespread deserts; climate warm and dry
	286	Paleozoic	Permian		Glaciers; continents rise and merge as Pangaea; climate variable
	360		Carboniferous		Lands low and swampy; climate warm and humid, becoming cooler later
	408		Devonian		Glaciers; inland seas
	438		Silurian		Most continents remain covered by seas; climate warm
	505		Ordovician		Sea covers most continents
	570		Cambrian		Oldest rocks with abundant fossils; lands low; climate mild and wet

advocate the *oxygen enrichment hypothesis* note that until late in Precambrian time, Earth possessed insufficient oxygen to support larger animals. The most important fossil site that documents the Cambrian explosion is the **Burgess Shale** in British Columbia (Fig. 20-8).

The major animal body plans, which are discussed in Chapter 28, were established so early in the history of the eukaryotes that little change of a basic nature has occurred since.

This probably indicates that, early in the Cambrian period, each animal phylum had reached a degree of adaptation that allowed it to exploit its environment and accommodate changes in its surroundings with relatively limited modifications in its body plan.

According to geologists, the continents were gradually flooded during the Cambrian period. In the Ordovician period, much of what is now land was covered by shallow seas

TABLE 20-1 Continued

Plants and Microorganisms	Animals
Decline of some woody plants; rise of herbaceous plants	Age of <i>Homo sapiens</i>
Extinction of some plant species	Extinction of many large mammals at end
Expansion of extensive grasslands and deserts; decline of forests	Many grazing mammals; large carnivorous mammals; first known human-like primates
Flowering plants continue to diversify	Great diversity of grazing mammals and songbirds
Spread of forests; flowering plant communities expand	Apes appear; present mammalian families are represented
Flowering plants dominant	Modern mammalian orders appear and diversify; modern bird orders appear
Semitropical vegetation (flowering plants and conifers) widespread	Primitive mammals diversify rapidly
Rise of flowering plants	Dinosaurs reach peak, then become extinct at end; toothed birds become extinct; primitive mammals
Gymnosperms common	Large, specialized dinosaurs; first toothed birds; primitive insectivorous mammals diversify
Gymnosperms dominant; ferns common	First dinosaurs; first mammals
Conifers diversify; cycads appear	Modern insects appear; mammal-like reptiles; extinction of many Paleozoic invertebrates and vertebrates at end of Permian
Forests of ferns, club mosses, horsetails, and gymnosperms; mosses and liverworts	First reptiles; spread of ancient amphibians; many insect forms; ancient sharks abundant
Vascular plants diversify and become well established; first forests; gymnosperms appear; bryophytes appear	Many trilobites; fishes with jaws appear and diversify; amphibians appear; wingless insects appear
Algae dominant in aquatic environments; vascular plants appear	Jawless fishes diversify; coral reefs common; terrestrial arthropods
Marine algae dominant; fossil spores of terrestrial plants	Invertebrates dominant; coral reefs appear; first fishes appear
Algae; bacteria and cyanobacteria; fungi	Age of marine invertebrates; modern and extinct animal phyla represented; first chordates

in which there was another burst of evolutionary diversification, although not as dramatic as the Cambrian explosion. The Ordovician seas were inhabited by giant cephalopods, squid-like animals with straight shells 5 to 7 meters (16 to 23 feet) long and 30 centimeters (12 inches) in diameter. Coral reefs first appeared during this period, as did the earliest vertebrates, which were small, jawless, bony-armored fishes called *ostracoderms* (Fig. 20-9). Lacking jaws, these fishes typically had

round or slitlike mouth openings that may have sucked in small food particles from the water or scooped up bottom organic debris. Ordovician deposits also contain fossil spores of terrestrial (land-dwelling) plants, which suggests that the colonization of land had begun.

During the Silurian period, jawless fishes diversified considerably, and jawed fishes first appeared. Definitive evidence of two life forms of great biological significance appeared in

Figure 20-8 Fossils from the Cambrian explosion. (a) *Marrella splendens* was a small arthropod. (b) In spite of its unusual appearance, *Wiwaxia* was actually a worm that was distantly related to earthworms. It had scaly armor and needle-like spines for protection. (c) *Waptia fieldensis* was a crustacean that may have been an ancestor of modern crustaceans such as shrimp. All three of these fossils were obtained from the Burgess Shale in the Canadian Rockies. (a, b, c, Chip Clark)

the Silurian period: terrestrial plants and air-breathing animals. The first known plants resembled ferns in that they possessed vascular (conducting) tissue and reproduced by spores. The evolution of plants allowed animals to colonize the land because plants provided the first terrestrial animals with food and shelter. All air-breathing land animals discovered in Silurian rocks were arthropods—millipedes, spider-like arthropods, and possibly centipedes. Interestingly, from an ecological perspective, the energy flow from plants to animals probably occurred via detritus, which is organic debris from decomposing organisms, rather than directly from living plant material. Millipedes eat plant detritus today, and spiders and centipedes prey on other animals.

A great variety of fishes appeared in the Devonian period. In fact, the Devonian period is frequently called the Age of Fishes. Jawless ostracoderms persisted into the Devonian, but this period also witnessed the explosive radiation of fishes with jaws, an adaptation that enables a vertebrate to chew and bite. Armored *placoderms*, an extinct group of jawed fishes, diversified to exploit varied lifestyles, from bottom-dwelling filter-feeders to the most voracious predators of the time (see Fig.

30–10b). Appearing in Devonian deposits are sharks and the two predominant types of bony fish: lobe-finned fishes (including the coelacanths and lungfishes) and ray-finned fishes, which gave rise to the major orders of modern fishes. Coelacanths, primitive bony fish with lobed fins, were originally thought to have become extinct; in 1938, however, the first living coelacanth was discovered in the deep waters off the coast of Madagascar (see Fig. 30–15). This discovery was of great scientific significance because it gave paleontologists an opportunity to test their hypotheses about fossil coelacanths by comparing them to the living species. Lungfishes, an ancient group of air-breathing fish, were most common during the Devonian period; only about six species persist today, in South America, Africa, and Australia.

Upper (more recent) Devonian sediments contain fossil remains of salamander-like amphibians that were often quite large, with short necks and heavy, muscular tails (see Fig. 30–17). These animals, whose skulls were encased in bony armor, were in many respects quite similar to the lobe-finned fishes, one of which may have been their immediate ancestor; for example, early amphibians possessed fishlike tail fins and

Figure 20-9 Representative ostracoderms. (a) *Thelodus*, (b) *Pterapsis*, and (c) *Jamoytius* are fossil ostracoderms, primitive jawless fishes that appeared in the Devonian period.

scaly body coverings. Early amphibians probably spent most of their time in and around water. Wingless insects also originated in the late Devonian period.

The early vascular plants diversified during the Devonian period in a burst of evolution that rivaled that of animals during the Cambrian explosion. With the exception of flowering plants, all major plant groups appeared during the Devonian. Forests of ferns, club mosses, horsetails, and seed ferns (an ex-

tinct group of ancient plants that had fernlike foliage but reproduced by forming seeds) flourished.

The Carboniferous period is named for the great swamp forests whose remains persist today as major coal deposits. Much of the land during this time was covered with low swamps filled with horsetails, club mosses, ferns, seed ferns, and gymnosperms (seed-bearing plants such as conifers) (Fig. 20–10).

Amphibians, which underwent adaptive radiation and exploited both aquatic and terrestrial ecosystems, were the dominant terrestrial carnivores of the Carboniferous period. Reptiles first appeared and diverged to form two major lines during the Carboniferous period. One line consisted of mostly small and mid-sized, insectivorous (insect-eating) lizards; this line would later lead to lizards, snakes, crocodiles, dinosaurs, and birds. The other reptilian line led to a diverse group of Permian and early Mesozoic mammal-like reptiles. Two groups of winged insects, cockroaches and dragonflies, appeared in the Carboniferous period. The dragonflies ranged in size from those smaller than today's dragonflies to some with wingspans of 75 centimeters (2.5 feet).

Amphibians continued in importance during the Permian period, but they were no longer the dominant carnivores in terrestrial ecosystems. During the Permian period, the mammal-like reptiles diversified explosively and dominated both carnivorous and herbivorous terrestrial lifestyles. One important group of mammal-like reptiles, originating in the Permian and extending into the Mesozoic era, were the *therapsids*, a group that included the ancestor of mammals (discussed shortly; also see Fig. 30–23).

During the Permian period, seed plants diversified and dominated most plant communities. Cone-bearing conifers were widespread, and cycads (plants resembling palms, with crowns of fernlike leaves and large, seed-containing cones) and ginkgoes (trees with broad, fan-shaped leaves and exposed, fleshy seeds) appeared.

The greatest mass extinction of all time occurred at the end of the Paleozoic era, between the Permian and Triassic periods, some 250 million years ago. For example, more than 90% of all existing marine species became extinct at this time. The Permian period was characterized by great changes in climate and topography. By the late Permian, the sea level had dropped, and the distribution of shallow seas on continental shelves shrank to less than one-third of their distribution during the early Permian. In the early Triassic, the sea level rose again, and shallow seas expanded. The cause of the late Permian mass extinction is controversial. Changes in sea level may account for the massive extinctions of marine invertebrates. The reduction of shallow seas also would have caused climate instability on land, perhaps triggering the extinction of terrestrial organisms observed at that time as well. Another hypothesis for the Permian-Triassic extinction episode is the development of widespread oxygen depletion in the ocean, an event that is supported by geochemical evidence reported in 1997. Cataclysmic volcanic eruptions that occurred in Siberia over a period of one million years have also been linked to the late Permian mass extinction; these eruptions may have caused global cooling.

Dinosaurs and other reptiles dominated the Mesozoic era

The **Mesozoic era** began about 248 million years ago and lasted some 183 million years. It is divided into the Triassic,

► **Figure 20–11 Representative animals of the Mesozoic era.** (a) This Triassic thecodont, *Euparkia*, was about 150 centimeters (5 feet) long. Because its forelimbs are shorter than its hind limbs, *Euparkia* was probably bipedal. (b) *Elasmosaurus* was a long-necked plesiosaur. Other plesiosaurs had short necks and superficially resembled seals. (c) *Ophthalmosaurus* was an ichthyosaur that superficially resembled a porpoise. (d) *Pteranodon* was a pterosaur from the Cretaceous period. Pterosaur wings were membranes of skin that were supported by an elongated fourth finger bone. Some pterosaurs had long tails, whereas others lacked tails. (e) *Tylosaurus* was a large (about 10 meters, or 33 feet, long) marine lizard (mosasaur). (f) *Giganotosaurus*, whose fossil remains were discovered in Argentina, was a predatory giant saurischian more than 12 meters (39 feet) in length. (g) *Argentinosaurus*, a herbivorous saurischian from Argentina, is the largest known animal to have ever walked on land. (h) *Hadrosaurus* was a duck-billed ornithischian. Some duck-billed dinosaurs reached 10 meters (33 feet) in length. (i) *Ankylosaurus* was a heavily armored ornithischian. Ankylosaurs ranged from 2 to 6 meters (7 to 20 feet) in length.

Jurassic, and Cretaceous periods. The outstanding feature of the Mesozoic era was the origin, differentiation, and ultimately the extinction of a large variety of reptiles. For this reason, the Mesozoic era is commonly called the Age of Reptiles. Most of the modern orders of insects appeared during the Mesozoic era. Snails and bivalves (clams and their relatives) increased in number and diversity, and sea urchins reached their peak diversity. From a botanical viewpoint, the Mesozoic era was dominated by gymnosperms until the mid-Cretaceous period, when the flowering plants first diversified.

During the Triassic period, reptiles underwent an adaptive radiation leading to many groups. On land, the dominant Triassic groups were the mammal-like therapsids, which ranged from small-sized insectivores (insect eaters) to moderately large herbivores, and a diverse group of *thecodonts*, early “ruling reptiles,” that were primarily carnivores (Fig. 20–11a). The thecodont group was ancestral to dinosaurs, flying reptiles, and possibly birds.

In the seas, several important marine reptile groups, the plesiosaurs and ichthyosaurs, appeared in the Triassic and persisted into the Cretaceous. *Plesiosaurs* were aquatic reptiles with bodies up to 15 meters (50 feet) long and paddle-like fins (Fig. 20–11b). *Ichthyosaurs*, also aquatic reptiles, had body forms superficially resembling those of sharks or porpoises, with short necks, large dorsal fins, and shark-type tails (Fig. 20–11c).

During the late Triassic period, many new reptiles and their descendants appeared. Turtles appeared over 210 million years ago. Both marine and land turtles have survived to the present with few skeletal changes. The first mammals to appear in the Triassic period were small insectivores that evolved from the mammal-like therapsids of the Triassic. Mammals diversified into a variety of mostly small, nocturnal insectivores during the remainder of the Mesozoic, with marsupial and placental mammals appearing in the Cretaceous period.

Pterosaurs, the first flying reptiles, appeared and underwent considerable diversification during the Mesozoic era (Fig. 20–11*d*). This group produced some quite spectacular forms, most notably the giant *Quetzalcoatlus*, known from fragmentary Cretaceous fossils in Texas to have a wingspan of 11 to 15 meters (36 to 49 feet). In addition, the two main dinosaur lines (discussed shortly) were established by the end of the Triassic period.

During the Jurassic and Cretaceous periods, other important groups—such as crocodiles, lizards, snakes, and birds—appeared, and the dinosaurs diversified dramatically to “inherit the Earth.” Crocodiles originated in the early Jurassic, probably from a thecodont ancestor. Lizards and snakes appeared in the late Jurassic and early Cretaceous periods, respectively. Most of the snakes and lizards found in Mesozoic fossil deposits are similar to their present-day descendants. One group of lizards, the *mosasaurs*, entered the seas as large, voracious predators during the late Cretaceous period. The mosasaurs, which attained lengths of 10 meters (33 feet) or more, did not survive to the present (Fig. 20–11*e*).

Birds appeared by the late Jurassic period and are thought to have directly evolved from either a specialized dinosaur or a relatively unspecialized thecodont. Excellent bird fossils, some even showing the outlines of feathers, have been preserved from the Jurassic period. *Archaeopteryx*, the oldest known bird, lived about 150 million years ago. It was about the size of a crow and had rather feeble wings (see Fig. 30–22). Although *Archaeopteryx* is considered a bird (witness the feathers), it had many reptilian features, including a mouthful of teeth and a long, bony tail. Some well preserved bird fossils have been found in Cretaceous deposits in China. These include *Sinornis*, a 135-million-year old sparrow-sized bird capable of perching, and the magpie-sized *Confuciusornis*, the earliest known bird with a toothless beak. *Confuciusornis* may date back as far as 142 million years. The Chinese fossils document a variety of very primitive birds that preserved many reptilian features yet were clearly able to fly.

Dinosaurs underwent an impressive radiation throughout the Jurassic and Cretaceous periods. There were two main groups of dinosaurs, the *saurischians*, with pelvic bones similar to those of modern-day lizards, and the *ornithischians*, with pelvic bones similar to those of birds (Fig. 20–12). Some saurischians were fast, bipedal forms ranging from those the size of a dog to the ultimate representatives of this group, the gigantic carnivores of the Cretaceous period, *Tyrannosaurus*, *Carcharodontosaurus*, and *Giganotosaurus* (Figs. 20–11*f* and 20–13). Other saurischians were huge, quadrupedal dinosaurs that ate plants. Some of these were the largest terrestrial animals that have ever lived, including *Argentinosaurus*, with an estimated length of 30 meters (98 feet) and an estimated weight of 72 to 90 metric tons (80 to 100 tons) (Fig. 20–11*g*). It is thought that *Argentinosaurus* and other plant-eating saurischians ate huge quantities of vegetation such as needles (leaves) from tall conifers.

The other group of dinosaurs, the ornithischians, was entirely herbivorous. Although some ornithischians were bipedal, the majority were quadrupedal. Some had no front teeth and possessed stout, horny, birdlike beaks. In some species these beaks were broad and ducklike, hence the common name, duck-billed dinosaurs (Fig. 20–11*h*). Other ornithischians had great armor plates, possibly as protection against the carnivorous saurischians. *Ankylosaurus*, for example, had a broad, flat body covered with armor plates (actually bony scales embedded in the skin) and large, laterally projecting spikes (Fig. 20–11*i*).

Many traditional ideas about dinosaurs—that they were cold-blooded, slow-moving monsters living in swamps, for example—have been reconsidered over the last 20 years. Recent evidence suggests that at least some dinosaurs may have been warm-blooded, agile, and capable of moving extremely fast. Many appear to have had complex social behaviors, including courtship rituals and parental nurturing of their young. Some species lived in social groups and hunted in packs.

At the end of the Cretaceous period, 65 million years ago, dinosaurs, pterosaurs, and many other animals abruptly became extinct. Many gymnosperms, with the exception of conifers, also perished. Several explanations for the mass extinction at the end of the Cretaceous period have been proposed. Interestingly, an increasing amount of scientific evidence suggests that a catastrophic collision of a large extraterrestrial body with Earth resulted in dramatic climate changes that contributed to the demise of the dinosaurs and many other organisms. Part of the evidence is a small band of dark clay with a high concentration of iridium located between Mesozoic and Cenozoic sediments at more than 200 sites around the world. Iridium is rare on Earth but abundant in meteorites, leading many to conclude that Earth was hit by a large extraterrestrial object at that time. (The force of the impact would have driven the iridium into the atmosphere to be deposited later on the land by precipitation.) The Chicxulub crater, which is buried under the Yucatán Peninsula in Mexico, is the apparent site of the collision at the close of the Cretaceous period. The impact produced giant tsunamis (tidal waves) that deposited materials from the extraterrestrial body around the perimeter of the Gulf of Mexico, from Alabama to Guatemala. It may have caused worldwide forest fires and giant dust clouds that lowered temperatures for many years.

Although it is widely accepted that a collision with an extraterrestrial body occurred 65 million years ago, there is no consensus about the effects of such an impact on organisms. The extinction of many marine organisms at or immediately after the time of the impact was probably the result of the environmental upheaval produced by the collision. However, a number of clam species associated with the mass extinction at the end of the Cretaceous period appear to have become extinct *before* the impact, suggesting that some of the massive extinctions occurring then were caused by other factors.

Figure 20–12 Saurischian and ornithischian dinosaurs. The two orders of dinosaurs are distinguished primarily by differences in their pelvic bones. (a) The saurischian pelvis. Note the opening in the hip socket, a trait possessed by no quadrupedal vertebrates other than dinosaurs. (b) The ornithischian pelvis also has the hole in the hip socket but differs from the saurischian pelvis in that it has a backward-directed extension of the pubis.

Figure 20–13 Reconstruction of a skull of *Carcharodontosaurus*. The fossil remains of this fearsome predator were discovered in North Africa. (Paul Sereno ©1999. Reprinted with permission of Discover Magazine.)

The Cenozoic era is known as the Age of Mammals

With equal justice the **Cenozoic era** could be called the Age of Mammals, the Age of Birds, the Age of Insects, or the Age of Flowering Plants. This era is marked by the appearance of all these forms in great variety and numbers of species. The Cenozoic era extends from 65 million years ago to the present. It is subdivided into two periods: the Tertiary period, encompassing some 63 million years, and the Quaternary period, which covers the last 2 million years. The Tertiary period is subdivided into five epochs, named from earliest to latest: Paleocene, Eocene, Oligocene, Miocene, and Pliocene. The Quaternary period is subdivided into the Pleistocene and Holocene epochs.

Flowering plants, which arose during the Cretaceous period, continued to diversify during the Cenozoic era. During the Paleocene and Eocene epochs, fossils indicate that tropical to semitropical plant communities extended to relatively high

MAKING THE CONNECTION

MAMMALIAN DIVERSITY AND THE CARRYING CAPACITY OF THE ENVIRONMENT

Has mammalian diversity peaked or is it declining? The fossil record indicates that during the 10 million years or so following the extinction of the dinosaurs, mammals underwent considerable adaptive radiation. According to conventional wisdom, mammals have continued to diversify, and the present is the time of maximum mammalian diversity.

John Alroy, a paleontologist at the Smithsonian Institution, disagrees. He assembled an extensive database of all mammalian genera* and species that occurred in North America (excluding bats and marine mammals), from the demise of the dinosaurs, about 65 million years ago, to the present. His data indicate that for the past 55 million years, North America has been home to a constant number (that is, a diversity equilibrium) of mammalian species.[†] (The actual *number* of species at the equilibrium point is not known, but Alroy's method provides diversity *estimates* at different time intervals that are accurate relative to one another.) What is remarkable about Alroy's data is that, despite the repeated turnover of players during the past 55 million years as existing mammalian species became extinct and others evolved, the number of mammalian species remains constant.

Why has North America been home to a constant number of mammalian species for the past 55 million years? Why not more or less? Alroy's research has sparked a connection between paleontology and ecology. Some scientists suggest that the North American continent has a finite amount of food and other resources to support mammals. In ecological terms, an environment's ability to support a group of organisms is known as its *carrying capacity* (see

Chapter 51). These scientists suggest that North America's carrying capacity for mammalian species is fixed.

Although either extinction or speciation could be the mechanism that causes diversity equilibrium, Alroy's data indicate that only speciation is a factor. When the number of species rises above the carrying capacity, greater competition among species decreases the rate of speciation so that mammalian diversity ceases to grow. When the species number falls below the carrying capacity, mammalian diversification increases because competition among species decreases and, as a result, the rate of speciation increases.

Alroy's data also indicate that mammals as a group are robust in an evolutionary sense. During the past 65 million years, mammals have not experienced a large mass extinction event of the magnitude of the one at the end of the Cretaceous period. The mammalian line has, however, undergone important changes in rates of extinction. The largest mass extinction event of the Cenozoic era occurred at the very end of the Pleistocene epoch. In addition to its extraordinary rapidity (less than 1000 years), the end-Pleistocene event is marked by numerous other features that implicate humans as the main cause.

*Recall from Chapter 1 that a genus (pl., *genera*) is a group of closely related species.

[†]Alroy, J. "Constant Extinction, Constrained Diversification, and Uncoordinated Stasis in North American Mammals." *Paleogeography, Paleoclimatology, Paleoecology*, Vol. 127, 1996.

latitudes. Palms, for example, are found in Eocene deposits in Wyoming. Later in the Cenozoic era, there is evidence of more open habitats. Grasslands and savannas occurred throughout much of North America during the Miocene epoch, with deserts developing later in the Pliocene and Pleistocene epochs. During the Pleistocene epoch, plant communities changed dynamically in response to fluctuating climates associated with the multiple advances and retreats of continental glaciers.

During the Paleocene epoch, an explosive radiation of primitive mammals occurred (see *Making the Connection: Mammalian Diversity and the Carrying Capacity of the Environment*). Most of these were small forest dwellers that are not closely related to modern mammals. During the Eocene epoch, there was an explosive radiation of mammals; all of the modern orders first appeared and diversified. Again, many of the mammals were small, but there were also some larger herbivores—the *titanotheres*, for example, which got progressively larger during the Eocene epoch (Fig. 20–14*a*).

During the Oligocene epoch, many modern families of mammals appeared, including the first fossil apes in Africa. A number of lineages showed specializations that suggest a more open type of habitat, such as grassland or savanna. For example, many of the animals were larger and had longer legs for running, specialized teeth for chewing coarse vegetation or for preying on animals, and increases in their relative brain sizes. These specializations continued in the Miocene and Pliocene epochs. Especially diverse during these epochs were hoofed mammals such as horses, which underwent adaptive radiation to include both browsing and grazing lifestyles. Carnivores specialized for long-distance running after prey also appeared in the Pliocene epoch. (Before that, carnivores were primarily ambush predators.) Human ancestors are found during the Pliocene epoch, about 4.4 million years ago, in Africa; the genus *Homo* appeared approximately 2.3 million years ago. (Primate evolution, including human evolution, is discussed in Chapter 21.)

Figure 20-14 Representative North and South American mammals of the Cenozoic era.

(a) *Brontotherium* was a titanothere from the late Eocene epoch. (b–f) Mammals of the Pliocene and Pleistocene epochs. (b) The elephant-like mastodon (*Mammuthus*) was at home in forests, lakes, and rivers. (c) The saber-toothed cat (*Smilodon*) was found in both North and South America. Its enlarged canine teeth were approximately 20 centimeters (8 inches) long and were curved like sabers. (d) This camel-like mammal (*Macrauchenia*) from South America probably browsed in forest clearings.

Macrauchenia is usually depicted with a short trunk because, like elephants, its nasal openings are on the skull roof rather than in the front of the skull. (e) *Megatherium* was a South American giant ground sloth. As long as 6 meters (20 feet), *Megatherium* had 18-centimeter (7-inch) claws that may have been used to strip bark from trees. Other paleontologists think *Megatherium* used its claws to stab prey.

(f) The giant armadillo (*Glyptodon*) lived on the pampas of South America. Encased in bony armor, *Glyptodon* was about 2 meters (6.5 feet) long. Later glyptodont species reached 4 meters (13 feet).

The Pliocene and Pleistocene epochs witnessed a spectacular North and South American large-mammal fauna, including mastodons, saber-toothed cats, camels, giant ground sloths, giant armadillos, and numerous other species (Fig. 20–14*b–f*). However, many of the large mammals became extinct at the end of the Pleistocene, perhaps due to climate change—the Pleistocene epoch was marked by several ice ages—and/or the influence of humans, who had spread from Africa to Europe and Asia, and later to North and South America by crossing a land bridge between Siberia and Alaska. Strong archaeological evidence exists that this mass extinction event is concurrent with the appearance of human hunters who possessed Clovis spear-point technology.

During the Eocene epoch, there was an explosive radiation of birds, which acquired specializations for many different habitats. The jaws and beak of the flightless giant bird *Diatryma*, for example, were adapted primarily for crushing and slicing vegetation in Eocene forests, marshes, and grasslands (Fig. 20–15). The songbirds diversified extensively during the Miocene epoch to become the most diverse order of living birds.

Figure 20–15 A representative bird from the Eocene epoch. *Diatryma*, a giant, flightless bird, stood 2.1 meters (7 feet) tall and weighed about 175 kilograms (385 pounds).

S U M M A R Y W I T H K E Y T E R M S

- I. Biologists generally agree that life originated from nonliving matter by **chemical evolution**. Although chemical evolution is very difficult to test experimentally, a number of hypotheses about the origin of life are testable.
 - A. Four requirements for chemical evolution are:
 1. The absence of oxygen, which would have reacted with and oxidized abiotically-produced organic molecules.
 2. Energy to form organic molecules.
 3. Chemical building blocks, including water, minerals, and gases present in the atmosphere, to form organic molecules.
 4. Sufficient time for molecules to accumulate and react.
 - B. Four steps are hypothesized in chemical evolution.
 1. Small organic molecules formed spontaneously and accumulated.
 2. Macromolecules assembled from the small organic molecules.
 3. Macromolecular assemblages called **protobionts** formed from macromolecules.
 - a. RNA molecules that could replicate themselves and carry out necessary chemical reactions may have been the first informational molecules to evolve.
 - b. Natural selection at the molecular level resulted in the DNA → RNA → protein information sequence.
 4. Cells arose from the macromolecular assemblages.
- II. The oldest cells in the fossil record are 3.1 to 3.5 billion years old. Non-fossil evidence places earliest life at 3.8 billion years old.
 - A. The first cells were prokaryotic **heterotrophs** that obtained organic molecules from the environment. They were almost certainly **anaerobes**.
 - B. Later, **autotrophs**, organisms that produce their own organic molecules by photosynthesis, arose.
 - C. The evolution of photosynthesis ultimately changed early life because it generated oxygen, which accumulated in the atmosphere, and permitted the evolution of **aerobes**, organisms that could use oxygen for a more efficient type of cellular respiration.
 - D. Eukaryotic cells arose from prokaryotic cells. According to the **endosymbiont theory**, certain eukaryotic organelles (mitochondria and chloroplasts) evolved from prokaryotic **endosymbionts** within larger prokaryotic hosts.
- III. Earth's history is divided into **eras, periods, and epochs**.
 - A. During **Precambrian time**, which extended from approximately 4.6 billion years ago up to 570 million years ago, life began and diverged into different groups of bacteria, protists (including algae), fungi, and animals.
 1. Signs of Precambrian life date back to about 3.8 billion years ago.
 2. One rich source of Precambrian fossil deposits is the Ediacaran Hills in South Australia. **Ediacaran fossils** of multicellular animals are from very late in Precambrian time—from 590 to 570 million years ago.
 - B. During the **Paleozoic era**, which began approximately 570 million years ago and lasted approximately 222 million years, all major groups of plants, except for flowering plants, and all animal phyla appeared.
 1. During the Cambrian period, the pace of evolution was so rapid that this period has been nicknamed the **Cambrian explosion**. The most important fossil site that documents the Cambrian explosion is the **Burgess Shale** in British Columbia.
 2. Fish and amphibians flourished, and reptiles appeared and diversified during the Paleozoic era.
 3. The greatest mass extinction of all time occurred at the end of the Paleozoic era, some 250 million years ago. More than 90% of all existing marine species became extinct at this time, as well as many terrestrial species.
 - C. The **Mesozoic era** began about 248 million years ago and lasted some 183 million years.

1. The Mesozoic era was characterized by the appearance of flowering plants and the evolutionary diversification of reptiles. Dinosaurs, which descended from early reptiles, dominated Earth during the Mesozoic era. Insects flourished, and birds and early mammals evolved.
2. At the end of the Cretaceous period, 65 million years ago, a great many animals abruptly became extinct. A collision of Earth with a large extraterrestrial body may have resulted in dramatic climate changes that played a role in this mass extinction episode.

D. In the **Cenozoic era**, which extends from 65 million years ago to the present time, flowering plants, birds, insects, and mammals diversified greatly.

1. All the modern orders of mammals appeared and diversified during the Eocene epoch.
2. Birds diversified during the Eocene epoch, adapting to various lifestyles and habitats. The songbirds diversified extensively during the Miocene epoch.

POST - TEST

1. Energy, the absence of oxygen, chemical building blocks, and time were the requirements for (a) chemical evolution (b) biological evolution (c) the Cambrian explosion (d) the mass extinction episode at the end of the Cretaceous period (e) continental drift
2. Protobionts (a) form spontaneously in hydrothermal vents in the ocean floor (b) obtain the organic molecules they need from the environment (c) are assemblages of abiotically produced organic polymers that resemble living cells in several ways (d) use sunlight to split hydrogen sulfide (e) are fossilized mats of cyanobacteria
3. Many scientists think that _____ was the first information molecule to evolve. (a) DNA (b) RNA (c) a protein (d) an amino acid (e) a lipid
4. According to the endosymbiont theory (a) life originated from nonliving matter (b) the pace of evolution quickened at the start of the Cambrian period (c) chloroplasts, mitochondria, and possibly other organelles originated from symbiotic relationships among prokaryotic organisms (d) banded iron formations reflect the buildup of sufficient oxygen in the atmosphere to oxidize iron at Earth's surface (e) the first photosynthetic organisms appeared 3.1 to 3.5 billion years ago

5. All geological time prior to the beginning of the Paleozoic era some 570 million years ago is informally known as (a) the Cenozoic era (b) the Paleozoic era (c) the Mesozoic era (d) Precambrian time (e) the Cambrian period
6. The correct chronological order of geological eras, starting with the oldest, is (a) Paleozoic, Cenozoic, and Mesozoic (b) Mesozoic, Cenozoic, and Paleozoic (c) Mesozoic, Paleozoic, and Cenozoic (d) Paleozoic, Mesozoic, and Cenozoic (e) Cenozoic, Paleozoic, and Mesozoic
7. The greatest time of evolutionary diversification in the history of life occurred during the (a) Cambrian period (b) Ordovician period (c) Silurian period (d) Carboniferous period (e) Permian period
8. The greatest mass extinction episode in the history of life occurred at what boundary? (a) Pliocene-Pleistocene (b) Paleozoic-Mesozoic (c) Mesozoic-Cenozoic (d) Cambrian-Ordovician (e) Triassic-Jurassic
9. The Age of Reptiles corresponds to the (a) Paleozoic era (b) Mesozoic era (c) Cenozoic era (d) Pleistocene epoch (e) Permian period
10. Flowering plants and mammals diversified and became dominant during the (a) Paleozoic era (b) Mesozoic era (c) Cenozoic era (d) Devonian period (e) Cambrian period

REVIEW QUESTIONS

1. What are the four requirements for chemical evolution, and why is each essential?
2. How did the presence of molecular oxygen in the atmosphere affect early life?
3. Give at least two types of evidence that support the endosymbiont theory.

4. Put the following organisms in order of appearance in the fossil record, starting with the earliest (a) eukaryotic cells, multicellular organisms, prokaryotic cells; (b) reptiles, mammals, amphibians, fish; (c) flowering plants, ferns, gymnosperms.

YOU MAKE THE CONNECTION

1. If you were experimenting on how protobionts evolved into cells and you developed a protobiont that was capable of self-replication, would you consider it a living cell? Why or why not?
2. Why did the evolution of complex multicellular organisms such as plants

and animals have to be preceded by the evolution of oxygen-producing photosynthesis?

3. How might studying outer space help us reconstruct the evolutionary history of life on Earth?

CHAPTER 21

The Evolution of Primates

Twelve years after Darwin wrote *The Origin of Species by Natural Selection*, he published another controversial book, *The Descent of Man*, which addressed human evolution. In it, Darwin hypothesized that humans and apes share a common ancestry. For nearly a century after Darwin, fossil evidence of human ancestry remained fairly incomplete. However, research over the last few decades, especially in Africa, has yielded fossils that provide an increasingly clear answer to the question, “Where did we come from?” Fossil evidence has allowed **paleoanthropologists**, scientists who study human evolution, to infer not only the structure but also the habits of early humans.

Humans and other primates, such as lemurs, tarsiers, monkeys, and apes, are mammals, members of the class Mammalia. Mammals are **endothermic** (they use metabolic energy to maintain a constant body temperature); produce body hair for such functions as insulation, protective coloration, and waterproofing; and feed their young with milk from mammary glands. Most mammals are **viviparous**, which means that their eggs develop into young offspring within the female body.

It is currently thought that the three groups of living mammals—the monotremes, marsupials, and placental mammals—are all derived from the same lineage. The **monotremes** are mammals, such as the duck-billed platypus, that lay eggs. The **marsupials**, such as kangaroos and opossums, carry their young in an abdominal pouch after giving birth to them in a very underdeveloped condition. **Placental mammals**, the largest and most successful group, possess a **placenta**, an organ that exchanges materials between the mother and the embryo/fetus developing in the uterus; placental mammals give birth to their young in a more developed condition than marsupials.

Mammals arose from mammal-like reptiles known as therapsids more than 200 million years ago, during the Mesozoic era (see Chapter 20). These early mammals remained a minor component of life on Earth for almost 150 million years be-

(Warren and Genny Garst/Tom Stack & Associates)

fore rapidly diversifying during the Cenozoic era (the last 65 million years). The first primates appeared at this time, apparently descendants of small shrewlike placental mammals that lived in trees and ate insects, much like the modern tree shrew pictured here. Many traits of humans and the 200 other living primate species are related to their **arboreal** (tree-dwelling) past.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Describe the structural adaptations that primates possess for life in trees and explain why even primates that live on the ground have these adaptations.

2. List the two semiorders of primates and give representative examples of each.

3. Distinguish among mammals, primates, anthropoids, hominoids, and hominids (hominines).

4. Describe skeletal and skull differences between apes and hominids.

5. Compare the following early hominids: *Ardipithecus ramidus*, *Australopithecus anamensis*, *Australopithecus afarensis*, and *Australopithecus africanus*.
6. Distinguish among the following members of genus *Homo*: *H. habilis*, *H. ergaster*, *H. erectus*, *H. heidelbergensis*, *H. neanderthalensis*, and *H. sapiens*.

7. Discuss the current debate over the origin of modern humans and briefly describe the opposing “out of Africa” and “multiregional” hypotheses.

8. Describe cultural evolution and its impact on the biosphere.

EARLY PRIMATE EVOLUTION REFLECTED AN ARBOREAL EXISTENCE

Fossil evidence indicates that the first true primates appeared by the early Eocene about 55 million years ago. These early primates had digits with nails, and their eyes were directed somewhat forward. The climate was milder then, and early primates were widely distributed over much of North America, Europe, and Asia. (Recall from Chapter 19 that North America was still attached to Europe at that time.) As the climate became cooler and drier toward the end of the Eocene epoch, many of these early primates became extinct.

Several novel adaptations evolved in early primates that allowed them to live in trees. One of the most significant features of primates is that they have five grasping digits: four fingers plus an opposable thumb or toe. The partially or fully opposable first digit enables primates to grasp objects such as branches. Nails (instead of claws) provide a protective covering for the tips of the digits, and the fleshy pads at the ends of the digits are sensitive to touch. Another arboreal feature is long, slender limbs that rotate freely at hips and shoulders, giving primates full mobility to climb and search for food in the tree tops. The location of eyes in front of the head provides stereoscopic, or three-dimensional, vision. Stereoscopic vision is essential for arboreal animals, especially those that leap from branch to branch, because an error in depth perception might cause a fatal fall. In addition to sharp sight, hearing is acute in primates.

Primates share several other characteristics, including a relatively large brain size. It has been suggested that increased sensory input associated with their sharp vision and greater agility favored the evolution of larger brains. Primates also have complex social behaviors. Females usually bear one offspring at a time; the baby is helpless and requires a long period of nurturing and protection.

TABLE 21-1 A Classification of Living Groups in the Order Primates	
Semiorder Strepsirhini	
Suborder Lemuriformes	
Family Cheirogaleidae (dwarf lemurs)	
Family Lemnidae (lemurs)	
Family Indridae (indris)	
Family Daubentoniidae (aye-ayes)	
Family Lorisidae (lorises)	
Family Galagidae (galagos)	
Semiorder Haplorhini	
Suborder Tarsiiformes	
Family Tarsiidae (tarsiers)	
Suborder Anthropoidea	
Family Callitrichidae (marmosets)	
Family Cebidae (New World monkeys)	
Family Cercopithecidae (Old World monkeys)	
Family Hylobatidae (gibbons)	
Family Pongidae (orangutans)	
Family Hominidae (gorillas, chimpanzees, and humans)	

LIVING PRIMATES ARE CLASSIFIED INTO TWO SEMIORDERS

Most biologists currently divide the order Primates into two semiorders (Table 21-1 and Fig. 21-1). The semiorder Strepsirhini includes lemurs, galagos, and lorises, whereas the semiorder Haplorhini includes tarsiers and **anthropoids** (monkeys, apes, and humans). This classification scheme indicates that tarsiers share a more recent common ancestor with anthropoids than do lemurs.

All lemurs are restricted to the island of Madagascar off the coast of Africa (Fig. 21-2). Because of extensive habitat destruction and hunting, they are highly endangered. Lorises, which are found in tropical areas of Southeast Asia and Africa,

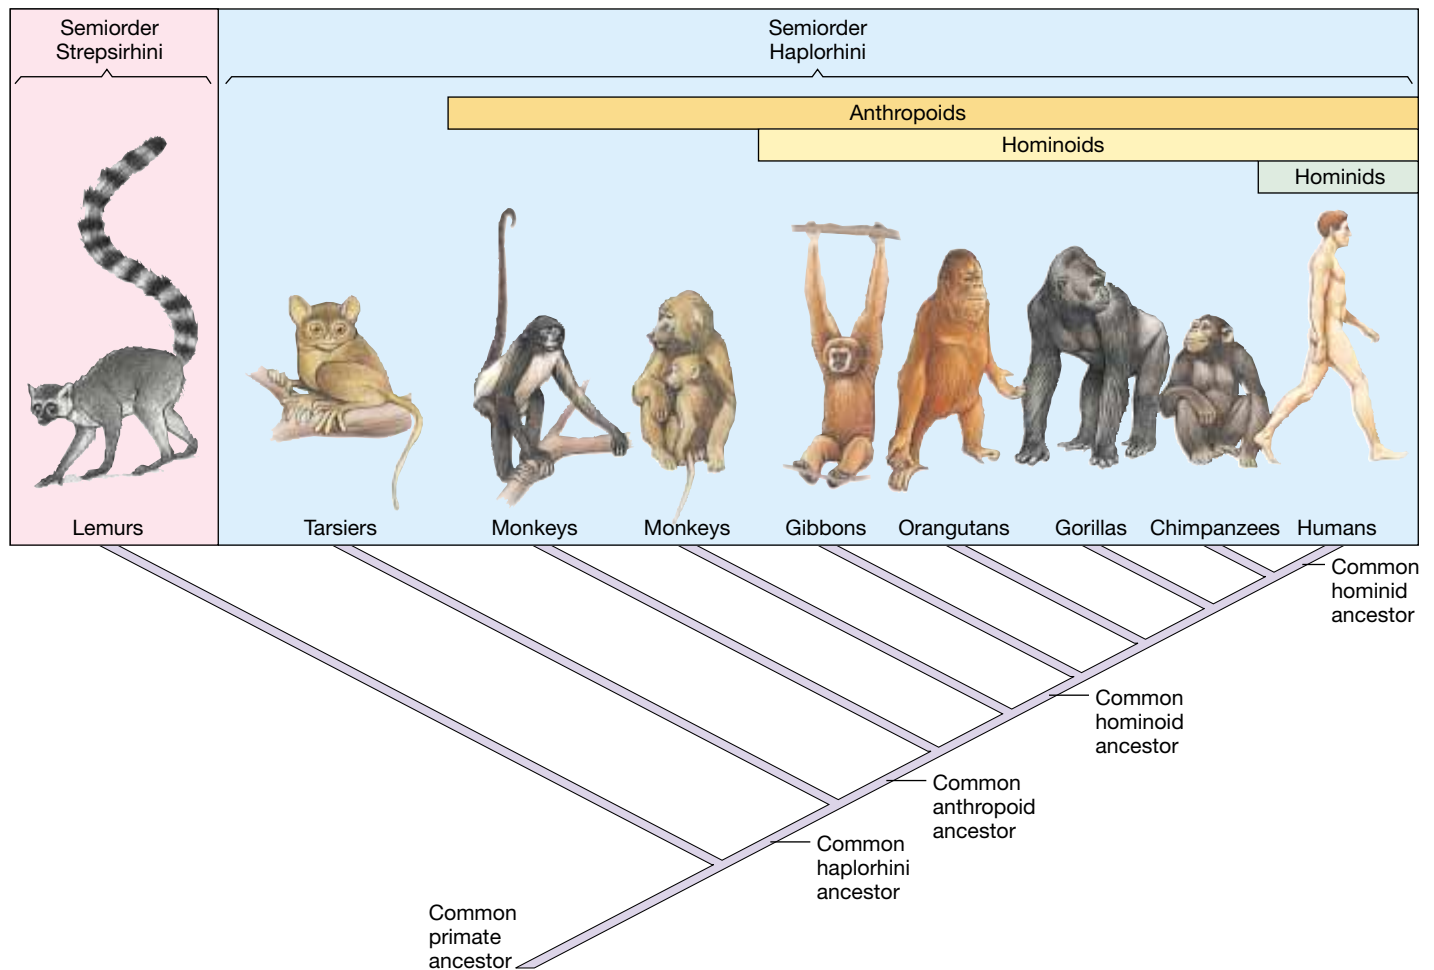

Figure 21-1 Primate evolution. This diagram shows hypothetical phylogenetic relationships among living primates, based on current scientific evidence. (Figures are not drawn to scale.)

resemble lemurs in many respects, as do galagos, which live in sub-Saharan Africa. Lemurs, lorises, and galagos have retained some early mammalian features, such as elongated, pointed faces and more lateral-facing eyes.

Tarsiers are found in rain forests of Indonesia and the Philippines. They are small primates the size of squirrels and are very adept climbers and leapers (Fig. 21-3). These nocturnal primates resemble anthropoids in a number of ways, including their shortened snouts and forward-pointing eyes.

The suborder Anthropoidea includes monkeys, apes, and humans

Anthropoid primates arose during the middle Eocene epoch, at least 45 million years ago. Several different fossil anthropoids have been identified from Asia and North Africa. However, there is currently no scientific consensus about the relationships of these fossil groups to one another or to living anthropoids. Evidence indicates that anthropoids originated in

Africa or Asia, quickly spread throughout Europe, Asia, and Africa, and arrived in South America later.

Probably the most significant difference between anthropoids and other primates is in the size of their brains. The cerebrum, in particular, is more developed in monkeys, apes, and humans, where it functions as the center for learning, voluntary movement, and interpretation of sensation.

Monkeys are generally diurnal (active during the day) tree dwellers. They tend to eat fruit and leaves, with nuts, seeds, buds, insects, spiders, birds' eggs, and even small vertebrates playing a smaller part in their diets. The two main groups of monkeys, New World monkeys and Old World monkeys, are named for the hemispheres where they diversified; monkeys in South and Central America are called New World monkeys, whereas monkeys in Africa, Asia, and Europe are called Old World monkeys. New and Old World monkeys have been evolving separately for millions of years. Fossil evidence indicates that monkeys lived in South America as long as 25 million years ago, but one of the most important unanswered

Figure 21–2 Lemurs. A mother ring-tailed lemur (*Lemur catta*) and her baby share a piece of fruit. Lemurs are native to Madagascar. (Frans Lanting/Minden Pictures)

Figure 21–3 Tarsiers. The huge eyes of the tarsier (*Tarsius bancanus*) help it find insects, lizards, and other prey when it hunts at night. Tarsiers live in the rain forests of Indonesia and the Philippines. (Doug Wechsler)

questions in anthropoid evolution concerns *how* monkeys got to South America. Africa and South America had already drifted apart (see Chapter 19), so the ancestors of New World monkeys may have rafted on logs from Africa to South America or dispersed from Asia to North America to South America.

New World monkeys are restricted to Central and South America and include marmosets, capuchins, howler monkeys, squirrel monkeys, and spider monkeys. New World monkeys are arboreal and some possess long, slender limbs that permit easy movement in the trees (Fig. 21–4*a*). Some have **prehensile** tails capable of wrapping around branches and serving as

(a)

(b)

Figure 21–4 New and Old World monkeys. (a) The white-faced monkey (*Cebus capucinus*) has a prehensile tail and a flattened nose with nostrils directed to the side. (b) The Anubis baboon (*Papio anubis*) is an Old World monkey native to Africa. Note how its nostrils are directed downward (a, C.C. Lockwood/DRK Photo; b, S. Meyers/Okapia/Photo Researchers, Inc.)

fifth limbs. Some New World monkeys have shorter thumbs, and in certain cases the thumbs are totally absent. Their facial anatomy is different from that of the Old World monkeys; they have flattened noses with the nostrils opening to the side. They live in groups and exhibit complex social behavior.

Old World monkeys are distributed in tropical parts of Africa and Asia. In addition to baboons and macaques (pronounced muh-kacks'), the Old World monkeys include guenons, mangabeys, langurs, and colobus monkeys. Most Old World monkeys are arboreal, although some, such as baboons and macaques, spend much of their time on the ground (Fig. 21–4*b*). The ground dwellers, which are **quadrupedal** ("four-footed"; they walk on all fours), arose from arboreal monkeys. None of the Old World monkeys has a prehensile tail, and some have extremely short tails. They have a fully opposable thumb, and unlike the New World monkeys, their nostrils are closer together and directed downward. Old World monkeys are very social animals.

Modern classification places apes and humans in three families

Old World monkeys shared a common ancestor with the **hominoids**, a group composed of apes and **hominids** (humans and their ancestors; also called **hominines**). One of the earliest anthropoids was discovered in Egypt and named *Aegyptopithecus* (Fig. 21–5*a*). *Aegyptopithecus*, a cat-sized, forest-dwelling arboreal monkey with a few apelike characteristics, lived during the Oligocene, approximately 35 million years ago. During the Miocene epoch, which began approximately 25 million years ago, apes and Old World monkeys diverged. At least 30 different early hominoids lived during the Miocene epoch, but most of them became extinct and were not the common ancestor of modern apes and humans. Fossils of an early, forest-dwelling, chimpanzee-sized ape, *Dryopithecus*, are of special interest because this hominoid may have given rise to modern apes as well as to the human line (Fig. 21–5*b*). Dryopithecines were arboreal, arm-swinging apes. The dryopithecines were distributed widely across Europe, Africa, and Asia. As the climate gradually cooled and became drier, their range became more limited.

Dryopithecus is not the only candidate for the lineage that gave rise to modern apes and humans. Fossil finds of two other early apes (*Kenyapithecus* and *Morotopithecus*) were each reported in 1996 to be the earliest fossil evidence discovered so far of an ape with a body plan similar to those of modern apes and humans. The new fossils have generated many questions about the relationships among the various early apes, and as these and future fossil finds are evaluated, they may lead to a rearrangement of ancestors in the hominoid family tree.

Many biologists classify the five genera of hominoids alive today into three families (Fig. 21–6): Gibbons (*Hylobates*) are known as lesser apes and are placed in the family Hylobatidae. Orangutans (*Pongo*) are placed in the family Pongidae. The family Homininae includes gorillas (*Gorilla*), chimpanzees (*Pan*), and humans (*Homo*).

(*a*) Early anthropoid, *Aegyptopithecus*

(*b*) Early ape, *Dryopithecus*

Figure 21–5 *Aegyptopithecus* and *Dryopithecus*. (*a*) Fossils of *Aegyptopithecus*, an early anthropoid, were discovered in Egypt. (*b*) *Dryopithecus*, a more advanced ape, may have given rise to modern hominoids. (Figures are not drawn to scale.)

Gibbons are natural acrobats that can **brachiate**, or arm-swing, with their weight supported by one arm at a time. Orangutans are also brachiating tree dwellers, but chimpanzees, bonobos, and especially gorillas have adapted to life on the ground. They have retained long arms typical of brachiating primates but use these to assist in quadrupedal walking, sometimes known as **knuckle-walking** because of the way they fold their digits when moving. Apes, like humans, lack tails. They are generally much larger than monkeys; gibbons are a notable exception.

Evidence of the close relatedness of orangutans, gorillas, chimps, and humans is abundant at the molecular level. The amino acid sequence of the chimpanzee's hemoglobin is identical to that of the human; those of the gorilla and rhesus monkey differ from the human's in 2 and 15 amino acids, respectively. DNA sequence analyses indicate that chimpanzees are likely to be our nearest living relatives among the apes (see Table 17–1 and Fig. 17–15). Molecular and fossil evidence demonstrates that gorillas may have diverged from the chimpanzee and hominid lines some 8 to 10 million years ago, whereas chimpanzees and hominids probably separated about 6 million years ago.

THE FOSSIL RECORD PROVIDES CLUES TO HOMINID EVOLUTION

Scientists have a growing storehouse of hundreds of fossil hominids, which provide much useful information about general trends in the body design, appearance, and behavior of ancestral humans. It is evident, for example, that early hominids

adopted a **bipedal** (two-footed) posture before their brains enlarged. Despite the wealth of fossil evidence, however, interpretations of hominid characteristics, taxonomy, and phylogeny continue to be vigorously debated, and every discovery raises new questions. Furthermore, hominid evolution, like other scientific fields, is influenced by the different perspectives of the various workers studying it. The lack of a scien-

Figure 21–7 Gorilla and human skeletons. When gorilla and human skeletons are compared, the skeletal adaptations for bipedalism in humans become apparent.

tific consensus regarding certain aspects of hominid evolution is, therefore, an expected part of the scientific process.

Evolutionary changes from the earliest hominids to modern humans are evident in some of the characteristics of the skeleton and skull. Compared with the ape skeleton, the human skeleton possesses distinct differences that reflect our ability to stand erect and walk on two feet (Fig. 21–7). These differences also reflect the habitat change for early hominids, from an arboreal existence in the forest to a life spent at least partly on the ground. The curvature of the human spine provides better balance and weight distribution for bipedal locomotion. The human pelvis is shorter and broader than the ape pelvis, providing a better attachment of muscles used for upright walking. The hole in the base of the skull for the spinal cord, called the **foramen magnum**, is located in the middle of the rear of the skull in apes. In contrast, the human foramen magnum is centered in the skull base, positioning the head for erect walking. An increase in the length of the legs relative to the arms, and alignment of the big toe with the rest of the toes, further adapted the early hominids for bipedalism.

Another major trend in hominid evolution was an increase in the size of the brain relative to the size of the body (Fig. 21–8). In addition, the ape skull possesses prominent bony ridges above the eye sockets, whereas these **supraorbital ridges** are lacking in modern human skulls. Human faces are flatter than those of apes, and the jaws are different. The arrangement of teeth in the ape jaw is somewhat rectangular, compared with a rounded, or U-shaped, arrangement in humans. Apes have larger front teeth (canines and incisors) than do humans, and their canines are especially large. Gorillas and orangutans also have larger back teeth (premolars and molars) than humans.

The earliest hominids belong to the genus *Ardipithecus*

Hominid evolution began in Africa. The earliest hominid, which belongs to the genus *Ardipithecus*, appeared about 4.4 million years ago (Fig. 21–9). *Ardipithecus* gave rise to *Australopithecus*, a genus that includes several species that lived between 4 and 1.25 million years ago. These two genera of early

Figure 21-8 Gorilla and human heads. (a) The ape skull has a pronounced supraorbital ridge. (b) The human skull is flatter in the front and has a more pronounced chin. The human brain, particularly the cerebrum (purple), is larger than that of an ape, and the human jaw is structured so that the teeth are arranged in a U shape. Human canines and incisors are also smaller than those of apes.

hominids, often referred to as **australopithecines** or “southern man apes,” had longer arms, shorter legs, and smaller brains relative to modern humans. The actual number of australopithecine species for which fossil evidence has been found is under debate. Differences in the relatively few skeletal fragments could indicate either variation among individuals within a species or evidence of separate species. Most paleoanthropologists recognize at least six species of australopithecines.

The first fossils of the earliest hominids were discovered in 1992 and assigned to *Ardipithecus ramidus* in 1995. The specific epithet *ramidus* is derived from a word meaning “root” in the Afar language, spoken in the region of Ethiopia where the fossils were found. This hominid, which is more primitive than any other known hominid, is quite close to the “root” of the human family tree, that is, to the last common ancestor of bipedal hominids and quadrupedal African great apes. Because no leg bones were found in the initial discovery, it has not yet been determined if *A. ramidus* was bipedal. Future discoveries may clarify this important point.

Figure 21-9 One interpretation of hominid evolution. Paleoanthropologists are not in complete agreement about certain specific details of the human family tree, and there are many possible interpretations of the human lineage.

The genus *Australopithecus* contains the immediate ancestors of the genus *Homo*

Hominids that existed between 3.9 and 4.2 million years ago are assigned to the species *Australopithecus anamensis*, first named in 1995 by Maeve Leakey and her coworkers from fossils discovered in East Africa. This hominid species presumably arose from *Ardipithecus ramidus*. The jaws of *A. anamensis* are like those of modern apes, whereas the teeth are more like those of later hominids. Males were about 1.55 meters (5 feet 1 inch) in height, and females were about 1.30 meters (4 feet 3 inches) tall.¹ A tibia (leg bone) indicates that *A. anamensis* had an upright posture and was bipedal, although it also may have foraged in the trees. Thus, bipedalism occurred early in human evolution and may have been the first human adaptation.

¹All heights given in this text represent average approximations based on available fossil data. It is reasonable to assume that individuals within a hominid species varied considerably in height, much like the variation observed in present-day humans.

Australopithecus afarensis, another primitive hominid, may have arisen from *A. anamensis*. Many fossils of *A. afarensis* skeletal remains have been discovered in Africa, including a remarkably complete skeleton nicknamed “Lucy” found in Ethiopia in 1974 by a team led by Donald Johanson. Lucy, a small hominid approximately 1.04 meters (3 feet 5 inches)—males were about 1.50 meters, or 4 feet 11 inches—is thought to be about 3.2 million years old. In 1976, beautifully preserved fossil footprints of three *A. afarensis* individuals who walked more than 3.6 million years ago were discovered by Mary Leakey and coworkers. In 1994 the first adult skull of *A. afarensis* was discovered by William Kimbel and other paleoanthropologists. The skull, characterized by a relatively small brain, pronounced supraorbital ridges, a jutting jaw, and large canine teeth, is an estimated 3 million years old. It is probable that *A. afarensis* did not construct tools or make fires, as no evidence of tools or fire has been found at fossil sites.

Many paleoanthropologists think *A. afarensis* gave rise to several australopithecine species, including *Australopithecus africanus*, which appeared approximately 3 million years ago. The first *A. africanus* fossil was discovered in South Africa in 1924, and since then hundreds have been found. Males were about 1.37 meters (4 feet 6 inches), and females were about 1.14 meters (3 feet 9 inches). This hominid walked erect and possessed hands and teeth that were distinctly human-like. Based on characteristics of the teeth, it is thought that *A. africanus* ate both plants and animals. Like *A. afarensis*, it had a small brain, more like that of its primate ancestors than of present-day humans.

Homo habilis* is the oldest member of the genus *Homo

The first hominid to have enough uniquely human features to be placed in the same genus as modern humans is *Homo habilis*. *Homo habilis* was a small hominid (males were about 1.32 meters, or 4 feet 4 inches, and females were about 1.17 meters, or 3 feet 10 inches) with a larger brain and smaller teeth than the australopithecines. This early human appeared approximately 2.3 million years ago and persisted for more than 0.75 million years. Fossils of *H. habilis* have been found in numerous areas in Africa. These sites contain primitive tools, stones that had been chipped, cracked, or hammered to make sharp edges for cutting or scraping.² Oldowan pebble choppers, for example, were probably used to cut through animal hides to obtain meat.

The relationship between the australopithecines and *H. habilis* is not clear. Using physical characteristics of their fossilized skeletons as evidence, many paleoanthropologists have

inferred that the australopithecines were ancestors of *H. habilis*. Discoveries of additional fossils may help clarify these relationships.

Homo erectus* apparently evolved from *Homo habilis

Numerous fossils of *Homo erectus* have been found throughout Africa and Asia. *Homo erectus* is thought to have originated in Africa about 2 million years ago and then to have spread quickly to Europe and Asia. The oldest fossils of *H. erectus* that have been found in Southeast Asia, for example, may be as old as 1.8 million years, although the most widely accepted date is about 1 million years. Peking man and Java man, discovered in Asia, were later examples of *H. erectus*, which existed until at least 200,000 years ago; some populations of *H. erectus* may have persisted until as recently as 27,000 to 53,000 years ago.

Homo erectus was taller than *H. habilis*; males were about 1.78 meters (5 feet 10 inches), and females were about 1.60 meters (5 feet 3 inches). Its brain, which was larger than that of *H. habilis*, got progressively larger during the course of its existence. Its skull, although larger, did not possess totally modern features, retaining the heavy supraorbital ridge and projecting face that are more characteristic of its ape ancestors (Fig. 21–10).

The increased mental faculties associated with an increased brain size enabled these early humans to make more advanced stone tools, known as Acheulian tools, including hand axes and other implements that have been interpreted as choppers, borers, and scrapers. Their intelligence also allowed them to survive in cold areas. *Homo erectus* obtained food by hunting or scavenging and may have worn clothing, built fires, and lived in caves or shelters. To date, no evidence of weapons has been unearthed at *Homo erectus* sites.

Ideas regarding *Homo erectus*, like many other aspects of human evolution, are changing with each new fossil discovery. Many scientists now hypothesize that the fossils classified as *Homo erectus* really represent two species: *Homo ergaster*, an earlier African species, and *Homo erectus*, a later eastern Asian offshoot. Researchers who support this split speculate that *Homo ergaster* may be the direct ancestor of later humans, whereas *Homo erectus* may be an evolutionary dead end. It is hoped that future fossil discoveries will help clarify the status of *Homo erectus*.

Archaic *Homo sapiens* appeared about 800,000 years ago

Archaic *Homo sapiens* are regionally diverse descendants of *Homo erectus* or *Homo ergaster* that lived in Africa, Asia, and Europe from about 800,000 to 100,000 years ago. They thus overlapped both *Homo erectus* populations and the later-appearing Neandertals (discussed shortly). Males were about 1.75 meters (5 feet 9 inches), and females were about 1.57 meters (5 feet 2 inches). Some researchers classify archaic *Homo sapiens* as a separate species, *Homo heidelbergensis*.

²The oldest known stone tools, discovered in the mid-1990s by Sileshi Semaw and colleagues, were found in Gona, Ethiopia. These ancient tools were made some 2.5 million years ago, but because no hominid remains have been found at the site yet, it is not known who made them. Evidence exists that certain australopithecines (for example, *Australopithecus robustus*) fashioned crude tools.

Figure 21–10 A replica of a *Homo erectus* skull. Note the receding forehead, pronounced supraorbital ridge, and projecting face and jaws. (Dennis Drenner)

Neandertals appeared approximately 230,000 years ago

Neandertals, formerly spelled Neanderthals,³ were first discovered in the Neander Valley in Germany. They lived throughout Europe and western Asia from about 230,000 to 30,000 years ago. These early humans had short, sturdy builds; males were about 1.65 meters (5 feet 5 inches) and weighed an estimated 83.9 kilograms (185 pounds), and females were about 1.55 meters (5 feet 1 inch) and weighed an estimated 79.4 kilograms (175 pounds). Their faces projected slightly, their chins and foreheads receded, they had heavy brow ridges and jaw bones, and their brains and front teeth were larger than those of modern humans. Their nasal cavities contained triangular bony projections not found in modern humans; scientists have suggested that these projections provided larger surface areas in Neandertal sinuses, enabling them to better warm the cold air of Ice Age Eurasia as air traveled through the head to the lungs.

Scientists have not reached a consensus about whether the Neandertals are a separate species from modern humans. Many think that anatomical differences between Neandertals and modern humans mean that they were separate species, *Homo neanderthalensis* and *Homo sapiens*. Other scientists disagree and think that Neandertals were a race of *Homo sapiens*.

Neandertal tools include the oldest known spear points; known as Mousterian tools, Neandertal tools were more sophisticated than those of *H. erectus*. Studies of Neandertal sites indicate that they hunted large animals. The existence of skele-

tons of elderly Neandertals and of Neandertals with healed fractures demonstrates that they cared for the aged and the sick, an indication of advanced social cooperation. They apparently had rituals, possibly of religious significance, and buried their dead. The presence of food, weapons, and flowers in some of their graves suggests that they possessed the abstract concept of an afterlife.

The disappearance of the Neandertals some 30,000 years ago is a mystery that has sparked debate among paleoanthropologists. Other groups of *H. sapiens* with more modern features coexisted for tens of thousands of years with the Neandertals. It is possible that the Neandertals interbred with these humans, diluting their features beyond recognition, although a 1997 analysis of mitochondrial DNA (mtDNA) extracted from a Neandertal bone⁴ suggests that Neandertals are an evolutionary dead end that did not interbreed with more modern humans. Alternatively, perhaps the other humans out-competed or exterminated the Neandertals, leading to their extinction.

The origin of modern *Homo sapiens* is hotly debated

Homo sapiens with anatomically modern features existed in Africa at least 100,000 years ago. Males were about 1.75 meters (5 feet 9 inches), and females were about 1.60 meters (5

³The silent “h” has been dropped in modern German.

⁴The Neandertal mtDNA sequence extracted by Svante Pääbo and his colleagues differs significantly from all modern human mtDNA sequences; the Neandertal mtDNA is, however, more similar to human than to chimpanzee mtDNA.

Figure 21–11 Cro-Magnon cave paintings. These are some of the earliest known examples of human art. Discovered in Lascaux, France, these images of reindeer have been interpreted as having religious significance, possibly to guarantee a successful hunt. (Photo by J. Beckett/D. Stipkovich, courtesy Department of Library Services, American Museum of Natural History)

feet 3 inches). The *H. sapiens* skull lacked a heavy brow ridge and possessed a distinct chin. The **Cro-Magnon** culture that existed in France and Spain about 30,000 years ago exemplifies these humans. Their weapons and tools were complex and often made of materials other than stone, including bone, ivory, and wood. They made stone blades that were extremely sharp. Cro-Magnons developed art, including cave paintings, engravings, and sculpture, possibly for ritualistic purposes (Fig. 21–11). Their sophisticated tools and art indicate that they may have possessed language, which would have been used to transmit their culture to younger generations.

Two opposing hypotheses currently exist about the origin of these modern humans: the “out of Africa” hypothesis and the “multiregional” hypothesis. The “out of Africa” hypothesis holds that modern *H. sapiens* arose in Africa and then migrated to Europe and Asia, displacing the more primitive humans living there. According to the “multiregional” hypothesis, modern humans originated from *H. erectus* as separately evolving populations living in several parts of Africa, Asia, and Europe. Each of these populations evolved in its own distinctive way but occasionally met and interbred with other populations, thereby preventing complete reproductive isolation; the variation found today in different geographical populations therefore represents a continuation of this multiregional process.

Data from *Homo* fossils, as well as molecular biology and population genetics studies of modern humans, have been cited in support of both hypotheses, and both have vigorous defenders and strong detractors. Such disagreement is an important part of the scientific process because it stimulates research that may ultimately resolve the issue. (See *Making the Con-*

nection: DNA and Human Evolution for a discussion of some of the current molecular data being used to help unravel details of human evolution.)

HUMANS UNDERGO CULTURAL EVOLUTION

Genetically speaking, humans are not very different from other primates. At the level of our DNA sequences, we are roughly 98% identical to gorillas and 99% identical to chimpanzees. Our relatively few genetic differences, however, give rise to several important distinguishing features, such as greater intelligence and the ability to capitalize on it through **cultural evolution**, which is the transmission of knowledge from one generation to the next. Human culture is dynamic; it is modified as we obtain new knowledge. Human cultural evolution is generally divided into three stages: (1) the development of hunter-gatherer societies; (2) the development of agriculture; and (3) the Industrial Revolution.

Early humans were hunters and gatherers who relied on what was available in their immediate environment. They were nomadic, and as the resources in a given area were exhausted or as the population increased, they migrated to a different area. These societies required a division of labor and the ability to make tools and weapons, which were needed not only to kill game but also to scrape hides, dig up roots and tubers, and cook food. Although we are not certain when hunting was incorporated into human society, we do know that it declined in importance approximately 15,000 years ago. This may have

MAKING THE CONNECTION

DNA AND HUMAN EVOLUTION

Can molecular biology provide clues about the origin of modern humans? The “out of Africa” hypothesis was originally supported by studies in the late 1980s of mitochondrial DNA from various human populations. In 1992 the statistical assumptions used in one analysis of mitochondrial DNA were found to be erroneous, leading to questions about the validity of this purported demonstration of the “out of Africa” hypothesis. Several other comparative molecular studies, however, have all produced essentially the same answer, that modern humans are descended from an early human population that lived in southern Africa.

One of the largest studies to date, reported in 1996 by Sarah Tishkoff,* supports an African origin for humans. Tishkoff examined the genetic variation in two stretches of DNA on human chromosome 12 from 1600 people living in 42 different populations around the world (13 African, 2 Middle Eastern, 7 European, 9 Asian, 3 Pacific, and 8 Amerindian). The DNA segments varied depending on where the populations lived. Based on her research, Tishkoff divided the present-day human population into three groups: sub-Saharan Africans,[†] northeastern Africans, and non-Africans. The sub-Saharan Africans exhibited the greatest genetic diversity, whereas the non-African populations were the least diverse. These findings are consistent with the predictions of the “out of Africa” hypothesis for two reasons. First, according to the hypothesis, the sub-Saharan populations are expected to be more diverse because they are older and have had a longer time to accumulate that diversity. Second, the small populations that emigrated

from Africa could not have been representative of the total diversity present in the larger African population (recall the discussion in Chapter 18 on the effect of genetic drift on allele frequencies).

Tishkoff’s work is significant because it provided scientists with an important way to evaluate human origins. Her research did not disprove the “multiregional” hypothesis, but pointed the direction for additional research on other segments of human DNA. A series of recent genetic studies of both mitochondrial and nuclear DNA has strengthened the case for Africa as the birthplace of modern humans. Some of this research has shown, however, that the “out of Africa” hypothesis may not be as simple as originally envisioned, that is, modern humans from Africa may not have completely replaced the humans on other continents but may have interbred with them. While many of the human genes that were analyzed have demonstrated an African ancestry, for example, a few appear to have arisen in Asia and to have been introduced at a later time into African populations, probably by migration from Asia to Africa. Thus, ancestral human populations in both Africa and Asia may have contributed to the gene pool of modern humans.

*Tishkoff, S. A. et al. “Global Patterns of Linkage Disequilibrium at the CD4 Locus and Modern Human Origins.” *Science*, Vol. 271, 8 Mar., 1996.

[†]Sub-Saharan Africa refers to all countries located south of the Sahara Desert.

been due to a decrease in the abundance of large animals, triggered in part by overhunting. A few isolated groups of hunter-gatherer societies, including the Inuit of northern polar regions and the Mbuti of Africa, have survived into the 20th century.

Development of agriculture resulted in a more dependable food supply

Evidence that humans had begun to cultivate crops approximately 10,000 years ago includes the presence of agricultural tools and plant material at archaeological sites. Agriculture, which involves keeping animals as well as cultivating plants, resulted in a more dependable food supply. Recent archaeological evidence suggests that agriculture arose in several steps. Although there is much variation from one site to another, plant cultivation, in combination with hunting, usually occurred first. Animal domestication followed later. Agriculture, in turn, often led to more permanent dwellings because considerable time was invested in growing crops in one area. Villages and cities often grew up around the farmlands, but the connection between agriculture and the establishment of vil-

lages and towns is complicated by recent discoveries. For example, Abu Hureyra in Syria was a village founded *before* agriculture arose. The villagers subsisted on the rich plant life of the area and the migrating herds of gazelle. Once people turned to agriculture, however, they seldom went back to hunting and gathering to obtain food.

Archaeological evidence indicates that agriculture developed independently in several different regions. There were three main centers of agriculture and several minor ones. Each of the main centers was associated with cultivation of a cereal crop, although other foods were grown as well. Cereals are grasses, which are members of the monocot group of flowering plants (see Chapter 27). The cereals associated with the three main centers of agriculture are wheat, corn, and rice.

Wheat was cultivated in the semiarid regions along the eastern edge of the Mediterranean. Other crops that originated there include peas, lentils, grapes, and olives. Central and South America were the sites of the maize culture. Squash, chili peppers, beans, and potatoes were also cultivated there. In southern China, evidence exists of the early cultivation of rice and other crops such as soybeans.

Corn, wheat, and rice are all propagated by seed, which requires fairly sophisticated agricultural practices. Growing plants that could be propagated vegetatively may have occurred earlier. Plants raised in this manner, such as bananas, yams, potatoes, and manioc, do not preserve as well as grains because of their high water content. For that reason, we may have no archaeological evidence of their cultivation.

Other advances in agriculture include the domestication of animals, which were kept to supply food, milk, and hides. In the Old World, animals were also used to prepare fields for planting. Another major advance in agriculture was irrigation, which began more than 5000 years ago in Egypt.

Producing food agriculturally was more time-consuming than hunting and gathering, but it was also more productive. In hunter-gatherer societies, everyone shares the responsibility for obtaining food. In agricultural societies, fewer people are needed to provide food for everyone. Thus agriculture freed some people to pursue other endeavors, including religion, art, and various crafts.

Cultural evolution has had a profound impact on the biosphere

Cultural evolution has had far-reaching effects on both human society and on other organisms. The Industrial Revolution, which began in the 18th century, caused populations to concentrate in urban areas near centers of manufacturing. Advances in agriculture encouraged urbanization, as fewer and

fewer people were needed in rural areas to produce food for everyone. The spread of industrialization increased the demand for natural resources to supply the raw materials for industry.

Cultural evolution has permitted the human population to expand so dramatically that there are serious questions about Earth's ability to support so many people indefinitely (see Chapter 51). In 1996 about 840 million people lacked access to the food needed to be healthy and lead productive lives. To further compound the problem, the United Nations projects that three billion *additional* people will be added to the world population, which reached 6 billion in 1999, in the next three to four decades.

Cultural evolution has resulted in large-scale disruption and degradation of the environment. Tropical rain forests and other natural environments are rapidly being eliminated. Soil, water, and air pollution occur in many places. Since World War II, soil degradation due to poor agricultural practices, overgrazing, and deforestation has occurred in an area equal to 17% of the Earth's total vegetated surface area. Many species cannot adapt to the rapid environmental changes caused by humans and thus are becoming extinct. The decrease in biological diversity due to extinction is alarming.

On a positive note, we are aware of the damage we are causing, and we have the intelligence to modify our behavior to improve these conditions. Education, including the study of biology, may help future generations develop environmental sensitivity, making cultural evolution our salvation rather than our destruction.

S U M M A R Y W I T H K E Y T E R M S

- I. Primates arose from small, **arboreal** (tree-dwelling), shrewlike mammals.
 - A. Primates are adapted for an arboreal existence by the presence of five grasping digits, including an opposable thumb or toe; long, slender limbs that move freely at the hips and shoulders; and eyes located in front of the head.
 - B. Primates are divided into two semiorders, Strepsirhini and Haplorhini.
 1. The semiorder Strepsirhini includes lemurs.
 2. The semiorder Haplorhini includes tarsiers and **anthropoids** (monkeys, apes, and humans).
- II. Anthropoids arose from early primate ancestors.
 - A. The early anthropoids branched into two groups, the New and Old World monkeys.
 - B. **Hominoids** (apes and humans) arose from the Old World monkey lineage.
 - C. There are four modern genera of apes: gibbons, orangutans, gorillas, and chimpanzees.
- III. The **hominid** (or **hominine**) line consists of humans and their ancestors.
 - A. Hominid evolution began in Africa.
 1. The earliest known hominids belong to *Ardipithecus ramidus*, which appeared about 4.4 million years ago.
 2. *Ardipithecus ramidus* presumably gave rise to *Australopithecus anamensis*. The genus *Australopithecus*, which includes at least six species that lived between about 4 and 1.25 million years ago, contains the immediate ancestors of the genus *Homo*.
 3. *Ardipithecus* and *Australopithecus* species are often referred to as **australopithecines**. Australopithecines were **bipedal** (walked on two feet), a hominid feature. (It is not yet known if *Ardipithecus* was bipedal.)
 - B. *Homo habilis* was the earliest known hominid with some of the human features lacking in the australopithecines, including a slightly larger brain. *H. habilis* fashioned crude tools from stone.
 - C. *Homo erectus* had a larger brain than *H. habilis*, made more sophisticated tools, and may have worn clothing, built fires, and lived in caves or shelters. Some scientists now think that fossils identified as *Homo erectus* represent two different species, *Homo ergaster*, an earlier African species that gave rise to archaic *Homo sapiens*, and *Homo erectus*, a later Asian offshoot that may be an evolutionary dead end.
 - D. **Archaic *Homo sapiens*** lived in Africa, Asia, and Europe from about 800,000 to 100,000 years ago. Some researchers classify archaic *Homo sapiens* as a separate species, *Homo heidelbergensis*.
 - E. **Neandertals** existed from about 230,000 to 30,000 years ago.
 1. Neandertals had short, sturdy builds, receding chins and foreheads, heavy brow ridges and jaw bones, larger front teeth, and nasal cavities with unusual triangular bony projections.
 2. Many scientists think that Neandertals were a separate species, *Homo neanderthalensis*, whereas some scientists think Neandertals were a race of modern humans.

3. The disappearance of Neandertals is a mystery.
- F. Anatomically modern humans (*Homo sapiens*) existed 100,000 years ago.
 1. The **Cro-Magnon** culture, which existed in France and Spain about 35,000 years ago, exemplifies early modern humans.
 2. The origin of modern humans is controversial. Two different hypotheses, the “out of Africa” and the “multiregional” hypotheses,

purport to explain the origin of modern humans. Comparative molecular data favor the African origin of modern humans.

- IV. **Cultural evolution** is the transmission of knowledge from one generation to the next.
 - A. Large human brain size makes cultural evolution possible.
 - B. Two significant advances in cultural evolution were the development of agriculture and the Industrial Revolution.

POST - TEST

1. The anthropoids are more closely related to _____ than to _____. (a) tarsiers; lemurs (b) lemurs; monkeys (c) tree shrews; tarsiers (d) lemurs; tarsiers (e) tree shrews; monkeys
2. Unlike Old World monkeys, some New World monkeys possess (a) body hair (b) five grasping digits (c) a well developed cerebrum (d) a bipedal walk (e) a prehensile tail
3. Apes and humans are collectively called (a) mammals (b) primates (c) anthropoids (d) hominoids (e) hominids
4. The _____ in humans is centered at the base of the skull, positioning the head for erect walking. (a) supraorbital ridge (b) foramen magnum (c) pelvis (d) sagittal crest (e) femur
5. The oldest evidence of bipedalism is found in the tibia of (a) *Australopithecus afarensis* (b) *Australopithecus anamensis* (c) *Australopithecus africanus* (d) *Homo erectus* (e) *Homo habilis*
6. Humans and their immediate ancestors are collectively called (a) mammals (b) primates (c) anthropoids (d) hominoids (e) hominids
7. The earliest hominids belong to the genus (a) *Aegyptopithecus* (b) *Dryopithecus* (c) *Ardipithecus* (d) *Australopithecus* (e) *Homo*
8. The earliest hominid to be placed in the genus *Homo* is (a) *H. habilis* (b) *H. ergaster* (c) *H. erectus* (d) *H. heidelbergensis* (e) *H. neanderthalensis*
9. Some scientists now think that fossils identified as *Homo erectus* represent which two different species? (a) *H. habilis* and *H. erectus* (b) *H. ergaster* and *H. erectus* (c) *H. heidelbergensis* and *H. ergaster* (d) *H. neanderthalensis* and *H. erectus* (e) *H. neanderthalensis* and *H. sapiens*
10. Archaic *Homo sapiens* appeared about _____ years ago. (a) 5 million (b) 800,000 (c) 230,000 (d) 100,000 (e) 5000
11. _____ were an early group of humans with short, sturdy builds and heavy brow ridges that lived throughout Europe and western Asia from about 230,000 to 30,000 years ago. (a) Australopithecines (b) Dryopithecines (c) Archaic *Homo sapiens* (d) Neandertals (e) Cro-Magnons

REVIEW QUESTIONS

1. Distinguish between each of the following pairs: (a) mammals and primates (b) anthropoids and hominoids (c) hominoids and hominids (d) australopithecines and the genus *Homo*
2. Describe three different ways primates are adapted to an arboreal existence.
3. Identify at least three differences between the skulls of apes and humans.
4. Explain at least three ways in which an ape skeleton differs from a human skeleton.
5. Distinguish between each of the following pairs (a) *Homo habilis* and *Homo erectus* (b) *Homo ergaster* and *Homo erectus* (c) *Homo erectus* and *Homo heidelbergensis* (d) *Homo neanderthalensis* and *Homo sapiens*
6. Describe the two currently proposed hypotheses that explain where modern humans originated.
7. What is cultural evolution, and how has it affected Earth?

YOU MAKE THE CONNECTION

1. What types of as-yet-undiscovered scientific evidence would help explain how monkeys got to South America from the Old World?
2. Why are classifying fossil hominid species and determining their evolutionary relationships to one another such controversial endeavors?
3. Which hypothesis of the origin of modern humans (“out of Africa” or “multiregional”) seems to more closely match our understanding of evolutionary processes in general? Explain your answer.
4. If you were evaluating whether other early humans exterminated the Neandertals, what kinds of archaeological evidence might you look for?
5. The remains of Cro-Magnons have been found in southern Europe alongside reindeer bones, but reindeer currently exist only in northern Europe and Asia. Can you explain the apparent discrepancy?

Henry Ortiz graduated with a B.S. in Biology from California State University, Northridge, in 1989. He teaches science in the bilingual program of a Los Angeles middle school. Henry also trains teachers for the Globe program headquartered in Washington, DC. In this program, students around the world participate in scientific research by collecting field data and feeding it via the Internet to the scientists who are conducting the research.

Henry emigrated from Cuba to Los Angeles when he was only four years old, along with his mother and five brothers. His father, a physician, did not receive permission to leave Cuba for five more years. Henry's immersion into English classes as a Spanish-speaking child in Los Angeles gives him special sensitivity to the learning difficulties of non-native students. His biology background offers a strong foundation in the basic principles of physical sciences as well as life sciences. It is the interconnectedness of all the sciences that fascinates him.

How did you find yourself at California State Northridge?

I went to junior high and high school in the Burbank-Glendale area in Southern California. I thought about going to UCLA but I wanted to live at home, and Northridge is close. At UCLA most people live in the dorms. I thought Northridge

Middle School Science Teacher

HENRY ORTIZ

was a good choice. I was not sure what I wanted to do in life so I appreciated the personal attention I got from professors at Northridge. I liked biology, so I majored in it.

What aspect of biology most intrigued you?

What really interested me was the way that knowledge changes, especially in the sciences. It is fascinating how the body of scientific knowledge continually builds on everything we know. Many other aspects are interesting too, such as views on how the Earth's systems evolve. Thinking logically, looking at evidence, and coming up with logical explanations have always been important to me. My family encouraged this way of thinking.

Did your father want you to pursue a medical career?

Yes, and I considered it. For a while, my future was medicine or a laboratory profession. But, I did not want to be in school that long. I wanted to have more free time for traveling and outdoor sports because they are important to me. So I decided to give teaching a try.

When did you get your teaching credential?

I graduated in 1989 with a biology degree. After that, it took me a year to earn my teaching credential. The credential program is like a fifth year of college. I took a methods-in-teaching-science class, a course in secondary education, and fulfilled the student teaching requirement. I taught for a year, then took a leave of absence. I went to Spain.

Why Spain?

I had always wanted to go to Europe, but I also wanted to perfect my Spanish. So, I spent a year at the University of Madrid. I took courses in Spanish like phonetics, grammar, art, history of Spain, and history

of Madrid. These classes were interesting and sharpened my Spanish communication skills.

How did you decide on teaching at the middle school level?

I did my student teaching in chemistry at the high school level. It was a fun subject to teach. The students liked the class. I even have some letters that were forwarded to me from students who wanted me to come back.

After that, I was ready to handle a class by myself. So, I went to a middle school that needed bilingual teachers. Since I was bilingual, I applied and got the job. It was a good decision. I did well, although it was a pretty tough school with a difficult group of students. I received an award that year for excellence in student teaching.

Was it your bilingual ability or your biology degree that helped you get the job?

I think it was both. In our district, having a science degree is very advantageous. Having a bilingual degree is also a plus, so both were important. I probably could have gotten a job as a science teacher at any school that needed a science teacher, but also at any school that needed a bilingual teacher. Both were important.

How much of your time do you spend speaking Spanish in the classroom?

We have a bilingual department at our school. I instruct in Spanish 50% of the time. The students who have come here recently from another country go into the bilingual program. They take core classes like history, science, and math in their native language. Sometimes they will have two periods of ESL (English as a Second Language) so that they learn English while

learning the core courses in their own language. The reasoning is to keep them from falling behind other students in those primary courses. As they learn English, they will then be able to transfer that knowledge from their language.

What kinds of printed material do you use?

There are major publishers in this country who have published exact translations from the English text. You can have a text that has English on one side of the page and Spanish on the other side of the page. I have some of those books. That way a teacher doesn't need different books for different classes. In addition, the teacher can keep the English and the Spanish students at the same level and pace. It makes it easier to prepare lessons.

Do you only teach bilingual classes?

No. Right now I have two bilingual science classes, one bilingual math class, and an honors physical science eighth grade class in English. I have mostly gifted students in the honors class. It's like teaching tenth graders. They come up with very clever ideas. It's fun to watch them learn, especially when they learn from each other on certain projects. It's a very good class.

What are the obstacles you face in teaching?

The biggest challenge for me are the students who do not value their education. I keep trying to reach these students. However, it's important for me to realize when to dedicate less time to them, so that the other students are not neglected. I like to teach to the top of the class. Some people don't agree with that. I give the students a lot of information. Some of it might be over their heads, but the better students are going to get it. Many of the C-average students will grasp some of it. Even a few of the underachievers learn something.

Do your colleagues have similar backgrounds to yours?

We have a few teachers that went to the same school that I did. Two of them also have science backgrounds. Many of the other teachers do not have science backgrounds. Some of them are even credentialed to teach science through an emergency credential but they don't have any background in science.

I'm unclear about the emergency credential.

It's a credential that is given to them either by the state or the district, which allows them to teach in the district while they work toward their credential. It's like on-the-job training while they are taking courses in college.

Do you feel like your biology degree gave you any advantages over some of these other teachers?

It is possible to teach high school science without a science degree, but because schools prefer teachers who have a background in science, my biology degree was an advantage. If you get the principles down in science, you will be a better science teacher. Some of the teachers who do not have a science background might understand the subject superficially because they've read it, but they might not grasp the scientific thinking behind it.

Can you describe your teaching style?

Like many teachers, I take a constructivist approach, connecting certain scientific ideas to build up the students' knowledge base. My biology degree adequately prepared me to teach students chemistry and physics concepts even though I wasn't a chemistry or physics major. Most of these concepts are very basic.

I don't know what makes me unique, unless it's just the relationships I develop with the students because I have been in their situation. Most of the students I teach have come from another country. If not, their parents did. I remind them that I came from another country, too.

A good teacher gets to know the students, develops a relationship with them, and shows them the type of person he or she is. It is important to show students that you understand them. Then, it becomes easier to help them understand their lessons. If you don't take a personal approach to teaching, half the class will be totally isolated. They won't care because you don't seem to care.

Do you have much interaction with the parents?

I try to maintain contact. For example, tomorrow I have a meeting with the bilingual parents. I'm going to talk to them about what I do in class. Then, they will perform an activity with some of the students. The parents don't have much time because they're working. Usually the parents who come to school are the parents who are very interested, but also have the time to meet.

What activity do you have planned for tomorrow?

We're going to be doing an ocean depth sounding to show how scientists measure depth in oceanography. We are also going to demonstrate how scientists can tell what the ocean bottom looks like by doing a geologic probe activity.

Do you take field trips?

Occasionally we take field trips to Yosemite National Park with the students. The Yosemite Institute has a program where we spend a week hiking and learning about the relationship of humans to

nature and our responsibility as stewards of the Earth.

We've also taken trips to Temescal Canyon in Pacific Palisades, California. It's a three-day program in the Santa Monica Mountains doing field work. The students do a "quadrat study," taking population counts of different organisms in a measured area, learning how to sample, and to work as a team.

We have another trip to the beach at San Pedro. We do similar activities, but out on the ocean. We take marine science measurements from a boat, work in the lab, and at the Cabrillo Museum. We also do a tide pool activity where we classify the different organisms that are present in various parts of the tidal zone.

What is the hardest concept for students at the eighth grade level to grasp about science?

The students have learned what science is, but they haven't learned how to do science. They still think of scientists as guys wearing white coats in laboratories. Some teachers don't emphasize that science is a process, that everyone can do science. It's not this magical activity that only chosen people can do. These misconceptions may continue even after the students are out of junior high school.

Also, students don't know how to apply a scientific concept to different situations. They might learn a specific principle, such as how to calculate the density of a particular type of matter. However, they don't know how to apply that principle to biology, chemistry, and physics. Students need the whole picture. That's the emphasis in science teaching now. I would like to teach students how to think, how to take a body of knowledge, and derive some sort of conclusion from it.

Do you participate in any ongoing teacher education programs?

Yes, I do teacher training for some agencies. I am a member of NSTA (National Science Teachers Association). I also train for the Globe Program out of Washington, DC.

Globe is a program where students, guided by their teachers, do scientific protocols that scientists have designed. We train teachers to do the protocols as the scientists would like to have them done, including how to go on-line and how to enter the data. Students send their data through the Internet to a scientific database. The scientists use this database as part of their research. For example, one scientist is doing a study on atmosphere, how clouds influence the temperature on Earth. Another scientist is classifying the different soils that are found in different parts of the world. Still another scientist is doing validation of land satellite images. Globe is a good program because the students are doing the science by collecting data from the field and supplying it electronically to the researchers. They are contributing information to a world-wide database, which involves over 60 countries.

Who are you training for Globe?

Globe offers workshops for teachers. The organization usually trains between 15 to 45 teachers at a time in different cities. There are usually one or two scientists on the team, a few teachers who have been doing the program, plus a facilitator and a technology person. We meet the day before training to get everything ready. Over the next four days, we train teachers to do the protocols as the scientists would like to have them done, how to go on-line, and how to enter the data. I have been training in the soils protocols mostly and have done some of the hydrology, atmosphere and G.P.S. protocols.

What advice would you give to someone considering your career?

If you are interested in continually learning while you teach, go for it. You have to stay current when you teach science. Do not go into science teaching if you don't want to stay current. That can be boring to you and your students. That will burn you out.

How do you stay current?

I read. I run workshops. I go to workshops. For example, I just attended a six-

week workshop at UCLA called LIMS—Leadership in Marine Science. We learned how to integrate marine biology as a theme in our class subjects. I learned how to use brain biology to teach earth science, physical science, chemistry and biology to secondary level students. That was a very positive experience.

What do you read to keep up to date?

I like *Scientific American* and some of the NSTA journals like *The Journal of College Teaching*. And I read other magazines like *National Geographic*.

Do you see yourself getting an advanced degree?

Yes, I do. I have been thinking about it for the last two years. I would like to get a Master's Degree in science—maybe biology or one of the earth sciences.

Does the school district require that for advancement?

No, they don't. If you take a certain number of units you get more pay. I have taken so many units since my undergraduate degree, that I'm maxed out. Even though I don't need any more units, I would still like to get an advanced degree for my own personal education.

Where do you see yourself in five years? Still teaching?

I might be helping other teachers increase their effectiveness as teachers, helping others develop their materials, new curricula, methods, or activities. Or, perhaps, I will be running programs like the one we have in Temescal Canyon. Right now I'm part-time teaching in the classroom and part-time coordinating some of our district's environmental education programs. I like the classroom, but perhaps in the future I'll get more involved in teacher training.

CHAPTER 22

Understanding Diversity: Systematics

About two million species¹ of living organisms have been described, and new species are being discovered almost daily. Biologists speculate that at least several million additional species remain to be discovered. The dwarf monkey (about 10 centimeters long and weighing about 190 grams) shown here represents a new primate species identified in 1997 in the Amazon jungle of Brazil. To study the diverse life forms that share our planet and to effectively communicate our findings, we need to organize our knowledge of them. The scientific study of the diversity of organisms and their evolutionary relationships is called **systematics**. An important aspect of systematics is **taxonomy**, the science of naming, describing, and classifying organisms. The term **classification** means ordering organisms into groups based on their similarities or relationships. Classifying organisms is a complex and often controversial endeavor.

Imagine that you were going to develop a classification system. How would you use what you already know about living things to assign them to categories? Would you place insects, bats, and birds in one category because they all have wings and fly? And would you, perhaps, place squid, whales, fish, penguins, and Olympic backstroke champions in another category because they all swim? Or would you classify organisms according to a culinary scheme, placing lobsters and tuna in the same part of the menu, perhaps identifying them as “seafood”? Any of these schemes might be valid, depending on your purpose. Similar methods have been used throughout history. Animals, for example, were classified by St. Augustine in the fourth century as useful, harmful, or superfluous—to humans. During the Renaissance, scholars began to develop categories based more on the characteristics of the organisms themselves. These categories were originally arranged roughly in order from simple to complex organisms.

Of the many classification systems that were developed, the one designed by Carolus Linnaeus in the mid-18th century (described briefly in Chapter 1) has survived with some modification to the present day. He devised a system for assigning species to a hierarchy of increasingly general groups. Linnaeus probably had no theory of evolution in mind when he set up his system. Neither did he have any concept of the vast number of extant (living) and extinct organisms that would later be discovered. Yet his system has proved to be re-

¹Recall that a **species** is a group of similar organisms defined by their common gene pool and ability to interbreed in their natural environment; members of a species are reproductively isolated from other organisms.

(AP/Wide World Photos)

markably flexible and adaptable to new biological knowledge and theory. Very few other 18th-century inventions survive today in a form that would still be recognizable to their originators. Most biologists currently use a hierarchical system that includes domain and/or kingdom, phylum, class, order, family, genus, and species, as well as many intermediate categories such as subphylum or suborder.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Offer at least two justifications for the use of scientific names and classifications of organisms.
 2. Arrange the Linnaean categories in hierarchical fashion, from most inclusive to least inclusive.
 3. List the three domains and six kingdoms of organisms introduced in this chapter, give the rationales for and against these systems of classification, and describe the distinguishing characters of the organisms assigned to each.
 4. Critically summarize the difficulties encountered in choosing taxonomic criteria.
 5. Contrast monophyletic, paraphyletic, and polyphyletic taxa.
 6. Apply the concept of shared derived characteristics to the classification of organisms.
 7. Describe the methods of molecular biology now used by taxonomists, and summarize their advantages.
 8. Contrast two approaches to systematics: phylogenetic systematics (cladistics) and classical evolutionary taxonomy.
-

ORGANISMS ARE NAMED USING THE BINOMIAL SYSTEM OF NOMENCLATURE

Before the mid-18th century, each species had a lengthy descriptive name, sometimes composed of ten or more Latin words! Then Linnaeus simplified scientific classification, developing a **binomial system of nomenclature** in which each species is assigned a unique two-part name. The first part designates the **genus** (pl., *genera*), and the second part is called the **specific epithet**. Note that the specific epithet is *not* the species. In fact, the same specific epithet can be used as the second name of species in different genera. For example, *Quercus alba* is the scientific name for the white oak, and *Salix alba* is the name for the white willow. (*Alba* comes from a Latin word meaning “white.”) Thus, both parts of the name must be used to accurately identify the species.

The genus name is always capitalized, whereas the specific epithet is usually not. Both names must be underlined or italicized. The genus name can be used alone to designate all species in the genus (e.g., *Quercus* is the genus that includes all oak species). However, the specific epithet is never used alone; it must always be preceded by the full or abbreviated genus name (e.g., *Quercus alba* or *Q. alba*).

Scientific names are generally derived from Greek or Latin roots or from Latin versions of the names of persons, places, or characteristics. For example, the generic (genus) name for the bacterium *Escherichia coli* is based on the name of the scientist Theodor Escherich, who first described it. The specific epithet *coli* reminds us that *E. coli* lives in the colon (large intestine).

Scientific names permit taxonomy to be a truly international study. Even though the common names of an organism may vary in different locations and languages, an organism can be universally identified by its scientific name. A researcher in Puerto Rico can know exactly which organisms were used in a study published by a Russian scientist and therefore can repeat or extend the Russian’s experiments using the same species.

Subspecies may become species

The species is the basic unit of classification, but not the smallest grouping in use. Geographically different populations within a species often display certain consistent characteristics that distinguish them from other populations of the same species. If they interbreed in nature, however, they are not truly separate species, but **subspecies**. For some kinds of microorganisms, such as bacteria, the term **strain** is used and for plants, subspecies or **variety**. The full scientific name of a subspecies consists of three names: the generic name; the specific epithet; and the subspecies, strain, or variety name. For example, peaches are *Prunus persica* var. *persica*, and nectarines, a smooth-skinned variety of peaches, are *Prunus persica* var. *nucipersica*.

Experts are usually able to distinguish among the subspecies of a particular species. However, subspecies may grade imperceptibly into one another at the borders of their geographical ranges, where there is opportunity for interbreeding. Some of these subspecies may be in the process of becoming reproductively isolated and may, in the course of time, become separate species. Thus, subspecies often provide an opportunity for field studies of gene pools and of the speciation process.

EACH TAXONOMIC LEVEL IS MORE GENERAL THAN THE ONE BELOW IT

A **taxon** (pl., *taxa*) is a formal grouping of organisms at any given level, such as the species, genus, or phylum. For example, class Mammalia is a taxon that includes many different orders. Similarly, subphylum Vertebrata is a taxon that contains seven classes, including Amphibia, Reptilia, and Mammalia.

The range of taxonomic categories from species to kingdom forms a hierarchy (Fig. 22–1; Table 22–1). Closely related species are assigned to the same genus, and closely related

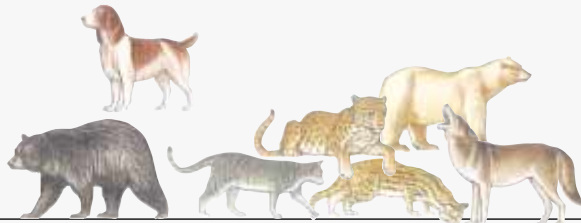

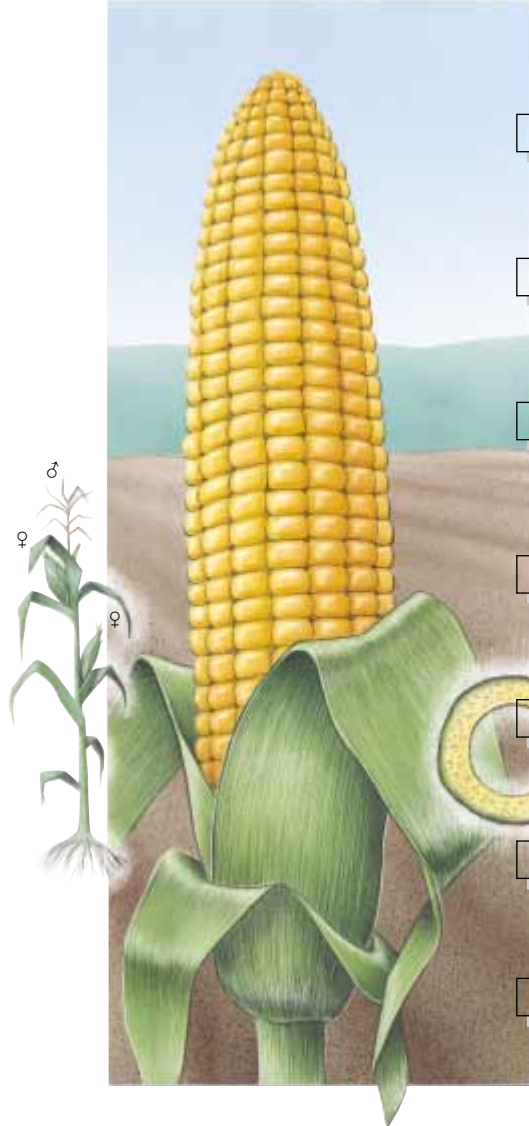

KINGDOM	
Animalia

TABLE 22-1 Classification of Corn

KINGDOM	Plantae Terrestrial, multicellular, photosynthetic organisms
PHYLUM	Anthophyta Vascular plants with flowers, fruits, and seeds
CLASS	Monocotyledones Monocots: Flowering plants with one seed leaf (cotyledon) and flower parts in threes
ORDER	Commelinales Monocots with reduced flower parts, elongated leaves, and dry 1-seeded fruits
FAMILY	Poaceae Grasses with hollow stems; fruit, a grain; and abundant endosperm in seed
GENUS	<i>Zea</i> Tall annual grass with separate female and male flowers
SPECIES	<i>Zea mays</i> Only one species in genus—corn

lated genera may be grouped together in a single **family**. Families are grouped into orders, orders into **classes**, classes into **phyla**,² and phyla into **kingdoms** and/or **domains**. These groupings can also be separated into subgroupings, for example, subphyla or superclasses.

²Plants and fungi have been traditionally classified in divisions rather than phyla. However, the International Botanical Congress has approved the phylum designation for plants and fungi.

Just how organisms are grouped can vary according to the judgment of taxonomists and their criteria and decisions for classification. Some taxonomists ignore minor variations and group organisms into already existing taxa. This practice is referred to as “lumping.” Other taxonomists subdivide taxa on the basis of minor differences, establishing separate categories for forms that do not fall naturally into one of the existing classifications. This practice is called “splitting.” Lumpers acknowledge very few animal and plant phyla, whereas “splitters” may recognize numerous phyla.

NEW DATA INFLUENCE CLASSIFICATION IN KINGDOMS

From the time of Aristotle to the mid-19th century, biologists divided organisms into two kingdoms, **Plantae** and **Animalia**. After the development of microscopes, it became increasingly obvious that many organisms could not be easily assigned to either the plant or the animal kingdom. For example, the unicellular organism *Euglena*, which has been classified at various times in the plant kingdom and in the animal kingdom, carries on photosynthesis in the light but in the dark uses its flagellum to move about in search of food (Chapter 24). In 1866 a German biologist, Ernst Haeckel, proposed that a third kingdom, **Protista**, be established to accommodate bacteria and other microorganisms that did not appear to fit into the plant or animal kingdoms. Today, many biologists place algae (including multicellular forms), protozoa, water molds, and slime molds in kingdom Protista (also referred to as *Protoctista*).

In 1937 the French marine biologist Edouard Chatton suggested the term *procariotique* (“before nucleus”) to describe bacteria, and the term *eucariotique* (“true nucleus”) to describe all other cells. This dichotomy between prokaryotes and eukaryotes is now universally accepted by biologists as a fundamental evolutionary divergence. In the 1960s advances in electron microscopy and biochemical techniques revealed further cellular differences that inspired many new proposals for classifying organisms.

In 1969 R. H. Whittaker proposed a five-kingdom classification. Whittaker suggested that the fungi (which include the mushrooms, molds, and yeasts) be removed from the plant kingdom and classified in their own kingdom **Fungi**. After all, fungi are not photosynthetic and must absorb nutrients produced by other organisms. Fungi also differ from plants in the composition of their cell walls, in their body structures, and in their modes of reproduction. Kingdom **Prokaryotae** (for-

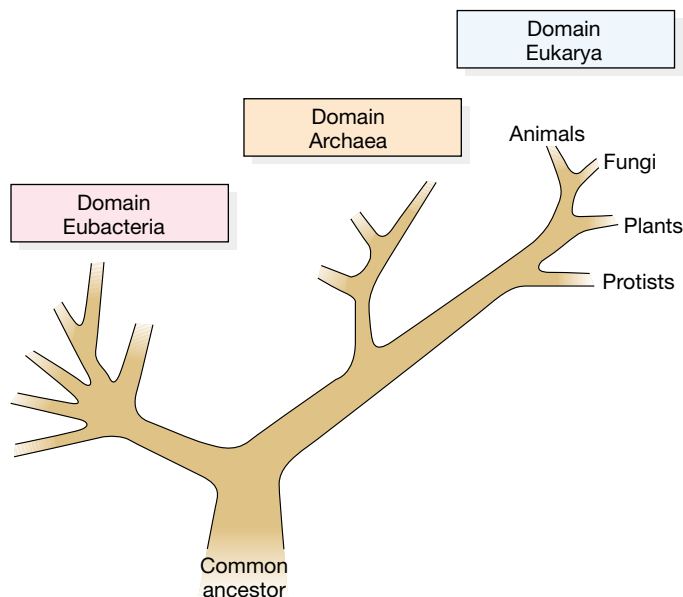

Figure 22-2 The three domains.

Figure 22-3 The six-kingdom system of classification.

merly called *Monera*) was established to accommodate the bacteria, which are fundamentally different from all other organisms in that they lack distinct nuclei and other membranous organelles.

In the late 1970s, Carl Woese and his colleagues used gene sequencing methods to challenge the long-held view that all of the prokaryotes were closely related and very similar to one another. These researchers proposed that there are two fundamentally different groups of bacteria, Archaeobacteria and Eubacteria, and that the prokaryotes account for two out of three of the major branches of organisms. This concept gained support in 1996 when Carol J. Bult of the Institute for Genomic Research in Rockville, Maryland reported in the journal *Science* that she and her colleagues had sequenced the complete genome of a methane-producing archaeobacterium *Methanococcus jannaschii*. When these researchers compared gene sequences with those of two previously sequenced eubacteria, they found that less than half of the genes matched. Based on this molecular evidence, many biologists now divide the prokaryotes into kingdom **Eubacteria** and kingdom **Archaeobacteria**, resulting in a six-kingdom system.

Based on fundamental molecular differences among the Eubacteria, Archaeobacteria, and eukaryotes, many systematists now use a level of classification above the kingdom, called a **domain**. They classify organisms in three domains: **Archaea** (which corresponds to kingdom Archaeobacteria), **Eubacteria** (also called *Bacteria*), and **Eukarya** (eukaryotes; Fig. 22-2). Gene sequencing indicates that the Archaea have a combination of bacteria-like and eukaryote-like genes, and appear to be more closely related to the Eukarya than to the Eubacteria.

The evolution of systematics reflects the creative and dynamic process of science. Systematists have been very responsive to new data, and consequently classification of organisms is a challenging and continuously changing process. In this edition of *Biology*, we use the six-kingdom approach: Eubacteria, Archaeobacteria, Protista, Fungi, Plantae, and Animalia (Fig. 22-3 and Table 22-2). Because many microbiologists prefer the three-domain approach, we use a domain approach in our discussion of bacteria in Chapter 23.

TABLE 22-2 Six Kingdoms: Eubacteria, Archaeobacteria, Protista, Fungi, Plantae, and Animalia

Kingdom	Characteristics	Ecological Role and Comments
Eubacteria	Prokaryotes (lack distinct nuclei and other membranous organelles); unicellular; microscopic; cell walls generally composed of peptidoglycan.	Most are decomposers; some parasitic (and pathogenic); some chemosynthetic autotrophs; some photosynthetic; important in recycling nitrogen and other elements; some used in industrial processes.
Archaeobacteria	Prokaryotes; unicellular; microscopic; cell walls do not have peptidoglycan; differ biochemically from eubacteria.	Methanogens are anaerobes that inhabit sewage, swamps, and animal digestive tracts; extreme halophiles inhabit salty environments; extreme thermophiles inhabit hot, sometimes acidic environments.
Protista	Eukaryotes; mainly unicellular or simple multicellular. Three informal groups (not taxa) include protozoa; algae; and slime molds and water molds.	
Protozoa	Microscopic; heterotrophic; most move by means of flagella, cilia, or pseudopodia.	Important part of zooplankton; important in many food webs; some are parasitic (and pathogenic).
Algae	Photosynthetic; sometimes hard to differentiate from protozoa; some have brown or red pigments in addition to chlorophyll; some have alternation of generations.	Very important producers, especially in marine and freshwater ecosystems; produce oxygen.
Slime molds and water molds	Heterotrophic; reproduce by forming spores.	Aquatic or terrestrial; varied modes of nutrition.
Fungi	Eukaryotes; heterotrophic; absorb nutrients; do not photosynthesize; body composed of threadlike hyphae that form tangled masses that infiltrate food or habitat; cell walls of chitin.	Decomposers; some parasitic (and pathogenic); some used as food; yeast used in making bread and alcoholic beverages; some used to make industrial chemicals or antibiotics; responsible for much spoilage and crop loss.
Plantae	Eukaryotes; multicellular; photosynthetic; possess multicellular reproductive organs; alternation of generations; cell walls of cellulose.	Terrestrial biosphere depends on plants in their role as primary producers; important source of oxygen in Earth's atmosphere.
Animalia	Eukaryotes; multicellular heterotrophs; many exhibit tissue differentiation and complex organ systems; most able to move about by muscular contraction; specialized nervous tissue coordinates responses to stimuli.	Consumers; some specialized as herbivores, carnivores, or detritus feeders.

SYSTEMATICS IS CONCERNED WITH RECONSTRUCTING PHYLOGENY

Systematists use systems of classification to reconstruct the evolutionary relationships, or **phylogeny** (literally, “production of phyla”), of organisms. Once these relationships are established, the classification of organisms can be based on common an-

cestry. A population has a dimension in space—its geographical range—and also a dimension in time. Each population extends backward in time. Somewhat like branches of a tree, a population may diverge from other populations sufficiently to become a new species. Species have various degrees of evolutionary relationship with one another, depending on the degree of genetic divergence since their populations branched from a common ancestor.

Taxa should reflect evolutionary relationships

Systematists recognize three kinds of evolutionary groupings: monophyletic, paraphyletic, and polyphyletic. A **monophyletic group** contains all of the descendants of the most recent common ancestor (Fig. 22–4*a*). Mammals, for example, form a monophyletic taxon because all mammals are thought to have evolved from a common ancestral mammal, and all descendants of this ancestor are mammals. Monophyletic taxa are, therefore, natural groupings because they represent true evolutionary relationships and include all close relatives. A **paraphyletic group** is a group that contains a common ancestor and some, but not all, of its descendants.

Some currently recognized groups are probably **polyphyletic**, consisting of several evolutionary lines and not including a common ancestor (Fig. 22–4*b*). The members of such a taxon might have been mistakenly grouped together because they share similar features arising from convergent evolution (see Chapter 17). Thus, by definition, polyphyletic taxa misrepresent evolutionary relationships. For this reason, taxonomists attempt to avoid constructing polyphyletic taxa.

Homologous structures are important criteria for classification

Just how to group species into higher taxa—genera, families, orders, classes, or phyla—can be a difficult decision. Traditionally, many biologists have based their judgments about the degree of relationship on the extent of similarity among living species, and, when available, on the fossil record.

When they evaluate similarities, systematists consider structural, physiological, behavioral, and molecular traits. When comparing structural similarities, they look for homology in different organisms. Recall from Chapter 17 that **homology** refers to the presence in two or more species of a structure derived from a common ancestor. In contrast, the

possession by two or more species of similar structures not derived from a shared ancestry sometimes occurs when unrelated or distantly related organisms become adapted to similar environmental conditions. For example, the shark and the dolphin have similar, but independently derived, body forms because they have become adapted to similar environments (aquatic) and lifestyles (predatory). Such similarity of attributes that appear to be homologous, but are actually independently acquired, is referred to as **homoplasy**.

Shared derived characters provide clues about phylogeny

Organisms sharing many homologous structures are considered to be closely related, while organisms sharing few homologous characters are presumed less closely related. However, distinguishing between homology and homoplasy is not always straightforward. Therefore, the appropriate choice of which similarities to use to show evolutionary relationships is extremely important.

How does a systematist interpret the significance of these similarities? In making decisions about taxonomic relationships, the systematist first examines the characteristics found in the largest group of organisms being studied and interprets them as indicating the most remote common ancestry. These **ancestral characters**, or **pleisomorphic characters**, are traits that were present in an ancestral species and that remain essentially unchanged in its descendants. For example, the vertebral column, present in all vertebrates, is an ancestral character for study of classes within the vertebrate subphylum. Studying the presence or absence of the vertebral column would not help us distinguish between various classes of vertebrates, e.g., between amphibians and mammals.

Derived characters, or **synapomorphic characters**, are traits found in two or more taxa that are present in their closest common ancestor. They are homologous traits not present in earlier ancestors because they evolved more recently. Birds

Figure 22–4 Evolutionary relationships. (a) Monophyletic and paraphyletic groups. Taxon 1 and taxon 3 are monophyletic. Each includes a common ancestor and all of its descendants. Taxon 2 is paraphyletic; it does not include all of the descendants of a common ancestor. (b) Taxon 4 is polyphyletic; members of this group do not share a close common ancestor.

and reptiles, for example, have a common ancestor, and both share the ancestral character of laying eggs. The feathers and beaks of birds, however, are derived characters that are not shared by reptiles.

A feature viewed as a *derived character* in a more inclusive (broader) taxon may also be considered an *ancestral character* in a less inclusive (narrower) taxon. More recent common ancestry is indicated by classification into less and less inclusive taxonomic groups with more and more specific shared derived characters. For example, the three small bones in the middle ear are useful in identifying a branch point between reptiles and mammals. The evolution of this derived character was a unique event, and only mammals have these bones. However, if we compare mammals with one another, the three ear bones are an ancestral character because all mammals have them. Consequently, they have no value in distinguishing among mammalian taxa. Other characters must be used to establish branch points among the mammals.

If we compare the mammals, dogs, goats, and dolphins, we find that dogs and goats have hair whereas dolphins do not. However, hair is an ancient trait in mammals and therefore cannot be used as evidence that dogs and goats share a more recent common ancestor. In contrast, the virtual absence of hair in dolphins is a derived character within mammals. When we compare dogs, dolphins, and whales, we find that dolphins and whales share this derived character, providing evidence that these animals branched from a common ancestor not shared by dogs.

Biologists carefully choose taxonomic criteria

Both fishes and dolphins have streamlined body forms, but this characteristic is homoplastic and does not indicate close evolutionary relationships. The dolphin shares important homologous derived characters with mammals such as humans: the ability to breathe air, nurse young, and use metabolic energy to maintain a constant body temperature (endothermy). Thus, the dolphin is classified as a mammal and is thought to have descended from a terrestrial mammalian ancestor.

Although dolphins have more shared derived characters in common with humans than with fishes, some characters are shared by all three of these animals. Among these ancestral characters are a dorsal tubular nerve cord and, during embryonic development, a notochord (skeletal rod) and rudimentary gill slits. These shared ancestral characters indicate a common ancestry and serve as a basis for classification. The ancestry is more remote between the dolphin and the fish than between the dolphin and the human. Therefore, while fishes, humans, and dolphins are grouped together in a more inclusive taxon, the phylum Chordata, humans and dolphins are also classified together in class Mammalia, a less inclusive taxon within phylum Chordata, indicating their closer relationship.

Deciding which traits best illustrate evolutionary relationships can be challenging. What, for example, are the most important taxonomic characteristics of a bird? We might list

Figure 22–5 Is this animal a bird? A few mammals share important characteristics with birds. The duck-billed platypus, a monotreme, lays eggs, has a beak, and lacks teeth. However, it does not have feathers, and it nourishes its young with milk secreted from mammary glands. (Jean Philippe Varin/Jacana/Photo Researchers, Inc.)

feathers, beak, wings, absence of teeth, egg-laying, and endothermy. Some mammals, for example, monotremes such as the duck-billed platypus, have many of these same characteristics: beaks, endothermy, absence of teeth, and egg-laying. Yet we do not classify them as birds (Fig. 22–5). No mammal, however, has feathers. Is this trait absolutely diagnostic of birds? According to the conventional taxonomic wisdom, the presence or absence of feathers determines what is and is not a bird. This applies only to modern birds, however. Some extinct reptiles may have had feathers.

Usually, organisms are classified on the basis of a combination of traits rather than on any single trait. The significance of these combinations is determined inductively, that is, by an integration and interpretation of the data. Such induction is a necessary part of the process of science. Taxonomists may hypothesize, for example, that birds should all have beaks, feathers, no teeth, and so on. Then, they reexamine the living world and observe whether there are organisms that might reasonably be called birds that do not fit the current definition of “birdness.” If not, the definition is permitted to stand. If too many exceptions emerge, the definition may be modified or abandoned. Sometimes, the taxonomist persuades the world that an apparent exception, the bat, for instance, resembles a bird only superficially and should not be considered one. The bat possesses all of the basic characteristics of a mammal, such as hair and mammary glands that produce milk for the young.

Systematics is a dynamic science that proceeds by the constant reevaluation of data, hypotheses, and theoretical constructs. As new data are discovered and old data are subjected to reinterpretation, the ideas of systematists change. In 1995,

MAKING THE CONNECTION

MOLECULAR BIOLOGY, EVOLUTION, AND TAXONOMY

How do molecular biology and evolution come together in the laboratory to provide data that can be used by systematists? Advances in molecular biology have provided the tools for biologists to compare the macromolecules of various organisms. Amino acid sequencing techniques, immunological methods, and DNA and RNA sequencing are among the procedures now used to compare macromolecules.

In Chapter 17 we discussed the respiratory protein cytochrome *c* present in all aerobic organisms. Although the structure and function of cytochrome *c* are similar in all aerobic organisms, some differences in amino acid sequences exist among species. Comparisons of these differences among about 100 species provide a good example of how data gained through amino acid sequencing contribute to taxonomic decisions. Interestingly, chimpanzee cytochrome *c* has the same amino acid sequences as human cytochrome *c*, but in a more distantly related primate, the rhesus monkey, 1 of the 104 amino acids in the sequence is different. In the dog, a nonprimate, 13 amino acids are different. Taxonomists use this type of information to help make decisions about classifying

organisms. Such decisions are generally based on data derived from studies of different proteins.

We have learned that among related species the DNA sequences for the same structural genes are very similar. Detailed restriction maps within large homologous regions of chromosomes of related organisms are also very similar (see Chapter 14). For example, the DNA region that codes for the equivalent of the human hemoglobin beta chain has been mapped in several primates. Even though the gorilla diverged from the human line 8 to 10 million years ago, 65 of the 70 restriction sites are identical.

Researchers have determined the nucleotide sequence of a portion of DNA from each of three species of primates (humans, gorillas, and chimpanzees). From their analysis of this 7000 nucleotide sequence, the investigators inferred a common ancestral gene. The simplest branching pattern that would account for the results suggests that the gorilla split off first from the common ancestor it shared with the chimpanzee and human (see Fig. 17–15). The chimpanzee and human lines diverged later (probably about 6 million years ago).

for example, a new species of animal (*Symbion pandora*) was discovered inhabiting lobster mouthparts. Its combination of traits did not fit those of any existing phylum, so phylum Cyclophora was established to accommodate this animal.

Molecular biology provides taxonomic tools

When a new species evolves, it does not always exhibit obvious phenotypic differences relative to closely related species. For example, two distinct species of fruit flies may appear identical. Some of their DNA, proteins, and other molecules, however, are different. Variations in the structure of specific macromolecules among species, just like differences in anatomical structure, result from mutations. Macromolecules that are functionally similar in two different types of organisms are considered homologous if their subunit structure is similar.

The emerging science of **molecular taxonomy** focuses on molecular structure (see *Making the Connection: Molecular Biology, Evolution, and Taxonomy*). Differences in subunit sequences of macromolecules provide new data useful in determining evolutionary relationships. Methods that permit taxonomists to compare the nucleotide sequences of nucleic acids and the amino acid sequences of proteins have become important taxonomic tools. Such comparisons provide systematists with valuable information about the degree of relatedness of two organisms. The greater the correspondence in subunit sequences, the more closely organisms are considered to be related. The number of differences in DNA or RNA nucleotide sequences or in amino acid sequences in two groups of organisms may reflect how much time has passed since the

groups branched from a common ancestor. (This can be true only if the rates of change have remained constant.) Thus, specific genes and specific proteins can be used as **molecular clocks** (see Chapter 17). Biologists can use such clocks to estimate the time of divergence of two groups from a common ancestor.

Many systematists are currently comparing ribosomal RNA structure to help determine phylogenies. The division of organisms into three domains was based, in large part, on the comparison of ribosomal RNA by Carl Woese and his research team at the University of Illinois. All known organisms have ribosomes that function in protein synthesis, and certain ribosomal RNA nucleotide sequences have been highly conserved in evolution. Prokaryotic ribosomes all contain three types of RNA named in order of increasing size: 5S, 16S, and 23S. The 5S and 16S RNAs have been extensively used to determine evolutionary relationships among bacteria. A common technique used to clone single-species ribosomal RNA genes is the PCR (polymerase chain reaction) discussed in Chapter 14.

Comparison of ribosomal RNA sequences was used to challenge the once widely accepted idea that fungi are more closely related to plants than to animals. In a study reported in *Science* in 1993, investigators suggested that, based on ribosomal RNA analysis, fungi are more closely related to animals than to plants. These biologists hypothesize that animals and fungi share a more recent common ancestor, perhaps a flagellated protist.

In 1997 molecular taxonomist Robert Wayne of the University of California, Los Angeles and his international team of researchers reported in the journal *Science* that mitochon-

Figure 22–6 Molecular taxonomy. Diagram of the relationships of 8 wolves and 15 dogs based on differences in mitochondrial DNA. 1030 base pairs of a stretch of mitochondrial DNA were compared. Wolf and dog sequences were very similar, differing by at most 12 substitutions. Dog and coyote sequences differed by at least 20 substitutions. Four clades were identified. (D, dog; W, wolf) (From Carles Vila *et al*, published in *Science*, Vol. 276 (5319) 13 June 1997)

drial DNA sequences were analyzed from 162 wolves at 27 different geographical locations and compared to those from domestic dogs of 67 different breeds (Fig. 22–6). Their results supported the hypothesis that dogs evolved more than 100,000 years ago from a common ancestor that was a wolf. Dog and wolf nucleotide sequences were similar, differing by no more than 12 substitutions. In contrast, dog sequences differed by at least 20 substitutions from jackal and coyote DNA. Their data suggest that repeated genetic exchange has taken place between dog and wolf populations, providing variation for selection. Using DNA sequences as a molecular clock, these investigators proposed that dogs evolved from wolves about 135,000 years ago, much earlier than the 14,000 year date formerly estimated.

SYSTEMATISTS USE TWO MAIN APPROACHES

In determining the relationships among organisms, systematists use a variety of methods and data. Which types of data are used more depends on the systematist's approach. **Phenetics**, or **numerical taxonomy**, was an early approach to the quantitative analysis of characters. First gaining attention of

systematists in the 1960s, phenetics is based on as many phenotypic similarities (that is, similarities in *appearance*) as possible. In the phenetic approach, computer programs are used to analyze data and group organisms according to the number of shared characteristics. No attempt is made to determine whether their similarities arose from a common ancestor or from convergent evolution. Pheneticists argue that it is not important to try to differentiate between homology and homoplasy because many more similarities are due to homology than to homoplasy. Thus, the number of similarities that two organisms have in common reflects the degree of homology.

A taxonomist who follows the phenetic system might explain that dolphins and porpoises are classified as mammals rather than as fish because they share more similarities with mammals. Phenetics is not widely used by taxonomists today because the use of homoplastic similarities can lead to inaccurate conclusions about evolutionary relationships. However, the use of computers for making quantitative comparisons of characters has been an important contribution to systematics.

Phenetic techniques are currently used in molecular taxonomy. For example, if each amino acid in a protein is considered as a trait, amino acid sequences of various animals can be determined in the laboratory and compared by computer. The information about differences in amino acid sequences can be used to construct phylogenetic diagrams. Species are placed at relative distances from each other, reflecting the extent of difference in amino acid sequence.

Two major approaches to the classification of organisms that are widely used today are **phylogenetic systematics**, known as **cladistics**, and **classical evolutionary taxonomy**, or simply, evolutionary taxonomy. Although we discuss them separately here, many modern systematists use aspects of both approaches in their work. In contrast to phenetics, cladism and classical evolutionary taxonomy intentionally include the use of evolutionary data.

Phylogenetic systematics (cladistics) emphasizes phylogeny

The cladistic approach to taxonomy emphasizes common ancestry, rather than phenotypic similarity, as the basis for classification. Cladistics uses shared derived characters to reconstruct phylogenies. According to cladistics, dolphins are classified with mammals rather than with fishes because dolphins and mammals share derived characters and thus have a more recent common ancestor than dolphins and fishes.

To determine which attributes are shared derived characters, cladism employs **outgroup analysis**. Three or more related groups are compared. If two groups have a characteristic that the third lacks, the attribute may be a shared derived character for the two groups. If all three groups share the characteristic, it is an ancestral character. Recall that these terms are relative. An attribute that is an ancestral character in one comparison may be a shared derived character in another.

Cladism determines the evolutionary relationships of organisms and expresses them in branching diagrams called

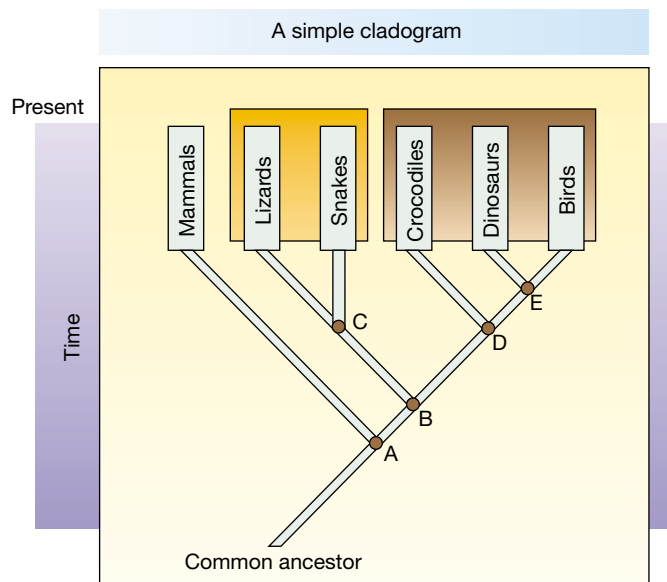

Figure 22–7 The cladistic approach. Cladists classify birds and some reptiles together because they have a common ancestor. Node D represents the common ancestor of crocodiles, dinosaurs, and birds.

cladograms. Each branch on a cladogram represents the divergence, or splitting, of two or more new groups from a common ancestor. Consider the evolutionary grouping of mammals, lizards, snakes, crocodiles, dinosaurs, and birds (Fig. 22–7). Birds, along with dinosaurs, are thought to share a common ancestor with modern crocodiles and alligators (point D on Fig. 22–7). Crocodiles, dinosaurs, and birds, then, comprise a monophyletic group, and cladists would classify them in the same **clade**, which is a monophyletic group in a cladogram. Similarly, snakes and lizards form a clade that is the closest group to birds, dinosaurs, and crocodiles. Finally, mammals form an additional clade. Cladists base their assessment on shared *derived* characters that can be structural, behavioral, physiological, or molecular. The characters must be homologous.

Phylogenies can be constructed by building and interpreting cladograms³

The first step in constructing a cladogram is to select the taxa, which may consist of individuals, species, genera, or other taxonomic levels. Here we use a representative group of eight chordates (Table 22–3). The next step is to select the homologous characters to be analyzed. In our example, we use seven characters. For each character, we must define all of the different conditions, or states, as they exist in our taxa. For simplicity, we will consider our characters to have only two dif-

³This discussion of building and interpreting cladograms is based on an essay contributed by Dr. John Beneski, Department of Biology, West Chester University, West Chester, PA.

TABLE 22–3 A Comparison of Eight Chordates

TAXA	CHARACTERS						
	Vertebrae (backbones)	Jaws	Tetrapod (4 limbs)	Amniotic egg	Mammary glands	Opposable thumb	Upright posture
Amphioxus (outgroup)	A	A	A	A	A	A	A
Hagfish	P	A	A	A	A	A	A
Sunfish	P	P	A	A	A	A	A
Newt	P	P	P	A	A	A	A
Lizard	P	P	P	P	A	A	A
Bear	P	P	P	P	P	A	A
Chimpanzee	P	P	P	P	P	P	A
Human	P	P	P	P	P	P	P

ferent states: present or absent. Keep in mind that many characters used in cladistics have more than two states. For example, black, brown, yellow, and red may be only a few of the many possible states for the character of hair color.

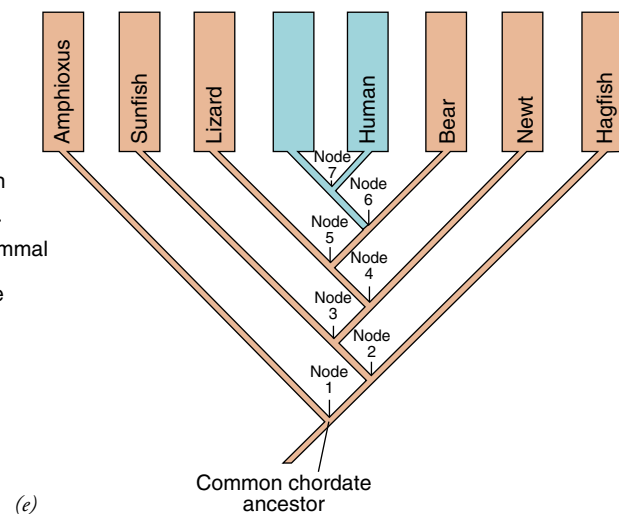

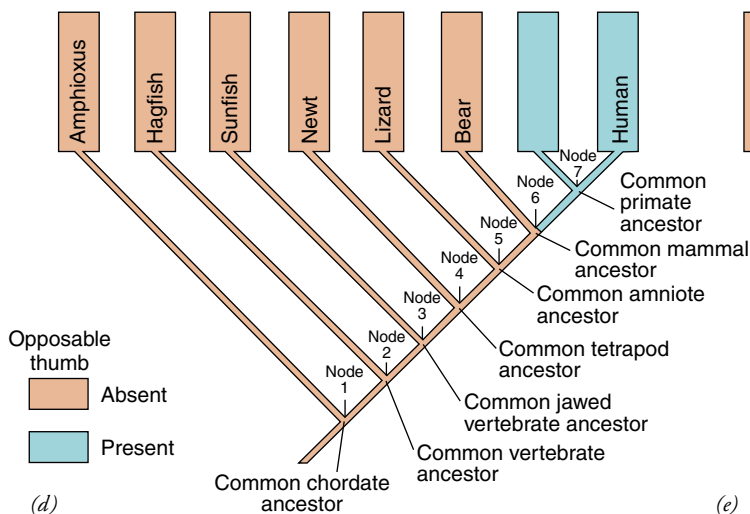

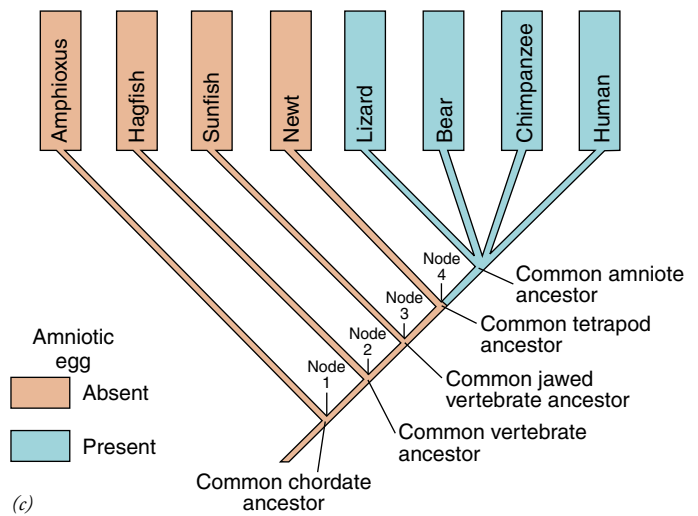

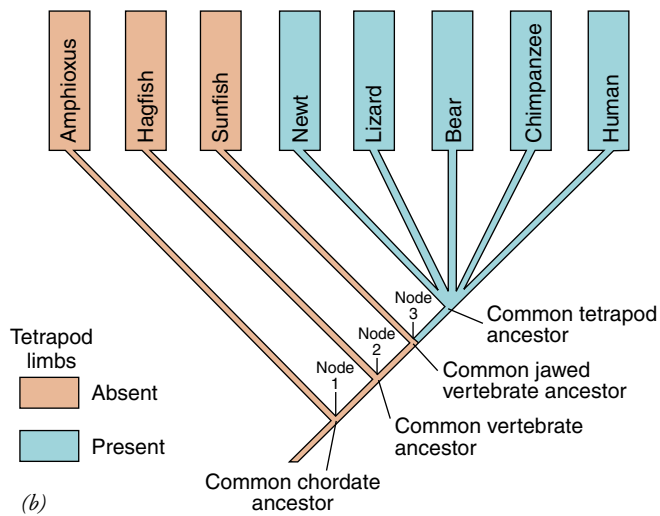

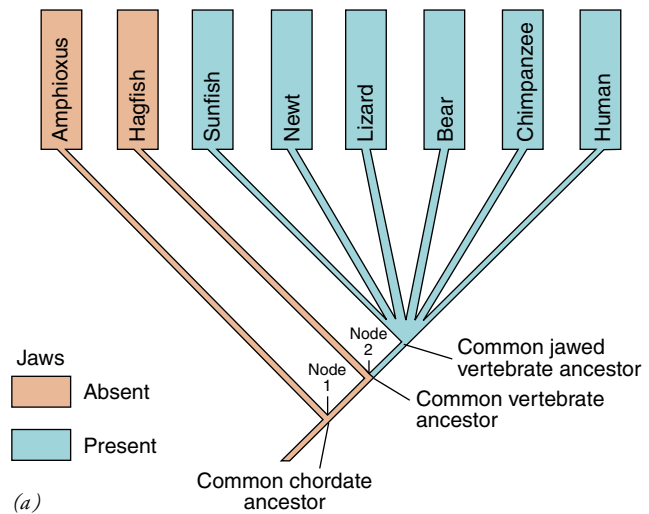

The last, and often the most difficult, step in preparing the data is to organize the character states into their correct evolutionary order. The most common method of accomplishing this task is by outgroup analysis. An *outgroup* is a taxon that is considered to have diverged earlier than any of the other taxa under investigation and thus to represent an approximation of the ancestral condition. In our example, amphioxus is the chosen outgroup. Therefore, the character state “absent” is the ancestral condition, and the character state “present” is the derived condition for all seven characters in Table 22–3.

Constructing a cladogram from the data

Our objective is to construct a cladogram that requires the fewest number of evolutionary changes in the characters. Recall that, in cladistics, taxa are grouped by the presence of shared derived characters. In order to form a valid monophyletic group, all members must share at least one derived character. Membership in a clade cannot be established by shared ancestral characters.

In our example, notice that all taxa except the outgroup possess vertebrae. We may therefore conclude that these seven vertebrate taxa form a valid clade. Next, among the seven vertebrate taxa, notice that jaws are present in all groups except for hagfish. Using these data, we may construct a preliminary cladogram (Figure 22–8a). The base of the cladogram represents the common ancestor for all taxa being analyzed. Each branch point (referred to as a *node*) represents the immediate

Figure 22–8 Building a cladogram. In this example, amphioxus is the chosen outgroup that represents an approximation of the ancestral condition.

common ancestor of the next monophyletic group depicted in the cladogram. In Fig. 22–8*a*, node 1 represents the common chordate ancestor from which the outgroup (amphioxus) and the seven vertebrate taxa evolved. Similarly, node 2 represents the common ancestor of the vertebrates and node 3, the common ancestor of the jawed vertebrates. Continuing with this procedure, notice that among the six jawed taxa, all but sunfish are tetrapods (Fig. 22–8*b*). Among the five tetrapods, all but newts have amniotic eggs (Fig. 22–8*c*). The branching process is continued using Table 22–3 data until all clades are established (Fig. 22–8*d*).

How to interpret the cladogram

In Figure 22–8*d*, notice that humans and chimpanzees are more similar to each other than to any other clade. This relationship is indicated by the presence of a common ancestor at node 7. In the same way, bears are more similar to the human-chimpanzee clade than to any other clade, as indicated by the common ancestor at node 6. In comparing the nodes, the order of divergence is indicated by distance from the base of the diagram. The further a node is located up the cladogram, the more recently the group diverged. In our example, node 7 represents the most recent divergence, and node 1 represents the most ancient divergence. Thus, in our example, humans are closely related to chimpanzees (through node 7) but more distantly related to bears (through node 6). Therefore, humans and chimpanzees would be assigned to a less inclusive taxon (order Primates) whereas humans, chimpanzees, and bears would be assigned to a broader, more inclusive taxon (class Mammalia). In addition, the cladogram reveals that lizards are more closely related to the mammal clade than to newts, sunfish, or any other clade. Can you explain why?

In interpreting cladograms, two points must be kept in mind. First, the relationships among taxa can only be determined by tracing along the branches back to the most recent common ancestor (i.e., node) and not by the relative placement of the branches along the horizontal axis. It is possible to represent the same relationships with many different branching diagrams. For example, the cladogram in Figure 22–8*e* is equivalent to the one in Figure 22–8*d*. (You should verify this by comparing the numbered nodes and by checking the relationships described earlier.) Second, the cladogram does not establish ancestor-descendant relationships among taxa. In other words, a cladogram does not suggest that a taxon gave rise to any other taxon; rather it tells us which taxa shared a common ancestor and how recently they shared a common ancestor. The ancestor itself remains unspecified.

Classical evolutionary taxonomy allows paraphyletic groups

Classical evolutionary taxonomy, or simply evolutionary taxonomy, uses a system of phylogenetic classification and presents evolutionary relationships in phylogenetic trees. Evolutionary taxonomists consider both evolutionary branching (as

Figure 22–9 The classical evolutionary taxonomy approach.

These taxonomists consider both common ancestry and extent of divergence that has occurred since two taxa split. The branching points and degrees of difference in the evolution of the major groups of reptiles are shown. Snakes, lizards, and crocodiles are most similar, but birds, dinosaurs, and crocodiles are most closely related because they branched most recently from a common ancestor.

do cladists) and the extent of divergence (structural and other changes) that has occurred in a lineage since it branched from a stem group (Fig. 22–9). They use a combination of shared ancestral characters and shared derived characters to evaluate both similarities and differences among groups.

A systematist using the evolutionary approach might explain that dolphins are mammals rather than fish because they share many characteristics with other mammals and because these characteristics can be traced to a common ancestor. Like cladists, evolutionary taxonomists classify organisms in the same taxon according to their shared characteristics only if those traits are derived from a demonstrable common ancestor. However, evolutionary taxonomists also consider the significance of the adaptations possessed by related organisms. If, for example, egg-laying mammals could be shown to have significantly different adaptations than other mammals, the evolutionary taxonomist might erect a separate taxon to accommodate them. On the other hand, common ancestry, although necessary for inclusion in the same category, would not by itself be sufficient grounds for inclusion (as it would be if a cladistic approach were used).

Many, perhaps most, of the taxa currently recognized by evolutionary taxonomists are monophyletic, based on the possession of shared derived characters. These taxa are also recognized by cladists. For example, proponents of both approaches agree that birds are a monophyletic taxon based on shared derived characters such as feathers. However, evolutionary taxonomy also recognizes paraphyletic taxa, groups that include some, but not all subgroups of organisms that share the same most recent common ancestor. Paraphyletic groups are based on shared ancestral characters. Cladists, for example, do not recognize reptiles as a natural grouping containing snakes,

lizards, crocodiles, dinosaurs, and turtles because they do not form a monophyletic clade. They recognize a class Reptilia that includes birds. In contrast, evolutionary taxonomists do recognize class Reptilia as a valid group that does not include birds, even though it is paraphyletic. It does not include all of

the subgroups, such as birds, that evolved from the ancestral reptile. Evolutionary taxonomists base their decision on different data; they consider that reptiles share numerous ancestral traits, such as ectothermy. They assign birds to a separate class because they have diverged markedly from the reptiles.

SUMMARY WITH KEY TERMS

- I. **Systematics** is the scientific study of the diversity of organisms and their evolutionary relationships.
 - A. **Taxonomy** is the branch of systematics devoted to naming, describing, and classifying animals.
 - B. The process of assigning organisms into groups based on their similarities or relationships is **classification**.
- II. Biologists use a system of classification based on the **binomial system** developed by Linnaeus in the mid-18th century.
 - A. In this system the basic unit of classification is the **species**. Different populations within the same species that have consistent distinguishing characteristics are called **subspecies**. In plants subspecies may be referred to as **varieties**; in bacteria they are known as **strains**.
 - B. The name of each species has two parts: the **genus** name and the **specific epithet**. For example, the scientific name of the human is *Homo sapiens*, and that of the white oak is *Quercus alba*.
- III. The hierarchical system of classification currently used includes **kingdom, phylum, class, order, family, genus, and species**.
- IV. The three-**domain** classification system assigns organisms to domain **Archaea**, domain **Eubacteria**, or domain **Eukarya**. The six-kingdom classification recognizes the kingdoms **Eubacteria, Archaeobacteria, Protista, Fungi, Plantae, and Animalia**.
- V. Modern systematics is based on similarity, as determined by shared characteristics, and on evolutionary relationships, or **phylogeny**.
 - A. A **monophyletic group** includes all of the descendants of the most recent common ancestor. A **paraphyletic group** consists of a common ancestor and some, but not all, of its descendants. The organisms in a **polyphyletic group** evolved from different ancestors.
 - B. **Homology** implies evolution from a common ancestor. **Homoplasy** refers to the evolution of similar, but independently evolved, characters that are not homologous.
 - C. **Shared ancestral characters**, or **pleisomorphic characters**, suggest a distant common ancestor. **Shared derived characters**, or **synapomorphic characters**, indicate a more recent common ancestor.
 - D. **Molecular taxonomy** provides methods for comparing macromolecules such as nucleic acids and proteins as a tool for confirming evolutionary relationships. Comparison of nucleotide sequences in ribosomal RNA has led to important taxonomic decisions regarding domains, kingdoms, and species.
- VI. Two main approaches to taxonomy are **phylogenetic systematics**, also known as **cladistics**, and **classical evolutionary taxonomy**.
 - A. **Phenetics**, or numerical taxonomy, is based on similarities of many characters; this was an early approach to the quantitative analysis of characters. Organisms were classified according to the number of characteristics they shared without trying to determine whether their similarities were homologous or homoplastic.
 - B. Cladistics insists that taxa be monophyletic. Each monophyletic taxon, or **clade**, consists of a common ancestor and all of its descendants and is based on shared derived characters.
 1. Cladists use **outgroup analysis** to determine which characters are ancestral and which are derived.
 2. Shared derived characters are used to determine relationships that can be illustrated in diagrams called **cladograms**.
 - C. Classical evolutionary taxonomy considers both evolutionary branching and the extent of divergence. Evolutionary taxonomy is based on shared ancestral characters as well as shared derived characters.

POST-TEST

1. The science of describing, naming, and classifying organisms is (a) systematics (b) taxonomy (c) cladistics (phylogenetic systematics) (d) phenetics (e) evolutionary taxonomy
2. Using the binomial system of nomenclature, the scientific name of each species consists of two parts (a) class, specific epithet (b) family, genus (c) genus, specific epithet (d) family, species (e) genus, species
3. The mold that produces penicillin is *Penicillium notatum*. *Penicillium* is the name of its (a) genus (b) order (c) family (d) species (e) specific epithet
4. Closely related genera may be grouped together in a single (a) phylum (b) domain (c) species (d) family (e) kingdom
5. Related classes are grouped together in the same (a) genus (b) phylum (c) order (d) paraphyletic taxon (e) family
6. In the six-kingdom system, the kingdom that includes the protozoa is (a) Plantae (b) Protista (c) Archaea (d) Eukarya (e) Fungi
7. Decomposers such as molds and mushrooms belong to kingdom (a) Plantae (b) Protista (c) Archaeobacteria (d) Eukarya (e) Fungi
8. A taxon that contains a recent common ancestor and all of its descendants is (a) polyphyletic (b) paraphyletic (c) monophyletic (d) phyletic (e) pleisomorphic
9. The presence of homologous structures in different organisms suggests that (a) they evolved from a common ancestor (b) convergent evolution has occurred (c) they belong to a polyphyletic group (d) answers a,b, and c are correct (e) answers a and c only are correct
10. The dolphin and the human both have the ability to nurse their young, whereas the less closely related fish does not. The ability to nurse their young is (a) shared derived character of mammals (b) shared ancestral character of all vertebrates (c) pleisomorphy (d) homologous behavior (e) two of the preceding answers are correct
11. Relative constancy in the rates of DNA and protein evolution permits biologists to use these macromolecules as (a) molecular clocks (b) polymerase chains (c) clades (d) paraphyletic clues (e) two of the preceding answers are correct
12. Phenetics is (a) a numerical taxonomy based on phenotypic similarities (b) an approach to taxonomy that emphasizes common ancestry (c) an approach that emphasizes polyphyletic groups (d) an approach used in molecular taxonomy (e) two of the preceding answers are correct
13. Systematists who classify crocodiles and birds in the same taxon because they are monophyletic follow a(n) (a) phyletic approach (b) cladistic approach (c) evolutionary taxonomy approach (d) polyphyletic approach (e) two of the preceding answers are correct

REVIEW QUESTIONS

1. Briefly describe the binomial system of nomenclature.
2. Define the terms: (a) species (b) class (c) phylum.
3. What are the advantages of a "six-kingdom" system over a "two-kingdom" one? What types of organisms are especially difficult to assign a place in the taxonomic hierarchy?
4. In which kingdom would you classify each of the following? (a) oak tree (b) amoeba (c) *Escherichia coli* (a bacterium) (d) tapeworm (e) black bread mold
5. Compare the cladistic and classical evolutionary approaches to taxonomy.
6. Of what use to a taxonomist is knowledge of the amino acid sequences of the proteins of various organisms?
7. What kind of grouping is represented by the shaded area?

YOU MAKE THE CONNECTION

1. What difficulties do we encounter when we attempt to use the concept of a species? Are members of a genus similar because they share a common ancestor, or do they belong to the same genus because they are similar? How might your answer vary depending on which approach to taxonomy you are following?
2. After many years of being considered old-fashioned, the science of systematics has reemerged on the cutting edge of biological research. Why do you think this shift has occurred?
3. The TATA-binding protein (TBP) is thought to be necessary for tran-

scription in all eukaryotic cell nuclei. Studies show that archaeobacteria, but not eubacteria, have a protein structurally and functionally similar to TBP. What does this similarity suggest regarding the evolution of archaeobacteria and eukaryotes? How might knowledge of this similarity affect how systematists classify these organisms?

4. Based on the information in question 3 and on studies that indicate that archaeobacterial gene sequences are more similar to those in eukaryotes than to those in eubacteria, do you think systematists should abandon the six kingdoms and classify organisms in three domains? Why or why not?

CHAPTER 23

Viruses and Bacteria

Bacteria have inhabited our planet for more than 3.5 billion years, whereas eukaryotes evolved about 2 billion years ago. Approximately one-half of the biomass, the mass of living material, on Earth consists of microorganisms, mostly bacteria and fungi. (In contrast, plants account for about 35% and animals for about 15% of the biomass of our planet.) Anton van Leeuwenhoek discovered bacteria and other microorganisms in 1674 when he looked at a drop of lake water through a glass lens. During the late 1800s, many microorganisms, including bacteria, fungi, and protozoa, were identified as **pathogens**, agents that cause disease. The bacterium (*Streptococcus pyogenes*) shown dividing in the TEM is a human pathogen that inhabits the human nose and throat. This bacterium can cause scarlet fever and inflammation of the heart tissue. The strain shown here is resistant to antibiotics, and infection can be fatal.

Although bacteria cause many diseases, including respiratory infections and food poisoning in humans, only a small minority of bacterial species are pathogens. In fact, bacteria play an essential role in the biosphere as decomposers, breaking down organic molecules into their components. Along with fungi, bacteria are nature's recyclers. Without these microorganisms, the available carbon, nitrogen, phosphorus, and sulfur would eventually be tied up in the wastes and dead bodies of plants and animals. Life as we know it would cease to exist because of the lack of raw materials for the synthesis of new cellular components.

Some bacteria are producers that carry on photosynthesis. Other bacteria perform a key role in agriculture by converting atmospheric nitrogen to ammonia and then to nitrates, a form that can be used by plants (see Figure 53–10). The conversion of nitrogen enables plants and animals (because they eat plants) to manufacture essential nitrogen-containing compounds such as proteins and nucleic acids.

In contrast to bacteria, viruses do not consist of cells. Biologists consider them to be nonliving particles. Viruses have no common ancestor and thus are not assigned to a kingdom. Why, then, include them here in a unit on the diversity of life? As we will discuss in this chapter, viruses evolved from various prokaryotic and eukaryotic cells. They contain the nucleic acid necessary to make copies of themselves, and they reproduce by invading living cells and commandeering their metabolic machinery. Viruses are intimately involved with living organisms, and it seems appropriate to discuss the diversity

(Dr. Kari Lounatmaa/Science Photo Library/Photo Researchers, Inc.)

and importance of these tiny, but potent, particles. Viruses are responsible for a wide variety of diseases in plants and animals. Among the viral diseases that affect humans are common colds, influenza, chickenpox, rabies, and AIDS.

This chapter examines the diversity and characteristics of viruses, bacteria, and the smaller viroids and prions. They are *not* a natural group of closely related organisms, and we discuss them in a single chapter only for convenience.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Describe the structure of a virus and compare a virus with a free-living cell.
2. Speculate about the evolutionary origin of viruses.
3. Characterize bacteriophages and contrast a lytic cycle with a lysogenic cycle.
4. Explain how viruses infect animals and plants.
5. Describe the reproductive cycle of a retrovirus such as HIV.
6. Characterize viroids and prions.
7. Compare the three domains: Eubacteria, Archaea, and Eukarya.
8. Describe asexual reproduction in bacteria and summarize three mechanisms (transformation, conjugation, and transduction) that may lead to genetic recombination.
9. Characterize the metabolic diversity of autotrophic and heterotrophic bacteria, including aerobes, facultative anaerobes, and obligate anaerobes.
10. Distinguish among the three main groups of archaea and among several groups of eubacteria as described in Table 23–3. Give examples of each group.
11. Discuss the ecological roles of bacteria, their importance as pathogens, and their commercial importance.

VIRUSES ARE INFECTIOUS AGENTS THAT ARE NOT ASSIGNED TO ANY OF THE SIX KINGDOMS

During the late 1800s, botanists searched for the cause of tobacco mosaic disease, which stunts the growth of tobacco plants and gives the infected tobacco leaves a spotted, mosaic appearance. They found that the disease could be transmitted to healthy plants by daubing their leaves with the sap of diseased plants. In 1892 Dmitrii Ivanowsky, a Russian botanist, showed that the sap was infective even after it had been passed through filters fine enough to remove particles the size of all known bacteria. A few years later his work was expanded by Martinus Beijerinck who provided evidence that the agent that caused tobacco mosaic disease had many characteristics of a living organism. He hypothesized that the agent could only reproduce within a living cell.

Early in the 20th century, scientists discovered infectious agents that could cause disease in animals or kill bacteria. Like the agents that cause tobacco mosaic disease, these pathogens passed through filters that removed known bacteria and were so small that they could not be seen with the light microscope. Curiously, they could not be grown in laboratory cultures unless living cells were present. These pathogens that infected plants or animals came to be known as viruses. Those that killed bacteria were called **bacteriophages** (“bacteria eaters”), or **phages**.

A virus particle consists of nucleic acid surrounded by a protein coat

A **virus**, or **virion**, is a tiny, infectious particle consisting of a nucleic acid core (its genetic material) surrounded by a protein coat called a **capsid**. Some viruses are also surrounded by an outer membranous envelope containing proteins, lipids, carbohydrates, and traces of metals. A typical small virus, like

the poliovirus, is about 20 nanometers in diameter (about the size of a ribosome), whereas a larger virus, such as the poxvirus that causes smallpox, might be 400 nm in length and 200 nm in width.

Viruses are not cellular and cannot independently perform metabolic activities. They do not have the components necessary to carry on cellular respiration or to synthesize proteins and other molecules. All living organisms contain both DNA and RNA, but a virus contains either DNA or RNA, not both. Viruses can reproduce, but only within the complex environment of the living cells they infect. In a sense, viruses come “alive” only when they infect a cell. Viruses have genetic information that can force the host cell to replicate the viral nucleic acid and to synthesize the capsid and envelope components. The genetic information in a virus can take over the translational or transcriptional mechanisms of the host cell.

The shape of a virus is determined by the organization of protein subunits that make up the capsid. Viral capsids are generally either helical, polyhedral, or a complex combination of both shapes (Fig. 23–1). Helical viruses, such as the tobacco mosaic virus, appear as long rods or threads. The capsid is a hollow cylinder. The RNA fits into a groove in the proteins. Polyhedral viruses, such as the adenovirus (which causes a number of human illnesses, including some respiratory infections), appear to be somewhat spherical. The T4 phage that infects *Escherichia coli* consists of a polyhedral “head” attached to a helical “tail.”

Viruses may have “escaped” from cells

Where did viruses come from? The hypothesis currently considered most likely is that viruses are bits of nucleic acid that “escaped” from cellular organisms. According to this view, some viruses may trace their origin to animal cells, others to plant cells, and still others to bacterial cells. Their multiple origins might explain why viruses are species-specific; perhaps they infect only those species that are closely related to the or-

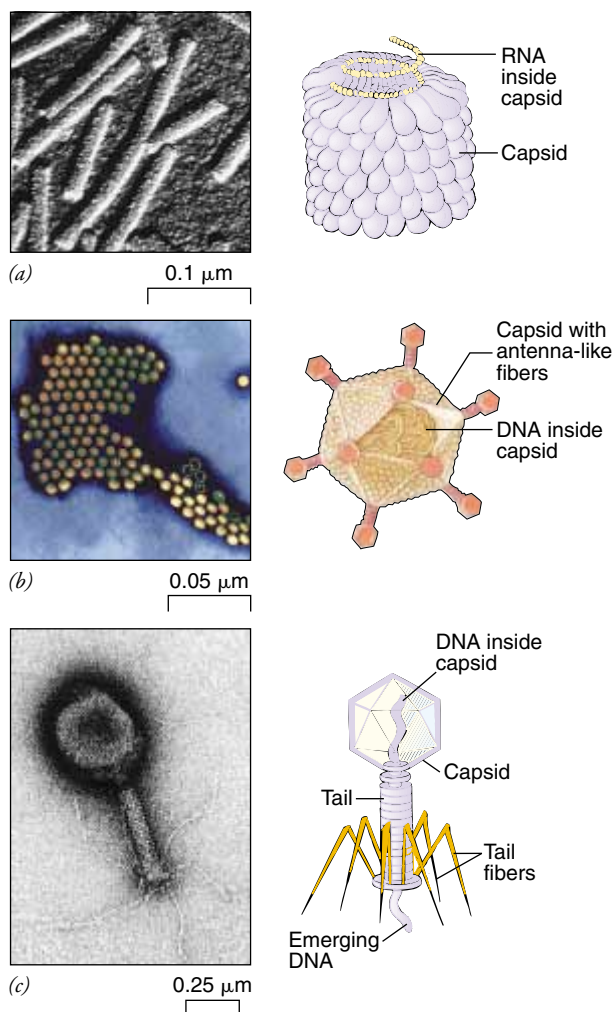

Figure 23-1 Virus structure. Viruses are typically either helical or polyhedral in shape, or a combination of both. (a) TEM of tobacco mosaic virus, which is a helical virus. (b) TEM of adenovirus, which has a polyhedral capsid with projecting protein spikes. (c) TEM of the bacteriophage known as T₄, which has a polyhedral head and a helical tail. (a, Omikron/Science/Photo Researchers, Inc. b, Oliver Meckes/E.O.S./Gelderblum/Photo Researchers, Inc.; c, Lee D. Simon/Science Source/Photo Researchers, Inc.)

ganisms from which they originated. This hypothesis is supported by the genetic similarity between a virus and its host cell—a closer similarity than exists between one virus and another.

Phages are viruses that attack bacteria

Much of our knowledge of viruses has come from studying phages because they can be cultured easily within living bacteria in the laboratory. As mentioned in Chapter 14, biologists use phages in genetic engineering research. Phages are among the most complex viruses (Fig. 23-1c). Their most common structure consists of a long nucleic acid molecule (usually DNA) coiled within a polyhedral head. Many phages have a tail attached to the head. The phage may use fibers extending from the tail to attach to a bacterium.

A lytic reproductive cycle destroys the host cell

A viral reproductive cycle can be lytic or temperate. In a **lytic** cycle, the virus lyses (destroys) the host cell. When the virus infects a susceptible host cell, it forces the host to use its metabolic machinery to replicate viral particles. Viruses that have a lytic cycle are described as **virulent** (lethal).

Five steps are typical in viral reproduction (see Fig. 23-2):

1. **Attachment (or absorption).** The virus attaches to receptors on the host cell wall.
2. **Penetration.** The nucleic acid of the virus moves through the plasma membrane and into the cytoplasm of the host cell. The capsid of a phage remains on the outside. In contrast, many viruses that infect animal cells enter the host cell intact.
3. **Replication.** The viral genome contains all the information necessary to produce new viruses. Once inside, the virus induces the host cell to synthesize the necessary components for its replication.
4. **Assembly.** The newly synthesized viral components are assembled into new viruses.
5. **Release.** Assembled viruses are released from the cell. Generally, lytic enzymes destroy the host cell.

The new viruses infect other cells, and the process begins anew. The time required for viral reproduction from attachment to the bacterium to the release of new viruses is approximately 30 to 35 minutes.

Temperate viruses can integrate their DNA into the host DNA

Temperate viruses do not always destroy their hosts. In a **lysogenic cycle** the viral genome becomes integrated with and is replicated along with the host DNA. In the case of some bacterial viruses, the phage DNA becomes integrated into the host bacterial DNA and is then referred to as a **prophage**. When the bacterial DNA replicates, the prophage also replicates (Fig. 23-3). The viral genes that code for viral structural proteins may be repressed indefinitely. Bacterial cells carrying prophages are called **lysogenic cells**. Certain external conditions (such as ultraviolet light and x rays) can cause temperate viruses to revert to a lytic cycle and then destroy their host. Sometimes temperate viruses become lytic spontaneously.

Bacterial cells containing certain temperate viruses may exhibit new properties. This is called **lysogenic conversion**. An interesting example involves the bacterium (*Corynebacterium diphtheriae*) that causes diphtheria. Two strains of this species exist, one that produces a toxin (and causes diphtheria) and one that does not. The only difference between these two strains is that the toxin-producing bacteria contain a specific temperate phage. The phage DNA codes for the powerful toxin that causes the symptoms of diphtheria. In the same way, the bacterium (*Clostridium botulinum*) that causes botu-

Figure 23–3 Lysogenic cycle. Temperate phages can integrate their nucleic acid into the host cell DNA, making it a lysogenic cell. The sequence of events includes (1) attachment, (2) penetration, (3) integration into bacterial DNA, and (4) replication when the bacterial DNA replicates.

lism (a serious form of food poisoning) is harmless unless it contains certain prophage DNA that induces synthesis of toxin.

Some viruses infect animal cells

Hundreds of different viruses infect humans and other animals. Most viruses cannot survive very long outside a living host cell, so their survival depends on their being transmitted from animal to animal.

The type of attachment proteins on the surface of a virus determines what type of cell it can infect. Some viruses, such as the adenoviruses, have fibers that project from the capsid and are thought to help the virus adhere to complementary receptor sites on the host cell. Other viruses, such as those that cause herpes, influenza, and rabies, are surrounded by a lipoprotein envelope with projecting glycoprotein spikes that aid in attachment to a host cell.

Receptor sites vary with each species and sometimes with each type of tissue. Thus, most human viruses can infect only humans, because their attachment proteins combine only with receptor sites found on human cell surfaces. The measles virus and pox viruses can infect many types of human tissue because their attachment proteins combine with receptor sites on a variety of cells. In contrast, polioviruses attach to specific types of cells, such as those that line the digestive tract.

Figure 23-4 Viruses cause diseases in humans and other animals. (a) Rubella (German measles) is caused by an RNA virus spread by close contact. When contracted during pregnancy, it can cause birth defects. Vaccination has greatly decreased the incidence of this disease. (b) The steps by which some viruses enter animal cells by endocytosis. (a, Centers for Disease Control and Prevention, U.S. Dept. of Health and Human Services)

Viruses have several ways to penetrate animal cells. After attachment to a host-cell receptor, some enveloped viruses fuse with the animal cell's plasma membrane. The viral capsid and nucleic acid are both released into the animal cell. Other viruses enter the host cell by endocytosis. In this process, the plasma membrane of the animal cell invaginates to form a membrane-

bounded vesicle that contains the virus (Fig. 23-4).

Like other viruses, those that infect animal cells multiply and produce new virus particles. During the time that viral nucleic acid is being replicated and viral proteins are being synthesized, the synthesis of host DNA, RNA, and protein may be inhibited.

Animal viruses can contain either DNA or RNA. In DNA viruses, the synthesis of viral DNA and protein is similar to the processes by which the host cell would normally carry out

its own DNA and protein synthesis. In most RNA viruses, transcription takes place with the help of an RNA-dependent RNA polymerase. However, **retroviruses** are RNA viruses that have a DNA polymerase called **reverse transcriptase** used to transcribe the RNA genome into a DNA intermediate (Fig. 23–5). This DNA is integrated into the host DNA by an enzyme also carried by the virus. Copies of the viral RNA are synthesized as the incorporated DNA is transcribed by host polymerases. The human immunodeficiency virus (HIV) that causes AIDS is a retrovirus. Certain cancer-causing viruses are also retroviruses.

After the viral genes are transcribed, the viral structural proteins are synthesized. The capsid is produced, and new virus particles are assembled. Viruses that do not have an outer en-

Figure 23–5 Life cycle of HIV, a retrovirus that attacks cells of the immune system known as helper T cells.

EMERGING VIRUSES

TEM of Ebola virus. (Courtesy of Frederick A. Murphy)

The 1995 Ebola virus outbreak serves as a grim reminder that pathogens can strike quickly and fatally. According to the U. S. Centers for Disease Control and Prevention, more than 200 new, continual, or reemerging pathogens have the potential to strike globally. Historically, new viral strains have claimed many human lives. For example, in 1918 an influenza epidemic killed more than 20 million people. Even at the level of our current knowledge about viruses and epidemiology, just how well could we contain a particularly virulent virus? How well are we containing HIV (the virus that causes AIDS), which claims more than two million lives each year?

Let us consider the deadly Ebola virus as an example of an emerging virus. In 1995 an outbreak of the Ebola virus occurred in Zaire, a country in Central Africa. Named after a river in Zaire, Ebola is an elongated, single-stranded RNA virus that causes a fatal disease. Within about three days of infection, victims develop a fever and weakness, followed by a rash and vomiting. The victim hemorrhages internally, and bleeds from the mouth, eyes, ears, and other body openings. Internal organs shut down, and 50% to 90% of victims die within about two weeks after infection.

Because early symptoms of Ebola resemble those of influenza or dysentery, health care workers did not immediately recognize the danger in the 1995 outbreak. When they became suspicious, blood samples from 16 patients were flown to the U. S. Centers for Disease Control and Prevention in Atlanta. Within 36 hours the Ebola virus was identified in blood from 14 of the 16 patients.

As soon as Ebola was identified in the 1995 outbreak, global health care teams, including epidemiologists, were sent into Central Africa to prevent its spread. Health officials confirmed that, like HIV (the virus that causes AIDS), Ebola is not spread by casual contact, but by direct contact with infected body fluids. Because victims of Ebola hemorrhage, infected blood appears to be the principal method of transmission. Infection-control methods, such as using gloves, gowns, and masks, were implemented. Patients were quarantined, and travel out of the infected area was monitored. Global cooperation and rapid response successfully contained the 1995 Ebola outbreak.

An important aspect of understanding an infectious agent is identifying *patient zero*, the first patient who contracted the virus. If the origin of the epidemic can be found, investigators might be able to trace where the virus came from and how it infects humans. Ebola is known to infect chimpanzees, but because they die quickly they are not thought to be the reservoir species. However, some other primate host might be the reservoir that would allow the virus to maintain itself indefinitely. Researchers continue to search for clues to the origin of Ebola and are working on the development of effective antiviral drugs and vaccines.

Ebola outbreaks have occurred several times during the past few decades. The virus was first identified in 1976 in Zaire and Sudan (outbreaks that killed more than 400 people). Between outbreaks the virus remains hidden. Like many other RNA viruses, Ebola makes frequent mistakes when it duplicates its RNA. This leads to a high mutation rate and thus to the rapid evolution of new strains.

Human activity, including social factors, such as urbanization and global travel, contributes to epidemics of infectious disease. For example, as human populations concentrate in cities, large numbers of people are in close contact, permitting rapid spread of viruses. Living conditions, including sanitation, nutrition, physical stress, level of health care, and sexual practices, are important factors in the spread of disease. In the United States and other developed countries, infectious disease accounts for about 4% to 8% of deaths compared to death rates of 30% to 50% in developing regions.

Changing natural habitats can create the conditions necessary for new pathogens to emerge. For example, cutting down forests can bring disease-carrying insects into contact with humans. Sometimes, even naturally occurring ecological changes can spawn outbreaks of disease. The 1993 outbreak of hantavirus in the Southwestern U.S. killed more than 50 persons. A mild winter coupled with heavy rainfall resulted in a large crop of seeds, which supported a population explosion of field mice. The mice carry the virus. Lessons learned from dealing with emerging viruses and the resurgence of old ones will help us contain future epidemics, but much more research is needed.

velope exit by cell lysis. The plasma membrane ruptures, releasing many new viral particles. Enveloped viruses receive their lipoprotein envelopes as they leave the infected cell.

Viral proteins damage the host cell in a variety of ways. These proteins may alter the permeability of the plasma membrane or may inhibit synthesis of host nucleic acids or proteins. Viruses sometimes damage or kill their host cells by their sheer numbers. A poliovirus may produce 100,000 new viruses within a single host cell!

Most of us suffer from two to six viral infections each year, including common colds. Other human diseases caused by viruses include chickenpox, herpes simplex (one type causes genital herpes), mumps, rubella (German measles), rubeola (measles), rabies, warts, infectious mononucleosis, influenza, hepatitis, and AIDS (Table 23–1 and *Focus On: Emerging Viruses*). Animal viruses cause hog cholera, foot-and-mouth disease, canine distemper, swine influenza, and certain types of cancer (for example, feline leukemia).

TABLE 23 – 1 Animal Viruses

Group	Diseases Caused	Characteristics
DNA Viruses		
Poxviruses	Smallpox, cowpox, and economically important diseases of domestic fowl	Large, complex double-stranded DNA; replicate in the cytoplasm of the host cell. The vaccinia (cowpox) virus is used to produce genetically engineered vaccines
Herpesviruses	Herpes simplex type 1 (cold sores); herpes simplex type 2 (genital herpes, a sexually transmitted disease); varicella-zoster (chickenpox and shingles); the Epstein–Barr virus causes infectious mononucleosis and Burkitt’s lymphoma	Medium to large, enveloped viruses; double-stranded DNA; replicate in host nucleus; frequently cause latent infections; some cause tumors
Adenoviruses	About 40 types known to infect human respiratory and intestinal tracts; common cause of sore throat, tonsillitis, and conjunctivitis; other varieties infect other animals	Double-stranded DNA; replicates in host nucleus
Papovaviruses	Human warts and some degenerative brain diseases; some cancers	Double-stranded DNA; the virus SV40 has been used as a vector to transport genes into cells
Parvoviruses	Infections in dogs, swine, arthropods, rodents; cause gastroenteritis in humans after eating infected shellfish	Single-stranded DNA; some require a helper virus in order to multiply
RNA Viruses		
Picornaviruses	About 70 types infect humans, including polioviruses; hepatitis A virus; enteroviruses infect intestine; rhinoviruses infect respiratory tract and are main cause of human colds; coxsackievirus and echovirus cause aseptic meningitis	Diverse group of small viruses; single-stranded RNA that can serve as mRNA
Togaviruses	Rubella	Large, diverse group of medium-sized, enveloped viruses; single-stranded RNA that can serve as mRNA; many transmitted by arthropods
Orthomyxoviruses	Influenza in humans and other animals	Medium-sized viruses that often exhibit projecting spikes; single-stranded RNA that serves as template for mRNA synthesis
Paramyxoviruses	Rubeola (measles); mumps; distemper in dogs	Resemble orthomyxoviruses but somewhat larger
Rhabdoviruses	Rabies	Single-stranded RNA
Reoviruses	Vomiting and diarrhea; encephalitis	Double-stranded RNA; no envelope
Retroviruses	AIDS; some types of cancer	RNA viruses that contain reverse transcriptase for transcribing the RNA genome into DNA; two identical molecules of single-stranded RNA
Flavivirus	Yellow fever	Single-stranded RNA
Filoviruses	Cause hemorrhagic fever; Ebola virus in this group	Single-stranded RNA
Bunyaviruses	St. Louis encephalitis	Single-stranded RNA

Viruses can infect plant cells

Viral diseases can be spread among plants by insects such as aphids and leafhoppers as they feed on plant tissues. Plant viruses can also be inherited by way of infected seeds or by asexual propagation. Once a plant is infected, the virus spreads through the plant body by passing through plasmodesmata (cytoplasmic connections) that penetrate the walls between adja-

cent cells (see Fig. 5–23). The genome of most plant viruses consists of RNA.

Symptoms of viral infection include reduced plant size, and spots, streaks, or mottled patterns on leaves, flowers, or fruits (Fig. 23–6). Infected crops almost always produce lower yields. Cures are not known for most viral diseases of plants, and so it is common to burn plants that have been infected.

(a)

(b)

Figure 23–6 Plant viruses.

(a) Virus-streaked tulips. The virus that causes this relatively harmless disease affects pigment formation in the petals. (b) Pepper leaves infected with tobacco mosaic virus. The leaf is characteristically mottled with light green areas. (a, Kenneth M. Corbett; b, Jack M. Bostrack/Visuals Unlimited)

Some agricultural scientists are focusing their efforts on prevention of viral disease by developing virus-resistant strains of important crop plants.

VIROIDS AND PRIONS ARE SMALLER THAN VIRUSES

The discovery of infective agents even smaller than viruses has challenged old ideas. Until **viroids** were studied, most biologists assumed that protein was necessary for an infectious agent to duplicate itself. However, no proteins are associated with viroids, and evidence suggests that the viroid genome does not code for any proteins. Each viroid consists of a very short strand of RNA (only 250–400 nucleotides) with no protective coat. Viroids are copied by host RNA polymerases; the viroid is used as a template. Viroids cause a variety of plant diseases and may also infect animals. These infective agents are generally found within the host cell nucleus and may interfere with gene regulation.

Even more heretical is the idea that a pathogen could exist and transfer information without nucleic acids. The **prion**, a protein-like infectious particle, has been linked to a group of fatal degenerative brain diseases. These diseases are called transmissible spongiform encephalopathies (TSEs) because the infected brain appears to develop holes, becoming somewhat spongelike. One of the most studied prion diseases is scrapie in sheep and goats. When infected, animals lose coordination, become irritable, and itch so severely that they scrape off their wool or hair.

A disease similar to scrapie became epidemic in cows in the United Kingdom in the 1990s. More than 160,000 cases of bovine spongiform encephalopathy (referred to as “mad cow disease”) were documented, and almost 1 million cattle were estimated to be infected. This outbreak led to a ban on the export and consumption of British cattle. Scientists hypothesized that the cattle became infected when they ate feed that had been mixed with sheep offal—brains and other organs—containing prions. In the spring of 1996, at least ten people died of what appeared to be a human variety of the cow disease, providing evidence that the disease is transmissible from cow to human. This disease, referred to as variant Creutzfeldt-Jakob disease (vCJD), appears to be related to a more common genetic type of CJD.

In 1997 Stanley Prusiner, professor of neurology and biochemistry at the University of California School of Medicine, San Francisco, won the Nobel Prize in Physiology or Medicine “for his discovery of prions—a new biological principle of infection.” Prusiner began his studies of prions in the early 1970s, motivated by the death of a patient from CJD. He found that the infective agent was not affected by radiation (which typically mutates nucleic acids), and he could not find DNA or RNA in the particles. In 1982 he named the infective agent *prion* for “proteinaceous infectious particle.” Researchers have determined the structure of the prion protein, which consists of 208 amino acids. Despite extensive searching by many investigators, no nucleic acid component has been found.

Because nucleic acids are the molecules replicated during cell division and reproduction, how prions reproduce has been of great biological interest. Prusiner and other researchers have

shown that mammals have a gene that codes the prion protein. Although its function is not known, this protein is normally harmless. The prion protein sometimes converts to a different shape, an insoluble variant that accumulates in the brains of patients with TSE. Genetically engineered mice that lack the prion protein gene are immune to TSE infection.

According to Prusiner, mutations in the prion protein gene increase the risk of the protein changing shape. The prion protein changes shape by a posttranslational process that involves refolding of the molecule. Twenty different mutations in the prion gene have been identified that have been linked with inherited prion diseases. Prusiner has genetically engineered mice that produce the mutant prion protein found in humans with inherited TSE. These mice develop TSE.

Many biologists remain skeptical about prions. Some think that eventually a viral component will still be discovered. Investigators agree that proving the prion theory will require production of insoluble prion protein in a nonbiological system in order to ensure no viral contamination. Researchers would then need to demonstrate that the prion protein causes TSE.

BACTERIA ARE PROKARYOTES

Thousands of species of bacteria have been described. In contrast to viruses, which consist only of nucleic acid and protein, **bacteria** are cellular organisms. Bacteria are prokaryotes, and their cell structure is fundamentally different from the cells of other living organisms. For this reason some biologists have assigned them to their own kingdoms: Archaeobacteria and Eubacteria. Other biologists, including most microbiologists, prefer to assign the bacteria to two domains: Archaea and Eubacteria.

Most bacterial cells are very small. Typically, their diameter ranges from 0.5 to 1.0 micrometer. Their cell volume is only about one-thousandth that of small eukaryotic cells, and their length is only about one-tenth. Most prokaryotes are unicellular, but some form colonies or filaments containing specialized cells.

Epulopiscium fishelsoni is an exception to the generalization that all bacteria are microscopic. This bacterium lives as a symbiont in the intestine of surgeonfish (Fig. 23–7). About 600 micrometers long and 80 micrometers wide, its volume is about a million times larger than that of a typical bacterium.

Bacteria have several common shapes

Although many species have irregular shapes, three common shapes are spherical, rod-shaped, and spiral (Fig. 23–8). Spherical bacteria, known as **cocci** (sing., *coccus*), occur singly in some species and in groups of independent cells in others. Cells may be grouped in twos (diplococci), in long chains (streptococci), or in irregular clumps that look like bunches of grapes (staphylococci). Rod-shaped bacteria, called **bacilli** (sing., *bacillus*), may occur as single rods or as long chains of rods. Some bacteria are helical. A bacterium shaped like a very short helix is called a **vibrio**. One that is a longer helix is known as a **spirillum** (plur., *spirilla*) if rigid, and as a **spirochete** if flexible. Shape is an important criterion in identifying bacterial species.

Prokaryotic cells lack membrane-bounded organelles

Recall that prokaryotic cells do not have membrane-bounded organelles typical of eukaryotic cells. Thus, bacterial cells do not have nuclei, mitochondria, chloroplasts, endoplasmic retic-

Figure 23–7 The giant bacterium (*Epulopiscium*). This bacterium, about a million times larger than a typical bacterium, is shown here with four paramecia (which are eukaryotes). (Esther R. Angert and Norman R. Pace, Indiana University)

Figure 23-8 Common shapes of bacteria. (a) SEM of *Micrococcus*, cocci bacteria. (b) SEM of *Salmonella*, bacilli bacteria. (c) SEM of *Spiroplasma*, spirilla bacteria. (Visuals Unlimited/David M. Phillips)

ula, Golgi complexes, or lysosomes (Fig. 23-9). The dense cytoplasm of the bacterial cell contains ribosomes and storage granules that hold glycogen, lipid, or phosphate compounds. Enzymes needed for metabolic activities may be located in the cytoplasm. Although the membranous organelles of eukaryotic cells are absent, in some bacterial cells the plasma membrane is extensively folded inward. Enzymes needed for cellular respiration and photosynthesis may be associated with the plasma membrane or its folds.

A cell wall typically covers the cell surface

Most prokaryotic cells have a cell wall surrounding the plasma membrane. The cell wall provides a rigid framework that supports the cell, maintains its shape, and keeps it from bursting under hypotonic conditions (see Chapter 5). Most bacteria seem to be adapted to hypotonic surroundings. When wall-less forms of bacteria are produced experimentally, they must be maintained in isotonic solutions to keep them from bursting. However, cell walls are of little help when a bacterium is in a hypertonic environment, as found in food preserved by means of a high sugar or salt content. That is why most bacteria grow poorly in jellies, jams, salted fish, and other foods preserved in these ways.

Bacteria were once classified with plants because they have cell walls. However, eukaryotic cell walls are homoplastic, not homologous, to bacterial cell walls; their structure and composition are different. Unlike plant cell walls, the bacterial cell wall is not made of cellulose. The eubacterial cell wall is composed of **peptidoglycan**, a complex polymer that consists of two unusual types of sugars (amino sugars) linked with short polypeptides. The sugars and peptides are linked to form a single macromolecule that surrounds the entire plasma membrane. The cell wall structure varies among species.

Differences in bacterial cell wall composition are of great

interest to microbiologists and are important clinically. In 1888 the Danish physician Christian Gram developed the Gram staining procedure. Bacteria that absorb and retain crystal violet stain in the laboratory are referred to as **gram-positive**,

Figure 23-9 Bacteria are prokaryotic cells. This bacillus is a gram-negative bacterium (discussed in text). Note the absence of a nuclear envelope surrounding the bacterial DNA.

(a) Gram-positive cell wall

(b) Gram-negative cell wall

Figure 23–10 Bacterial cell walls.

(a) In the gram-positive cell wall, many layers of peptidoglycan are held together by amino acids. (b) In the gram-negative cell wall, a thin peptidoglycan layer is covered by a thick outer membrane.

whereas those that do not retain the stain when rinsed with alcohol are **gram-negative**. The cell walls of gram-positive bacteria are very thick and consist primarily of peptidoglycan. The cell walls of gram-negative bacteria consist of two layers, a thin peptidoglycan wall and a thick outer membrane. The outer membrane resembles the plasma membrane but contains polysaccharides bonded to lipids (Fig. 23-10).

Distinguishing between gram-positive and gram-negative bacteria is important in treating certain diseases. For example, the antibiotic penicillin interferes with peptidoglycan synthesis, ultimately resulting in a fragile cell wall that cannot protect the cell (see Chapter 6). Predictably, penicillin works most effectively against gram-positive bacteria.

Some species of bacteria produce a **capsule** or slime layer that surrounds the cell wall. In free-living species, the capsule may provide the cell with added protection against phagocytosis (engulfment; see Chapter 5) by other microorganisms. In disease-causing bacteria, the capsule may protect against phagocytosis by the host's white blood cells. For example, the ability of *Streptococcus pneumoniae* to cause bacterial pneumonia depends on its capsule. A strain of *S. pneumoniae* that lacks a capsule does not cause the disease. Bacteria also use their capsules to attach to surfaces such as rocks, plant roots, or human teeth (where they cause dental plaque).

Some bacteria have hundreds of hairlike appendages known as **pili** (sing., *pilus*). These protein structures are organelles of attachment that help bacteria adhere to one another or to certain surfaces, such as the cells they infect. Some pili are involved in the transmission of DNA between bacteria.

Many types of bacteria are motile

Can you imagine trying to swim through molasses? Water has the same relative viscosity to bacteria that molasses has to humans. Most motile bacteria move by means of rotating **flagella**. The number and location of flagella are important in classification of some bacterial species.

Prokaryotic flagella are quite different than eukaryotic flagella (see Chapter 4). The bacterial flagellum is not composed of microtubules. It consists of three parts: a basal body, a hook, and a single filament (Fig. 23–11). The basal body is a complex structure that anchors the flagellum into the cell wall by disc-shaped plates. The curved hook connects the basal body to the long, hollow filament that extends into the outside environment. The basal body is a motor. The bacterium uses energy from ATP to pump protons out of the cell. Diffusion of these protons back into the cell powers the motor that spins the flagellum like a propeller. Thus, the flagellum produces a rotary motion that pushes the cell much as a propeller pushes a ship through the water.

Bacteria have a single DNA molecule

The genetic material of a bacterium lies in the cytoplasm and is not surrounded by a nuclear envelope. It is contained in a single, circular DNA molecule. If stretched out to its full length, this molecule would be about 1000 times longer than the cell itself. Unlike eukaryotic chromosomes, the bacterial DNA has little protein associated with it.

Figure 23-11 Bacterial flagella. (a) Phase contrast LM of *Lophotrichous spirillum*, a bacterium with a tuft of flagella at one end of the cell. (b) Structure of a bacterial flagellum. The bacterium uses energy from ATP to pump protons out of the cell. Diffusion of these protons into the cell powers the protein motor that spins the flagellum like a propeller. The motor consists of a series of protein rings that (1) anchor the flagellum to the cell wall and plasma membrane and (2) spin the hook and filament of the flagellum. (a, E.C.S. Chan/Visuals Unlimited)

In addition to the genomic DNA, a small amount of genetic information may be present as **plasmids**, smaller circular fragments of DNA. Plasmids can replicate independently of the genomic DNA (see Chapter 14). Bacterial plasmids often have genes that code for catabolic enzymes, for genetic exchange, or for resistance to antibiotics.

Bacteria reproduce by binary fission

Bacteria reproduce asexually, generally by **binary fission**, a process in which one cell divides into two similar cells (see chapter opener). First the circular bacterial DNA replicates, and then a transverse wall is formed by an ingrowth of both the plasma membrane and the cell wall.

Binary fission occurs with remarkable speed; under ideal conditions some bacterial species divide in less than 20 minutes. At this rate, if nothing interfered, one bacterium would give rise to more than 1 billion bacteria within 10 hours! However, bacteria cannot reproduce at this rate for very long because their growth is eventually affected by lack of food or by the accumulation of waste products.

Bacteria can also reproduce asexually by budding or fragmentation. In **budding** a cell develops a bulge, or bud, that enlarges, matures, and eventually separates from the mother cell. In **fragmentation** walls develop within the cell, which then separates into several new cells.

Although sexual reproduction involving the fusion of gametes does not occur in bacteria, genetic material is sometimes exchanged between individuals. This exchange takes place by three different mechanisms: transformation, transduction, and conjugation.

1. In **transformation**, fragments of DNA released by a cell are taken in by another bacterial cell. Recall that this mechanism was used experimentally to demonstrate that genes can be transferred from one bacterium to another and that DNA is the chemical basis of heredity (see Chapter 11).
2. In the second process of gene transfer, **transduction**, a phage carries bacterial genes from one bacterial cell into another (Fig. 23-12).
3. In **conjugation**, two cells of different mating types come together, and genetic material is transferred from one to the other (Fig. 23-13). In contrast to transformation and transduction, conjugation involves contact between two cells.

Conjugation has been most extensively studied in the bacterium *Escherichia coli*. In the *E. coli* population there are donor cells (sometimes referred to as male cells) that have plasmids that can be transmitted to recipient (female) cells. A pilus on the donor cell recognizes the recipient cell and makes the first contact. A cytoplasmic bridge forms between the two cells, and DNA is transferred from donor to recipient cell.

Some bacteria form endospores

When the environment becomes unfavorable, such as when it gets very dry, the cells of some bacteria become dormant. Cells lose water, shrink slightly, and remain inactive until water is again available. Some other bacteria form dormant, extremely durable cells called **endospores**. After the endospore forms, the cell wall of the original cell lyses, releasing the endospore. Endospores can survive in very dry, hot, or frozen environments, or when food is scarce (Fig. 23-14). Some endospores

Figure 23–12 Transduction. In this process, a phage transfers bacterial DNA from one bacterium to another.

are so resistant that they can survive an hour or more of boiling, or centuries of freezing. When environmental conditions are again suitable for growth, the endospore germinates, forming an active, growing bacterial cell.

Endospores are not comparable to the reproductive spores of fungi and plants, and endospore formation is not really a kind of reproduction in bacteria. Only one endospore is formed per original cell, so the total number of individuals does not increase.

Figure 23–13 Conjugation. SEM of *Serratia marcescens* bacteria, which are connected by a pilus. Plasmid DNA is transferred through cytoplasmic bridges (not shown). (Manfred Kage/Peter Arnold, Inc.)

Figure 23–14 Endospores. Colorized TEM of *Clostridium tetani*, the bacterium that causes tetanus. Each bacterial cell contains one endospore, a resistant, dehydrated cell that develops within the original cell. (Alfred Pasiaka/Peter Arnold, Inc.)

Metabolic diversity is evident among bacteria

A bacterial cell contains about 5000 different kinds of molecules. The functions of these molecules, how they interact, and how the bacterium synthesizes them from the nutrients it takes in are complex biochemical problems that have interested researchers for years. Much of the knowledge gained from studying these mechanisms in bacterial cells has been successfully applied to cells of humans and other organisms. The basic biochemical processes of all organisms are surprisingly similar.

Bacteria are either heterotrophs or autotrophs. Most bacteria are **heterotrophs** that must obtain organic compounds from other organisms. The majority of these heterotrophic bacteria are free-living **saprobies** (also called **saprotrophs**), organisms that get their nourishment from dead organic matter. Other heterotrophic bacteria obtain their nourishment from living organisms, in some cases harming them by causing diseases, and in other cases actually providing a beneficial service for their host. In fact, survival of most animals, including humans, depends on the microorganisms that inhabit them.

Autotrophic bacteria are either photosynthetic or chemosynthetic and are able to manufacture their own organic molecules from simple raw materials. **Photosynthetic autotrophs**, or simply **photoautotrophs**, obtain their energy from light. Chemosynthetic autotrophs, or **chemoautotrophs**, obtain energy by oxidizing inorganic chemicals.

Whether they are heterotrophs or autotrophs, most bacterial cells are **aerobic** (like animal and plant cells), requiring atmospheric oxygen for cellular respiration. Some bacteria are **facultative anaerobes**, meaning that they can use oxygen for cellular respiration if it is available but can also carry on metabolism anaerobically when necessary. Other bacteria are **obligate anaerobes** that can carry on energy-yielding metabolism only anaerobically. Certain obligate anaerobes are actually killed by even low concentrations of oxygen. Some bacteria respire with terminal electron acceptors other than oxygen, for example, sulfate (SO_4^{2-}), nitrate (NO_3^-), or iron (Fe^{2+}).

ARCHAEA AND EUBACTERIA ARE FUNDAMENTALLY DISTINCT

Under a microscope, most bacteria appear similar in size and form. However, evidence from molecular biology, particularly differences in ribosomal RNA, has led microbiologists to conclude that ancient prokaryotes split into two lineages early in the history of life. Microbiologists classify the modern descendants of these two ancient lines in two domains: the **Archaea**, which include a group of prokaryotes that produce methane gas from simple carbon sources and two groups that live in extreme environments, and the **Eubacteria**, also called **Bacteria**, which comprise all other prokaryotes (Fig. 23–15). The Eubacteria include the bacteria most familiar to biologists, whereas the Archaea are less familiar. In this system, eukaryotes are classified in domain Eukarya.

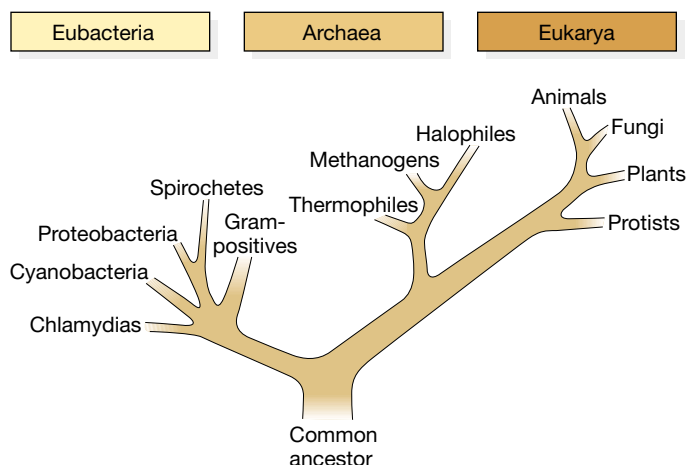

Figure 23–15 Three domains. Representative groups of each domain are shown. Gram-positive bacteria include actinomycetes, lactic acid bacteria, mycobacteria, streptococci, staphylococci, and clostridia. Spirochetes, proteobacteria, and chlamydias are gram-negative bacteria.

One of the most distinguishing features of the Archaea is the absence of peptidoglycan in their cell walls (Table 23–2). The lipids in their plasma membranes differ somewhat in structure (ether-linked rather than ester-linked) from those of Eubacteria and Eukarya. In some ways, the Archaea are more like the eukaryotes than the Eubacteria. Archaea do not have the simple RNA polymerase found in Eubacteria. Like eukaryotes, their transcription process is not sensitive to the antibiotic rifamycin. This antibiotic specifically inhibits the type

TABLE 23–2 Characteristics of the Three Domains

Characteristic	Eubacteria	Archaea	Eukarya
Peptidoglycan in cell wall	Present	Absent	Absent
Nuclear envelope	Absent	Absent	Present
Membrane-bounded organelles	Absent	Absent	Present
Simple RNA polymerase	Present	Absent	Absent
70S ribosomes*	Present	Present	Absent
Flagellum (if present) has single filament	Yes	Yes	No
Transcription is sensitive to the antibiotic rifamycin	Yes	No	No

*The number 70S refers to the sedimentation coefficient (a measure of relative size) when centrifuged.

of RNA polymerase found in Eubacteria. The translational mechanisms of archaeobacteria are also more like those of eukaryotes.

More than 1220 genera and 4000 species of prokaryotes have been classified. The editors of *Bergey's Manual of Determinative Bacteriology*¹, considered the definitive reference text by microbiologists, have divided prokaryotes into several groups based on their ribosomal RNA. Each group has distinctive nucleotide sequences in their ribosomal RNA. These sequences are known as **signature sequences**. Several representative groups of prokaryotes are described in Table 23–3.

The Archaea include methanogens, extreme halophiles, and extreme thermophiles

Many extant members of the Archaea survive in environments that are similar to conditions on early Earth. The **methanogens** are a large, diverse group that inhabit oxygen-free environments in sewage and swamps and are common in the digestive tracts of humans and other animals. They are strict anaerobes that produce methane gas from simple carbon compounds. The methanogens are important in recycling components of organic products of organisms that inhabit swamps.

Extreme halophiles are heterotrophs that live in saturated brine solutions such as salt ponds (Fig. 23–16). Some extreme halophiles capture the energy of sunlight with a purple pigment (bacteriorhodopsin) that is very similar to the pigment rhodopsin involved in animal vision. The process is different from photosynthesis carried out by plants or cyanobacteria (see Table 23–3).

Extreme thermophiles normally grow in hot (45°–110°C), sometimes acidic, environments. One species is found in the hot sulfur springs of Yellowstone Park at temperatures near 60°C and pH values of 1 to 2 (the pH of concentrated sulfuric acid). Others inhabit volcanic areas under the sea. One species, found in hot deep-sea vents on the sea floor, lives at temperatures from 80° to 110°C.

Eubacteria are the most familiar prokaryotes

The Eubacteria are widely distributed in the environment and are better known to microbiologists than the Archaea. Several groups of eubacteria are described in Table 23–3.

Bacteria are of great ecological importance

Bacteria are vital members of the biosphere. These microorganisms, especially actinomycetes and the myxobacteria, are the most numerous inhabitants of soil. As described in the

Figure 23–16 Extreme halophiles. These members of the Archaea thrive in salty environments. Seawater evaporating ponds near San Francisco Bay are colored pink, orange, and yellow from the large number of extreme halophiles that inhabit them. The salt that remains after the water has evaporated has commercial value. (Helen E. Carr, Biological Photo Service)

chapter introduction, bacteria are essential as decomposers and in recycling nutrients, including nitrogen, oxygen, carbon, phosphorus, sulfur, and many trace elements. (A discussion of the roles of bacteria in biogeochemical cycles is found in Chapter 53.)

Because nitrogen is constantly removed from the soil by plants and other natural processes, as well as by human activity, it must be continually added to the soil. Plant growth depends on the availability of usable nitrogen. Several types of bacteria transform atmospheric nitrogen to forms that can be used by plants (Fig. 23–17; also see *Making the Connection: Bacteria, Nitrogen Fixation, and Agriculture on page 500*).

Bacterial photosynthesis is ecologically very important, accounting for up to half of primary production in aquatic habitats. Like algae and plant cells, cyanobacteria carry out photosynthesis, using water as the electron source and generating oxygen. Other photosynthetic bacteria use compounds other than water, for example, hydrogen sulfide, as the electron source and do not produce oxygen.

¹*Bergey's Manual of Determinative Bacteriology*, 9th ed., Williams & Wilkins, Baltimore, Philadelphia, 1994.

Figure 23–17 LM of *Anabaena*, a cyanobacterium that fixes nitrogen. Nitrogen fixation takes place in the rounded cells, called heterocysts. (Dennis Drenner)

Some bacteria cause disease

A small percentage of bacterial species are important pathogens of plants and animals (Fig. 23–18). Other bacterial species have evolved along with eukaryotes and are interdependent

with them. All plants and animals harbor a population of microorganisms that are considered normal microbiota—harmless symbiotic bacteria. In fact, the number of bacteria that normally inhabit the human body (approximately 700 trillion cells) exceeds the number of its own human cells (about 70 trillion cells). The presence of some of these bacterial populations prevents harmful microorganisms (including other bacteria) from flourishing. Some of the normal bacterial (and viral) inhabitants are opportunistic pathogens that can cause disease only under certain conditions. For example, if one's immune system is compromised, opportunistic bacteria may increase in number and cause disease.

Pathogenic microorganisms can enter the body in food, dust, droplets, or through wounds. Many diseases are transmitted by insect or animal bites. In order to cause disease, a pathogen must adhere to a specific cell type, multiply, and produce toxic substances. Adherence and multiplication can occur only when the pathogen competes successfully with the normal microbiota and counteracts the host's defenses against invasion.

Pathogens produce a variety of substances that increase their success. Some bacteria produce **exotoxins**, strong poisons that either are secreted from the cell or leak out when the bacterial cell is destroyed. The toxin, not the presence of the bacteria themselves, is responsible for the disease. As mentioned previously, diphtheria is caused by a gram-positive bacillus that is lysogenized by a phage. The diphtheria toxin kills cells and causes inflammation.

Figure 23–18 Pathogenic bacteria. SEM of pus containing *Neisseria gonorrhoea* (small pink spheres), the bacteria that cause gonorrhea, a common sexually transmitted disease. The larger cells are white blood cells. (M.I. Walker/Science Source/Photo Researchers, Inc.)

TABLE 23 – 3 Some Major Groups of Bacteria

Eubacteria with Gram-Negative Cell Walls

Proteobacteria A large, very diverse group.

10.0 μm

SEM of *Escherichia coli* colony. (David Scharf/Peter Arnold, Inc.)

Enterobacteria include decomposers that live on decaying plant matter, pathogens, and a variety of bacteria that inhabit humans. *Escherichia coli* inhabits the intestinal tracts of humans and other animals as part of the normal microbial population; however, certain strains can cause moderate to severe diarrhea. For example, in 1993 almost 500 people developed bloody diarrhea and three people died in the Pacific Northwest after ingesting hamburger meat contaminated with a new strain of *E. coli*. One species of *Salmonella* infects food and produces a toxin that causes a form of food poisoning; another species causes typhoid fever.

Vibrios are mainly marine; some are bioluminescent. One species is the causative agent of cholera.

Rhizobium species live symbiotically in root nodules of leguminous plants convert atmospheric nitrogen to a form usable by plants (nitrogen fixation).

Pseudomonads are heterotrophs that produce nonphotosynthetic pigments. They cause disease in plants and animals, including humans.

Azotobacteria inhabit the soil and fix nitrogen under aerobic conditions. They form a resting cell termed a cyst that is resistant to drying.

Rickettsias are very small, rod-shaped bacteria. A few species are pathogenic to humans and other animals and are transmitted by arthropods through bites or contact with their excretions. Among these are typhus (transmitted by fleas and lice) and Rocky Mountain spotted fever (transmitted by ticks).

Myxobacteria (slime bacteria) secrete slime and glide or creep along. When nutrients are exhausted, these bacteria form masses that develop into stalked, multicellular reproductive structures called fruiting bodies. During this process, bacterial cells within the fruiting body enter a resting stage equivalent to spores. When conditions are favorable, the spores break open and the resting cells become active.

Other medically important Proteobacteria include *Neisseria gonorrhoeae*, which causes gonorrhea, and *Legionella pneumophila*, which causes Legionnaires' disease.

10 μm

SEM of fruiting body of the myxobacterium *Stigmatella aurantiaca*. Protective resting cells form within the fruiting bodies that are very resistant to heat and drying. (From Grilicone, P. L., and Pangborn, J., Journal of Bacteriology 124:1558, 1975)

Other Gram-Negative Eubacterial Groups

5 μm

TEM of *Chlamydia trachomatis* in oviduct cell. (David M. Phillips/Visuals Unlimited)

Chlamydias lack peptidoglycan in their cell walls and do not depend on arthropod vectors for transmission. Although they do contain many enzymes and can carry on some metabolic processes, chlamydias are energy parasites, that is, completely dependent on their host for ATP. Chlamydias infect almost every species of bird and mammal. Perhaps 10% to 20% of the human population of the world is infected. Trachoma, the leading cause of blindness in the world, is caused by a strain of *Chlamydia*; sexually transmitted chlamydias are a major cause of pelvic inflammatory disease (PID) in women.

Spirochetes are spiral-shaped bacteria with flexible cell walls. They move by means of unique internal flagella called axial filaments. Some species are free-living and inhabit freshwater and marine habitats, whereas other species form symbiotic associations; a few are parasitic. The spirochete of greatest medical importance is *Treponema pallidum*, which causes syphilis. Lyme disease, a tick-borne disease of humans and some other animals, is caused by a spirochete belonging to the genus *Borrelia*.

Cyanobacteria, formerly known as blue-green algae, are gram-negative, photosynthetic bacteria that inhabit ponds, lakes, swimming pools, moist soil, dead logs, and the bark of trees. They contain chlorophyll *a* and use a photosynthetic process similar to that of plants and algae. The chloroplasts in algae and plants probably evolved from that of ancient cyanobacteria. Many species also fix nitrogen.

5 μm

LM of *Treponema pallidum*, the spirochete that causes syphilis. (Charles W. Stratton/Visuals Unlimited/Science VU)

TABLE 23 – 3 Continued

Eubacteria with Gram-Positive Cell Walls5 μm

SEM of *Actinomyces naeslundii*, a soil-dwelling bacterium, forms filamentous colonies. (David M. Phillips/Visuals Unlimited)

Actinomycetes superficially resemble fungi in that their cells remain together, forming branching filaments, and many produce moldlike spores. However, they have peptidoglycan in their cell walls, lack nuclear envelopes, and have other prokaryotic characteristics. Actinomycetes decompose organic materials in soil. Most members of this group are saprobes, and some are anaerobic. Several species of the genus *Streptomyces* produce antibiotics such as streptomycin, erythromycin, chloramphenicol, and the tetracyclines. In fact, most known antibiotics are derived from actinomycetes. Some actinomycetes cause serious lung disease or generalized infections in humans and other animals.

Lactic acid bacteria ferment sugar, producing lactic acid as the main end-product. They inhabit decomposing plant material, milk, and other dairy products. The characteristic taste of yogurt, acidophilus milk, pickles, sauerkraut, and green olives is due to the action of lactic acid bacteria. They are also among the normal inhabitants of the human mouth and vagina.

Mycobacteria are slender, irregular rods. They contain a waxy substance in their cell walls. One species causes tuberculosis; another causes leprosy.

Streptococci inhabit the mouth and digestive tract of humans and some other animals. Among the harmful species are those that cause “strep throat,” dental caries, a form of pneumonia, scarlet fever, and rheumatic fever.

Staphylococci normally live in the nose and on the skin. They are opportunistic pathogens that cause disease when the immunity of the host is lowered. *Staphylococcus aureus* causes boils and skin infections (some extremely serious) and may infect wounds. Certain strains of *S. aureus* cause a form of food poisoning, and other strains cause toxic shock syndrome.

Clostridia are anaerobic. One species causes tetanus, another causes gas gangrene. *Clostridium botulinum* can cause botulism, an often fatal type of food poisoning. Botulism results from consuming foods, such as canned vegetables and smoked meats and fish, that have been inadequately sterilized; its endospores, which are resistant to heat, grow and produce the most potent toxin known. Approximately one microgram of toxin is enough to kill a human.

Eubacteria That Lack Cell Walls5 μm

SEM of *Mycoplasma* sp. on fibroblast cell. (David M. Phillips/Visuals Unlimited)

Mycoplasmas lack cell walls. These bacteria inhabit soil and sewage; some are parasitic on plants or animals. Some inhabit human mucous membranes but do not generally cause disease; one species causes a mild type of bacterial pneumonia in humans.

The Archaea: Bacteria with Cell Walls That Have No Peptidoglycan1 μm

TEM of a methanogen (*Methanospirillum hungatii*) undergoing cell division. Two other bacteria are visible in cross-section. Normally these bacteria are spiral-shaped. (Dr. Kari Lounatmaa/Science Photo Library/Photo Researchers, Inc.)

Methanogens are anaerobes that produce methane gas from simple carbon compounds.

Extreme

Halophiles inhabit saturated salt solutions.

Extreme

Thermophiles grow at 70°C or higher; some thrive above 100°C.

MAKING THE CONNECTION

BACTERIA, NITROGEN FIXATION, AND AGRICULTURE

How does the mutualistic relationship between certain bacteria and plants benefit agriculture? Rhizobial bacteria (bacteria in the genus *Rhizobium*) form symbiotic associations with the roots of legumes, a large family of herbs, shrubs, and trees. Legumes include such important crops as peas, beans, lentils, soybeans, and peanuts, as well as clover and alfalfa, which are grown for livestock feed and to fertilize the soil.

Rhizobial bacteria are motile bacilli that inhabit the soil. After they infect the roots of a legume, the roots develop nodules (see Fig. 53–11*a*). The nodules consist of plant tissue in which the bacteria reside and fix nitrogen. Rhizobial bacteria and the roots of legumes form a mutualistic type of symbiotic relationship. In a mutualistic relationship both partners benefit (see Chapter 52). The

bacteria living in nodules supply the plant with all the nitrogen it requires, and the plant provides the bacteria with organic compounds, including sugar needed for cellular respiration.

Because legumes, like other plants, produce sugar by photosynthesis, a correlation exists between photosynthesis and nitrogen fixation. When a legume is photosynthesizing at a higher rate, it provides more sugar for its bacterial partners. The bacteria are then able to fix larger amounts of nitrogen. Plants without nodules must obtain nitrogen from the soil (see Chapter 34). Because many soils are deficient in nitrogen, legumes that have formed mutualistic associations with rhizobial bacteria have a decided advantage over other plants.

Botulism, a type of food poisoning that can lead to paralysis and sometimes death, results from ingestion of improperly canned food. Botulism is caused by an exotoxin released by the gram-positive bacterium, *Clostridium botulinum*. This exotoxin is so powerful that one gram could kill a million humans! Like many exotoxins, the one that causes botulism can be inactivated by heating. (Food must be heated to 80°C for 10 minutes, or boiled for 3 to 4 minutes.)

Endotoxins are not secreted by pathogens but are components of the cell walls of most gram-negative bacteria. These compounds affect the host only when the bacteria die and release them. Endotoxins bind to macrophages and stimulate them to release substances that cause fever and other symp-

toms of infection. Unlike exotoxins, which cause specific symptoms, all endotoxins appear to cause systemic symptoms such as fever. Endotoxins are not destroyed by heating.

Bacteria are used in many commercial processes

Many foods and beverages are produced with the help of microbial fermentation. Lactic acid bacteria are used in the production of acidophilus milk, yogurt, pickles, olives, and sauerkraut, and several types of bacteria are used to produce cheese (Fig. 23–19). Bacteria are involved in making fermented meats like salami and in the production of vinegar, soy sauce, chocolate, and certain B vitamins (B₁₂ and riboflavin). Bacteria are also used in the production of citric acid, a compound added to candy and to most soft drinks. Some bacteria produce biocides that are used commercially to destroy insect pests.

Some types of microorganisms produce antibiotics, compounds that limit competition for nutrients by inhibiting or destroying other microorganisms. By the 1950s antibiotics had become important clinical tools that transformed the treatment of infectious disease. Today about 100 clinically useful antibiotics are available, and literally tons of antibiotics are produced annually. Pharmaceutical companies obtain most antibiotics from three groups of microorganisms: a large group of soil bacteria known as actinomycetes, gram-positive bacteria of the genus *Bacillus*, and molds (eukaryotes belonging to kingdom Fungi).

Because of their prolific reproduction rates, bacteria are ideal “factories” for the production of biomolecules. They have been genetically engineered (Chapter 14) to produce certain vaccines, human growth hormone, insulin, and many other clinically important compounds. About 50% of the insulin used to treat diabetics is derived from transgenic bacteria. Researchers are in the process of developing genetically engineered

Figure 23–19 LM of lactic acid bacteria (*Lactobacillus acidophilus*). (George J. Wilder/Visuals Unlimited)

bacteria for production of many other medically useful products.

Bacteria are used in sewage treatment and to break down solid wastes in landfills. They are also being used in bioremediation, a process in which a contaminated site is exposed to

microorganisms that break down the toxins, leaving behind harmless metabolic byproducts such as carbon dioxide and chlorides. To date, more than 1000 different species of bacteria and fungi have been used to clean up various forms of pollution.

S U M M A R Y W I T H K E Y T E R M S

- I. A **virus**, or **virion**, is a tiny particle consisting of a DNA or RNA genome surrounded by a **capsid** (protein coat).
 - A. Viruses are subcellular particles that cannot metabolize on their own and are not considered to be truly living organisms.
 - B. Viruses may be bits of nucleic acid that originally “escaped” from other organisms. They infect all types of organisms.
 1. **Phages (bacteriophages)** are viruses that infect bacteria.
 2. Many different viruses infect humans and other animals. Examples of human viral diseases include chickenpox, herpes simplex, infectious mononucleosis, mumps, warts, influenza, hepatitis, AIDS, as well as certain types of cancer. **Retroviruses**, such as HIV, use reverse transcriptase to transcribe their RNA genome into a DNA intermediate.
 3. Plant viruses cause serious agricultural losses. Viral diseases can be spread among plants by insect vectors.
 - C. A viral reproductive cycle can be lytic or temperate.
 1. In a **lytic** cycle, the virus destroys the host cell. The five steps in a lytic cycle include: **attachment** to the host cell; **penetration** of viral nucleic acid into the host cell; **replication** of the viral nucleic acid; **assembly** of newly synthesized components into new viruses; and **release** from the host cell.
 2. **Temperate** viruses do not always destroy their hosts. In a **lysogenic** cycle the viral genome is replicated along with the host DNA.
 - a. In some phages, the phage nucleic acid becomes integrated into the bacterial DNA; it is then called a **prophage**. Bacterial cells that carry prophages are **lysogenic cells**.
 - b. In **lysogenic conversion**, bacterial cells containing certain temperate viruses exhibit new properties.
- II. **Viroids** and **prions** are smaller than viruses.
 - A. A viroid consists of a short strand of RNA with no protein coat.
 - B. The prion appears to consist only of protein. Prions cause transmissible spongiform encephalopathies (TSEs).
- III. Prokaryotes are divided into two groups: kingdom **Archaeobacteria** and kingdom **Eubacteria**. Many biologists prefer classifying the bacteria into two domains: **Archaea** and **Eubacteria** (or simply, **Bacteria**).
 - A. Prokaryotic cells do not have membrane-bounded organelles such as nuclei and mitochondria. Common shapes of bacterial cells include **coccus**, or spherical; **bacillus**, or rod-shaped; and spiral. Spiral bacteria include the **vibrio**, which is a short helix; **spirillum**, a longer, rigid helix; and **spirochete**, a longer, flexible helix.
 - B. Most eubacteria have cell walls composed of **peptidoglycan**. The walls of **gram-positive** bacteria are very thick and consist mainly of peptidoglycan. The cell walls of **gram-negative** bacteria consist of a thin peptidoglycan layer and a thick outer membrane resembling the plasma membrane. Some species produce a **capsule** that surrounds the cell wall.
 - C. Some bacteria have **pili**, protein organelles that extend out from the cell and help bacteria adhere to one another or to certain other surfaces.
 - D. Bacterial **flagella** are structurally different from eukaryotic flagella; each flagellum consists of a basal body, hook, and filament. Unlike eukaryotic flagella, they produce a rotary motion.
 - E. The genetic material of a prokaryote is a single circular DNA molecule. **Plasmids** may also be present.
 - F. Bacteria reproduce asexually by **binary fission**, **budding**, or **fragmentation**.
 - G. Genetic material may be exchanged by **transformation**, **transduction**, or **conjugation**.
 - H. Some bacteria form dormant, durable cells called **endospores**.
 - I. Bacteria are metabolically diverse; some are **heterotrophs**, whereas others are **autotrophs**.
 1. The majority of heterotrophic bacteria are free-living **saprobies**, organisms that obtain nourishment from dead organic matter.
 2. Autotrophs may be **photoautotrophs** or **chemoautotrophs**.
 3. Most bacteria are aerobic, but some are **facultative anaerobes**; others are **obligate anaerobes**.
- IV. The cell walls of Archaea do not have peptidoglycan, and their translational mechanisms more closely resemble eukaryotic than other prokaryotic mechanisms. The three main groups of archaeobacteria are the **methanogens**, the **extreme halophiles**, and the **extreme thermophiles**.
 - A. The methanogens produce methane gas from simple carbon compounds. They inhabit anaerobic environments such as marshes, marine sediments, and the digestive tracts of animals.
 - B. The extreme halophiles inhabit saturated salt solutions.
 - C. The extreme thermophiles can inhabit environments at 70°C or higher. Some can even thrive at temperatures above 100°C.
- V. See Table 23–3 to review some of the major groups of Eubacteria.
- VI. Bacteria play essential ecological roles as decomposers and are important in recycling nutrients.
- VII. Many bacteria are symbiotic with other organisms; some are important **pathogens** of plants and animals. Some pathogenic bacteria produce **exotoxins**; others produce **endotoxins**.

P O S T - T E S T

1. Pathogens (a) are agents that cause disease (b) include most bacteria (c) include most cyanobacteria (d) include many autotrophs (e) three of the preceding answers are correct
2. The genome of a virus consists of (a) DNA (b) RNA (c) prions (d) DNA and RNA (e) DNA or RNA.
3. The capsid of a virus (a) consists of protein (b) consists of nucleic acid (c) is almost always helical (d) is a simple carbohydrate (e) answers b and c only are correct
4. Viruses that kill the host cell are (a) lysogenic (b) lytic (c) viroids (d) prophages (e) temperate.
5. The correct sequence in viral reproduction is (a) attachment, penetration, assembly, replication, release (b) penetration, absorption, assembly, replication, release (c) attachment, penetration, replication, assembly, release (d) release, assembly, penetration, replication, attachment (e) attachment, penetration, replication, release, assembly.
6. In lysogenic conversion (a) bacterial cells may exhibit new properties

- (b) the host cell dies (c) prions sometimes convert to viroids (d) reverse transcriptase transcribes DNA into RNA (e) prion proteins convert to infective agents
- Peptidoglycan is a chemical compound found in the cell walls of (a) most Eubacteria (b) most Archaea (c) prions (d) most viroids (e) Eukarya
 - Retroviruses (a) are DNA viruses (b) are RNA viruses (c) use reverse transcriptase to transcribe DNA into RNA (d) use prion protein to transcribe RNA (e) answers b and c are correct
 - Bacterial flagella (a) are homologous with eukaryotic flagella (b) are used in classifying some bacterial species (c) consist of a basal body and nine pairs of microtubules (d) are important in transduction (e) are gram-positive
 - In conjugation (a) two bacterial cells of different mating types come together, and genetic material is transferred from one to another (b) a bacterial cell develops a bulge that enlarges and eventually separates from the mother cell (c) fragments of DNA released by a broken cell are taken in by another bacterial cell (d) a phage carries bacterial genes from one bacterial cell into another (e) walls develop in the cell, which then divides into six new cells
 - Endospores (a) are formed by some viruses (b) are extremely durable cells (c) are comparable to the reproductive spores of fungi and plants (d) cause fever and other symptoms in the host (e) answers b and c are correct
 - The majority of heterotrophic bacteria are (a) free-living saprobes (b) photoautotrophs (c) chemoautotrophs (d) facultative anaerobes (e) obligate anaerobes
 - The Archaea include (a) bacteria that produce methane from carbon dioxide and hydrogen (b) thermophiles (c) halophiles (d) all of the gram-positive bacteria (e) answers a, b, and c are correct

REVIEW QUESTIONS

- What characteristics does a virus share with a living cell? What characteristics of life are absent in a virus?
- List the steps in a lytic cycle. Draw diagrams to illustrate your answer.
- Contrast the sequence of events in a lysogenic cycle with that of a lytic cycle.
- What are the distinguishing characteristics of viroids? Of prions?
- What are the differences between the Archaea and the Eubacteria?
- Contrast the cell wall of a gram-positive bacterium with that of a gram-negative bacterium.
- Using Table 23–3 as a guide, give the distinguishing characteristics of each of the groups of bacteria described, and give examples of each group.
- Label the diagram. Use Figure 23–9 to check your answers.

YOU MAKE THE CONNECTION

- Historically, biologists thought that viruses, because of their simple structure, evolved before cellular organisms. Based on what you have learned about viruses, present an argument against this hypothesis.
- Imagine that you discover a new microorganism. After careful study you determine that it should be classified in the domain Archaea. What characteristics might lead you to this classification?
- How might life on planet Earth be different if bacteria had never evolved?

CHAPTER 24

The Protist Kingdom

In Chapter 22 you learned that the kingdom Protista was first proposed in 1866 to include bacteria and other microorganisms that differ from plants and animals. When Robert Whittaker recommended the five-kingdom system of classification in 1969, only unicellular eukaryotic organisms were placed in kingdom Protista. The boundaries of this kingdom have expanded somewhat since then, although there is still no universal agreement among biologists about what constitutes a protist.

Kingdom Protista currently consists of a vast assortment of primarily aquatic eukaryotic organisms whose diverse body forms, types of reproduction, modes of nutrition, and lifestyles make them difficult to characterize. **Protists** are unicellular, colonial, or simple multicellular organisms that possess a eukaryotic cell organization. The word *protist*, from Greek, meaning “the very first,” reflects the idea that protists were the first eukaryotes to evolve (discussed later in the chapter).

Eukaryotic cells, the unifying feature of protists, are common to complex multicellular organisms belonging to the three other eukaryotic kingdoms (Fungi, Animalia, and Plantae) but clearly differentiate protists from members of the prokaryotic kingdoms (Eubacteria and Archaeobacteria). Recall from Chapter 4 that, unlike prokaryotic cells, eukaryotic cells possess nuclei and other membrane-bounded organelles such as mitochondria and plastids, 9 + 2 flagella, and multiple chromosomes in which DNA is complexed with proteins. Sexual reproduction, meiosis, and mitosis are also characteristic of eukaryotes.

Size varies considerably within the protist kingdom, from microscopic protozoa to giant kelps, which are brown algae that can reach 75 meters (250 feet) in length. Although most protists, like the dinoflagellates (*Ceratium* sp.) shown in the LM, are unicellular, some form **colonies** (loosely connected groups of cells), some are **coenocytic** (consisting of a multinucleate mass of cytoplasm), and some are multicellular. Unlike animals, fungi, and plants, most multicellular protists have relatively simple body forms without specialized tissues.

(from *Freshwater Algae: Their Microscopic World Explored*. Biopress, 1995. Photo by Hilda Canter-Lund)

Because of their huge numbers, members of kingdom Protista are important to the natural balance of the living world. Protists are an important source of food for other organisms, and photosynthetic protists also supply oxygen to aquatic and terrestrial ecosystems. Certain protists are economically important, while others cause diseases. Consideration of all protist phyla is beyond the scope of this text, but we will discuss sixteen representative phyla that include animal-like heterotrophs (protozoa), plantlike autotrophs (algae, including seaweeds), and fungus-like heterotrophs (slime molds and water molds).

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Characterize the features common to the members of kingdom Protista.
 2. Discuss in general terms the diversity inherent in the protist kingdom, including modes of nutrition, body forms, motility, and reproduction.
 3. Briefly describe and compare these representative protozoa: amoebas, foraminiferans, actinopods, zooflagellates, ciliates, and apicomplexans.
 4. Briefly describe and compare these representative algae: euglenoids, dinoflagellates, diatoms, golden algae, brown algae, green algae, and red algae.
 5. Briefly describe and compare these representative fungus-like protists: plasmodial slime molds, cellular slime molds, and water molds.
 6. Explain how multicellularity may have arisen within the protists, using the volvocine line as an example.
 7. Discuss the controversies surrounding the evolutionary relationships both among the protists and between the protists and other eukaryotic kingdoms.
-

PROTISTS HAVE EVOLVED A VARIETY OF CELL STRUCTURES, ECOLOGICAL ROLES, AND LIFE HISTORIES

Size and structural complexity are not the only variable features of protists. During the course of evolutionary history, organisms in the kingdom Protista have evolved diversity in their (a) means of locomotion, (b) ways of obtaining nutrients, (c) interactions with other organisms, (d) habitat, and (e) modes of reproduction.

Protists, most of which are motile at some point in their life cycle, have various means of locomotion. They may move by pushing out cytoplasmic extensions (**pseudopodia**) as an amoeba does, by flexing individual cells, by gliding over surfaces, by waving **cilia** (short hairlike structures), or by lashing **flagella** (long, whiplike structures). Some protists use a combination of two or more means of locomotion, for example, both flagella and amoeboid movement.

Methods of obtaining nutrients differ widely in kingdom Protista. Most of the algae are autotrophic and photosynthesize as plants do. Some heterotrophic protists obtain their nutrients by absorption, as fungi do, whereas others resemble animals in that they ingest food. Some protists switch their modes of nutrition and are autotrophic at certain times and heterotrophic at others.

Although many protists are free-living, others form symbiotic associations with various organisms. These intimate associations range from *mutualism*, a more or less equal partnership where both partners benefit, to *parasitism*, where one partner (the parasite) lives on or in another (the host) and is metabolically dependent on it (see Chapter 52). Some parasitic protists are important pathogens (disease-causing agents) of plants or animals. Specific examples of symbiotic associations involving protists are described throughout this chapter.

Most protists are aquatic and live in the ocean or in freshwater ponds, lakes, and streams. They make up most of the **plankton**, the floating, often microscopic organisms that inhabit surface waters and are the base of the food web in aquatic

ecosystems. Other aquatic protists attach to rocks or other surfaces in the water. Even parasitic protists are aquatic because they live in the watery environments of other organisms' body fluids. Terrestrial protists are restricted to damp places such as soil, cracks in bark, and leaf litter.

Reproduction is varied in the kingdom Protista. Almost all protists reproduce asexually, and many also reproduce sexually, often by **syngamy**, the union of gametes. However, most protists do not develop multicellular reproductive organs, nor do they form embryos the way more complex organisms do.

Based on the diversity in their structures, ecological lifestyles, and reproduction, most biologists regard the protist kingdom as a polyphyletic group of organisms; that is, protists probably do not share a single common ancestor. Some biologists think as many as 50 phyla would be needed to reflect natural relationships within the protists! If a cladist were classifying these organisms based on evidence for a shared evolutionary history (see Chapter 22), many protist phyla would be converted to kingdom status, and there would be many more than six kingdoms. Fortunately, recent molecular analyses, such as comparison of ribosomal RNA sequences, are starting to clarify relationships among the various protist phyla and among protists and the other kingdoms (Fig. 24–1).

PROTOZOA ARE ANIMAL-LIKE PROTISTS

The name **protozoa** (from the Latin, meaning “first animals”; sing., *protozoon*) was originally given to animal-like organisms that are not multicellular. The term *protozoa* is used today as an informal designation for those protists that ingest food (as animals do). Protozoa are a polyphyletic group, and their evolutionary relationships are continually being reevaluated as additional evidence becomes available. In this chapter we consider six groups of protozoa: amoebas, foraminiferans, actinopods, zooflagellates, ciliates, and apicomplexans (see Table 24–1, p. 508).

Figure 24–1 One interpretation of evolutionary relationships among certain protists. This evolutionary tree is based on a comparison of ribosomal RNA data for several protist phyla as well as the other five kingdoms. Foraminiferans, actinopods, diatoms, red algae, and plasmodial slime molds are not shown. Biologists are not in complete agreement about the details of the protist family tree, and there are other interpretations of the protist lineage than the one depicted here.

Amoebas move by forming pseudopodia

Amoebas (phylum Rhizopoda) are unicellular organisms found in soil, fresh water, and the ocean. Because of the extreme flexibility of their outer plasma membrane, many members of this group have an indefinite body structure and continually change shape as they move. (The word *amoeba* is derived from a Greek word meaning “change.”) An amoeba moves by pushing out temporary cytoplasmic projections called pseudopodia (sing., *pseudopodium*, meaning “false foot”) from the surface of the cell. More cytoplasm flows into the pseudopodia, enlarging them until all the cytoplasm has entered and the organism as a whole has moved. Pseudopodia are also used to engulf and capture food by surrounding and forming a vacuole around it (Fig. 24–2). Food particles are di-

gested when the food vacuole fuses with a lysosome containing digestive enzymes. Digested materials are absorbed from the food vacuole, which gradually shrinks as it empties. Amoebas reproduce asexually by cell division after mitotic division of the nucleus; sexual reproduction has not been observed.

Parasitic amoebas include *Entamoeba histolytica*, which causes amoebic dysentery, a serious human intestinal disease characterized by severe diarrhea and the formation of large ulcers in the intestinal wall. In especially severe cases, the organism spreads from the large intestine and causes abscesses in the liver, lungs, or brain. According to the World Health Organization, about 48 million people were newly infected with this amoeba in 1996, and 70,000 people died. *Entamoeba histolytica* is transmitted as **cysts** in contaminated drinking water. (A cyst is a thick-walled, resistant, resting stage in the life

Figure 24-2 Amoebas. LM of a giant amoeba (*Chaos carolinense*), a single-celled protist that moves and feeds by means of pseudopodia, which are shown surrounding and ingesting a colonial green alga. (Michael Abbey/Photo Researchers, Inc.)

history of some protists.) Other amoebas, like *Acanthamoeba*, are usually free-living but can produce opportunistic infections such as eye infections in contact lens users.

Foraminiferans extend cytoplasmic projections through tests

Almost all **foraminiferans** (phylum Foraminifera) are marine organisms that produce shells, or **tests** (Fig. 24-3*a*). The ocean contains enormous numbers of foraminiferans, which secrete

chalky, many-chambered tests with pores through which cytoplasmic projections can be extended. The group gets its phylum name from this characteristic, as *foraminifera* is derived from Latin words that mean “bearing openings.” The cytoplasmic projections form a sticky, interconnected net that entangles prey.

Dead foraminiferans sink to the bottom of the ocean, where their tests form a gray mud that is gradually transformed into chalk. With geological uplifting, these chalk formations can become part of the land, like the white cliffs of Dover in England (Fig. 24-3*b*). (The white cliffs of Dover are composed of the remains of a variety of carbonate organisms, not only foraminiferans.) Because foraminiferan tests are often found in rock layers covering oil deposits, geologists involved in oil exploration look for foraminiferan tests in rock strata.

Actinopods project slender axopods

Actinopods (phylum Actinopoda) have long, filamentous cytoplasmic projections called **axopods** that protrude through pores in their shells (Fig. 24-4). Each axopod is strengthened by a cluster of microtubules. Unicellular algae and other prey become entangled in these axopods and are engulfed outside the main body of the actinopod; cytoplasmic streaming carries the prey back within the shell. Many actinopods contain algal **endosymbionts** that provide them with the products of photosynthesis. (An endosymbiont lives inside the body of the organism with which it has formed a close relationship.)

Some actinopods secrete elaborate and beautiful shells made of silica. When actinopods die, their skeletons settle and become mud on the ocean floor; eventually they are compressed into sedimentary rock.

(*a*)

(*b*)

Figure 24-3 Foraminiferans. These protists with shells, or tests, live primarily in marine environments. (*a*) SEM of a foraminiferan test. Note the pores through which cytoplasm can extrude. (*b*) The white cliffs of Dover, England, consist largely of the tests of foraminiferans. (*a*, Biophoto Associates; *b*, Lynn McLaren/Photo Researchers, Inc.)

TABLE 24-1 Representative Phyla in the Protist Kingdom

Common Name	Phylum	Morphology	Locomotion	Photosynthetic Pigments	Energy Reserves	Special features
Protozoa						
Amoebas	Rhizopoda	Unicellular, no definite shape	Pseudopodia	—	—	Some have shells (tests)
Foraminiferans	Foraminifera	Unicellular	Cytoplasmic projections	—	—	Pore-studded shells (tests)
Actinopods	Actinopoda	Unicellular	Some produce flagellated reproductive cells	—	—	Axopods protrude through pores in shell
Zooflagellates	Zoomastigina	Unicellular; some colonial	One to many flagella; some amoeboid	—	—	Symbiotic forms often highly specialized
Ciliates	Ciliophora	Unicellular	Cilia	—	—	Macronuclei and micronuclei
Apicomplexans	Apicomplexa	Unicellular	Move by flexing	—	—	Parasitic; develop resistant spores
Algae						
Euglenoids	Euglenophyta	Unicellular	Two flagella (one very short)	Chlorophylls <i>a</i> and <i>b</i> ; carotenoids	Paramylon	Flexible outer covering (pellicle)
Dinoflagellates	Dinoflagellata	Unicellular; some colonial	Two flagella	Chlorophylls <i>a</i> and <i>c</i> ; carotenoids, including fucoxanthin	Oils or polysaccharides	Many covered with cellulose plates
Diatoms	Bacillariophyta	Unicellular; some colonial	Most nonmotile; some glide over secreted slime	Chlorophylls <i>a</i> and <i>c</i> ; carotenoids, including fucoxanthin	Oils or carbohydrates	Silica in shell

Zooflagellates move by means of flagella

Zooflagellates (phylum Zoomastigina) are mostly unicellular (a few are colonial) organisms with spherical or elongated bodies, a single central nucleus, and from one to many long, whip-like flagella that enable them to move. Zooflagellates move rapidly, pulling themselves forward by lashing flexible flagella that are usually located at the anterior (front) end. Some zooflagellates are also amoeboid and engulf food by forming pseudopodia. Other zooflagellates ingest food by means of a definite “mouth,” or *oral groove*, and “throat,” or *cytopharynx*.

Zooflagellates are heterotrophic and obtain their food either by ingesting living or dead organisms or by absorbing nutrients from dead or decomposing organic matter. They may

◀ **Figure 24-4 Actinopods.** LM of a living actinopod from the Red Sea. Note the many slender axopods that project from the cell. (Robert Brons/Biological Photo Service)

TABLE 24-1 Continued

Common Name	Phylum	Morphology	Locomotion	Photosynthetic Pigments	Energy Reserves	Special features
Golden algae	Chrysophyta	Unicellular; some colonial	Two flagella	Chlorophylls <i>a</i> and <i>c</i> ; carotenoids, including fucoxanthin	Oils or carbohydrates	Covered with tiny scales of silica or calcium carbonate
Brown algae	Phaeophyta	Multicellular	Usually two flagella on reproductive cells	Chlorophylls <i>a</i> and <i>c</i> ; carotenoids, including fucoxanthin	Laminarin	Kelps have bodies with blades, stipes, and holdfasts
Green algae	Chlorophyta	Unicellular; coenocytic; colonial; multicellular	Most flagellated at some stage in life; some entirely nonmotile	Chlorophylls <i>a</i> and <i>b</i> ; carotenoids	Starch	Reproduction highly variable
Red algae	Rhodophyta	Most multicellular; some unicellular	No flagellated stages	Chlorophyll <i>a</i> ; carotenoids; phycocyanin; phycoerythrin	Floridean starch	Some reef builders
Fungus-like protists						
Plasmodial slime molds	Myxomycota	Multinucleate plasmodium	Cytoplasmic streaming; flagellated or amoeboid reproductive cells	—	—	Reproduce by spores formed in sporangia
Cellular slime molds	Acrasiomycota	Unicellular feeding stage; multicellular (slug and fruiting body)	Pseudopodia (for single cells); cytoplasmic streaming (for multicellular forms)	—	—	Aggregation of cells signaled by cyclic AMP
Water molds	Oomycota	Coenocytic mycelium	Biflagellate zoospores	—	—	Cellulose and/or chitin in cell walls

be free-living or symbionts. For example, trichonymphs, complex, specialized zooflagellates with many flagella, live in the guts of termites (Fig. 24-5*a*). These zooflagellates possess the enzymes to digest cellulose in the wood that termites eat, and both the termite and the zooflagellates obtain their nutrients from this source. Termites would starve to death without their flagellated endosymbionts, as would the trichonymphs, which have the ability to digest but not to ingest wood.¹

Some parasitic zooflagellates cause disease. For example, the zooflagellate *Trypanosoma* is a human parasite that causes African sleeping sickness (Fig. 24-5*b*). It is transmitted by the bite of infected tsetse flies. Early symptoms include recurring attacks of fever. Later, when the trypanosomes have invaded

the central nervous system, infected individuals have difficulty speaking or walking; if untreated, African sleeping sickness can cause death.

Giardia intestinalis is a parasitic zooflagellate that causes backpackers' diarrhea, a common infection among campers and hikers, particularly in the mountains of the western United States. *Giardia* is eliminated as a resistant cyst in the feces of many vertebrate animals. These cysts are a common contaminant in mountain streams. Campers and hikers become infected when they drink or rinse dishes in the "clean" mountain water. In a heavy infection, much of the wall of the small intestine is coated with these zooflagellates, which interfere with the absorption of digested nutrients and cause weight loss, abdominal pain, and diarrhea.

Choanoflagellates (collared zooflagellates) are one of the classes of zooflagellates in the phylum Zoomastigina. These sessile marine and freshwater zooflagellates are attached by a stalk, and their single flagellum is surrounded by a delicate col-

¹The zooflagellate endosymbionts of termites in turn possess endosymbionts, bacteria that reside within the zooflagellates. These bacteria, rather than the zooflagellates, may produce the enzymes that digest cellulose.

lar of microvilli (Fig. 24–5c). They are of special interest because of their striking resemblance to collar cells in sponges (see Fig. 28–6). Some biologists think choanoflagellates are related to the ancestor of animals.

Ciliates use cilia for locomotion

Ciliates (phylum Ciliophora) are unicellular organisms with a flexible outer covering called a **pellicle** that gives them a definite but changeable shape. In *Paramecium*, the surface of the

Figure 24–5 Zooflagellates. (a) LM of a complex zooflagellate (*Trichonympha* sp.) that lives in the gut of wood-eating termites and digests the cellulose of the wood particles eaten by its host, from which it obtains sugar for itself and its host. *Trichonympha* has hundreds of flagella. (b) LM of the zooflagellate (*Trypanosoma gambiense*) that causes sleeping sickness, among red blood cells in a human blood smear. (c) Choanoflagellates obtain food by waving their flagella, causing water currents to carry small particles of food into the collar of microvilli. Shown is a colonial form. (a, M.A. Abbey/Visuals Unlimited; b, Biophoto Associates/Photo Researchers, Inc.)

cell is covered with several thousand fine, short, hairlike organelles, called cilia, that extend through pores in the outer covering and permit movement (Fig. 24–6a,b). The cilia beat in such a precisely coordinated fashion that the organism can not only go forward but can also back up and turn around. Just under the pellicle, many ciliates possess numerous small **trichocysts**, organelles that discharge filaments thought to aid in trapping and holding prey.

Not all ciliates are motile. Some sessile forms are stalked, and others, although capable of some swimming, are more likely to remain attached to a rock or other surface at one spot (Fig. 24–6c). Their cilia set up water currents that draw food toward them.

Figure 24-6 Ciliates. (a) Note the complex cell structure seen in this LM of *Paramecium* sp., a freshwater ciliate. Like many ciliates, *Paramecium* has multiple nuclei—a macronucleus and one or more smaller micronuclei. (b) Food particles are swept into *Paramecium*’s ciliated oral groove and incorporated into food vacuoles. Lysosomes fuse with the food vacuoles, and the food is digested and absorbed; undigested wastes are eliminated through the anal pore. *Paramecium* absorbs water by osmosis from its freshwater surroundings, but it does not swell because contractile vacuoles fill with excess water and then contract to discharge it into the environment. (c) LM of *Stentor*, a sessile ciliate. Note the numerous cilia that direct food particles into its funnel-like “mouth.” (a, M. Abbey/Photo Researchers, Inc.; c, Eric Gravé/Photo Researchers, Inc.)

Most ciliates ingest bacteria or other tiny protists; their cilia draw the food into a simple opening in some species and into a funnel-like oral groove in others. A vacuole forms around the food at the end of the opening, and the food is digested. Water regulation in freshwater ciliates is controlled by special organelles called **contractile vacuoles**. Being hypertonic to their environment, freshwater ciliates continually take in water by osmosis; the contractile vacuole continually expels excess water from the ciliate back to the environment.

Ciliates differ from other protozoa in having two kinds of nuclei: one or more small, diploid **micronuclei** that function in the sexual process, and a larger, polyploid **macronucleus** that controls cell metabolism and growth. Most ciliates are capable of a sexual process called **conjugation** where two individuals come together and exchange genetic material. Each ciliate species is divided into several different mating types. Individuals with different mating types are identical in appearance but genetically different in terms of sexual compatibility. Because there are no physical differences between the mating types, it is not appropriate to refer to them as “male” and “female.”

During conjugation in *Paramecium*, two individuals of different mating types press their oral surfaces together. Within each individual the macronucleus disintegrates and the micronucleus undergoes meiosis, forming four haploid nuclei.

Three of these degenerate, leaving one. This nucleus then divides mitotically to form two identical haploid nuclei. One of these remains within the cell and the other nucleus crosses through the oral region into the other individual, where it fuses with the haploid nucleus in that cell. Thus, a single act of conjugation yields two cross fertilizations as each cell fertilizes the other. This results in two “new” cells that are genetically identical to each other but different from what they were before conjugation. Actual cell division need not follow immediately after conjugation. Cell division is a complex process involving more than simply splitting in half, because complex organelles must be duplicated. In addition, after the new micronucleus divides, a new macronucleus develops from one of the micronuclei.

Apicomplexans are spore-forming parasites of animals

Apicomplexans (phylum Apicomplexa) are a large group of parasitic protozoa, some of which cause serious diseases such as malaria in humans. They are thought to have evolved from parasitic dinoflagellates living in the intestines of marine invertebrates (dinoflagellates are discussed later in this chapter). Apicomplexans lack specific structures for locomotion but move by flexing. At some stage in their lives, they develop a

spore, a small infective agent transmitted to the next host. Many apicomplexans spend part of their life cycle in one host species and part in a different host species.

Malaria, which is caused by an apicomplexan, is the world's most serious infectious disease. According to the World Health Organization, approximately 300 to 500 million people currently have malaria, and 1.5 to 2.7 million people, many of them children, die each year from it. Although the disease was described for centuries in Chinese, Greek, Arabic, and Roman writings, its causal agent and mode of transmission were not identified until the end of the 19th century. *Plasmodium*, the apicomplexan that causes malaria, enters human blood through the bite of an infected female *Anopheles* mosquito (Fig. 24–7). *Plasmodium* first enters liver cells and then red blood cells, where it multiplies. When each infected red blood cell bursts, many new parasites are released. The released parasites infect new red blood cells, and the process is repeated. The simultaneous bursting of millions of red cells causes the symptoms of malaria: a chill, followed by high fever caused by toxic substances that are released and affect other organs of the body.

Malaria is currently recurring in many countries where it had been under control for decades. Formerly effective control methods—antimalarial drugs and pesticides—have lost much of their effectiveness. Chloroquine and several other antimalarial drugs are taken prophylactically to prevent malaria, but *Plasmodium* has evolved resistance to several of these in many areas, necessitating the use of a combination of drugs. Pesticides are used to control *Plasmodium*'s vector, the mosquito, but mosquitoes have evolved resistance to many pesticides. New antimalarial drugs and several possible vaccines against malaria are currently being tested.

ALGAE ARE PLANTLIKE PROTISTS

Algae (sing., *alga*) are an informal group of mostly photosynthetic protists that range in size from unicellular, microscopic forms to large, multicellular seaweeds. (The word *alga* is derived from a Latin word for “seaweed.”)

Figure 24–7 The life cycle of *Plasmodium* sp., the apicomplexan that causes malaria.

(1) A female *Anopheles* mosquito bites an infected person and obtains gametocytes along with human blood. (2) In the mosquito's digestive tract, the gametocytes develop into gametes and fertilization occurs. (3) The zygote embeds in the mosquito's stomach lining and produces sporozoites (spores), which are released and migrate to the salivary gland. (4) The mosquito bites an uninfected human and transmits sporozoites to the human's blood. (5) The sporozoites enter liver cells and divide to produce merozoites that infect red blood cells. (6) In the blood cells, merozoites divide to form more merozoites, which infect more red blood cells. Some merozoites form gametocytes, which can be transmitted to the next mosquito that bites that human, and the process is repeated.

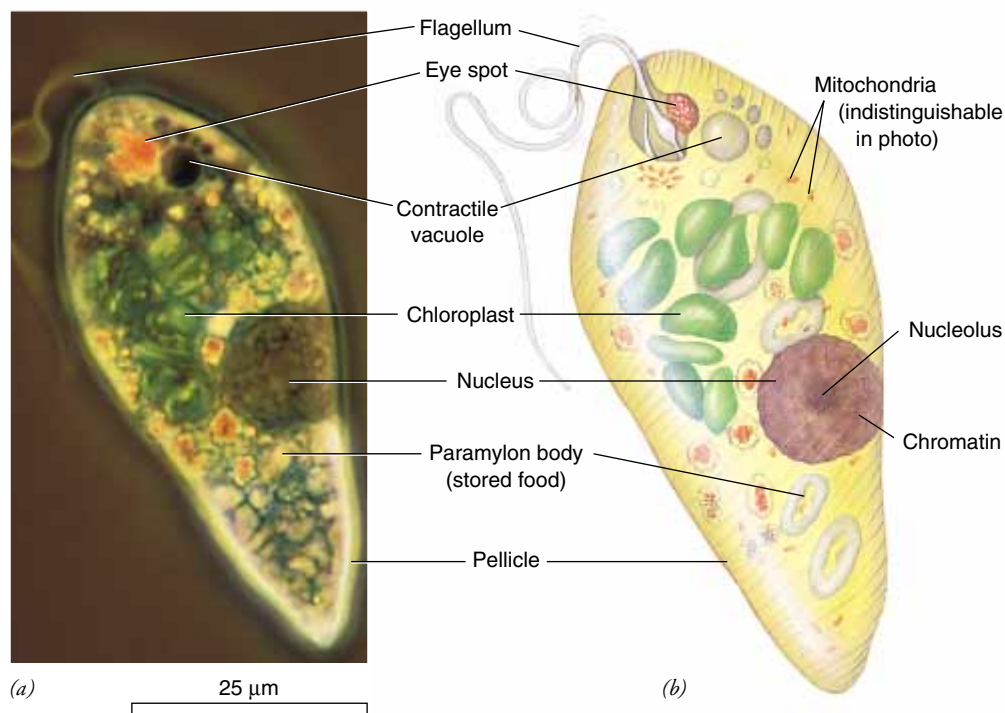

Figure 24-8 Euglenoids.

(a) Note the complex cell structure shown in this LM of a unicellular, flagellated euglenoid (*Euglena* sp.). (b) The eyespot is thought to shield a light detector at the base of the long flagellum, thereby helping *Euglena* move to light of an appropriate intensity. *Euglena*'s pellicle is flexible and enables it to change shape easily. (Biophoto Associates)

Although most algae are photosynthetic like plants, they are not considered plants because they lack many plant structures, such as roots, stems, and leaves. Algae lack a cuticle, which is a waxy covering over the aerial parts of plants that reduces water loss. When actively growing, algae are restricted to damp or wet environments, such as the ocean; freshwater ponds, lakes, and streams; hot springs; polar ice; alpine snow; moist soil, trees, and rocks; and the bodies of certain animals including sloths, sea anemones, corals, and worms. Also, most algae do not have multicellular **gametangia** (sing. *gametangium*; reproductive structures in which gametes are produced); algal gametangia generally are formed from single cells.

In addition to green chlorophyll *a* and yellow and orange **carotenoids**, which are photosynthetic pigments found in all algae (and plants), different algal phyla possess a variety of other pigments that are also important in photosynthesis. Classification into phyla is largely based on their pigment composition and what kinds of materials they produce to store energy reserves (fuel molecules). Other characteristics used to classify algae include their cell wall composition, the number and placement of flagella, and chloroplast structure. We will consider seven groups of algae: euglenoids, dinoflagellates, diatoms, golden algae, brown algae, green algae, and red algae (see Table 24-1).

Euglenoids are unique freshwater unicellular flagellates

Most **euglenoids** (phylum Euglenophyta) are unicellular flagellates, and about one-third of them are photosynthetic (Fig. 24-8). They generally possess two flagella, one long and whip-

like and one so short that it does not extend outside the cell. Some euglenoids, such as *Euglena* sp., change shape continually as they move through the water because their pellicle (outer covering of protein) is flexible rather than rigid. Euglenoids reproduce asexually by longitudinal cell division; none has ever been observed to reproduce sexually.

Euglenoids have at various times been classified in the plant kingdom (with the algae) and in the animal kingdom (when protozoa were considered animals). Based on molecular data, euglenoids are thought to be closely related to zooflagellates. We include euglenoids in our discussion of algal protists rather than the discussion of zooflagellates because many species contain chloroplasts and photosynthesize. They have chlorophyll *a*, chlorophyll *b*, and carotenoids, which are the same pigments found in green algae and plants.² Their energy reserves are stored as *paramylon*, a polysaccharide. Some photosynthetic euglenoids lose their chlorophyll when grown in the dark and obtain their nutrients heterotrophically by ingesting organic matter. Other species of euglenoids are always colorless and heterotrophic.

Euglenoids inhabit freshwater ponds and puddles, particularly those with large concentrations of organic material. For that reason they are used as indicator species of organic pollution. Some euglenoids are also found in marine waters and mud flats.

²Although the euglenoids have the same pigments as the green algae and plants, they are not thought to be closely related to either group.

Figure 24-9 Dinoflagellates. (a) SEM of *Protoperidinium* sp., a unicellular, photosynthetic, bi-flagellate dinoflagellate. Note the cellulose plates that encase the unicellular body. The two flagella (not visible) are located in grooves. (b) A species of *Gonyaulax*, showing the two flagella located in grooves. (c) Aerial shot of a red tide around Matushima Island, Japan. The water is colored by the presence of billions of dinoflagellates. (a, Courtesy of T.K. Mauget, University of Maryland; c, Suisan Aviation Company)

Most dinoflagellates are a part of marine plankton

One of the most unusual protist phyla is that of the **dinoflagellates** (phylum Dinoflagellata). Most dinoflagellates are unicellular, although a few are colonial. Their cells are often covered with shells of interlocking cellulose plates impregnated with silicates (Fig. 24-9a,b). The typical dinoflagellate has two flagella: one flagellum is wrapped around a transverse groove in the center of the cell like a belt, and the other is located in a longitudinal groove (perpendicular to the transverse groove) and projects behind the cell. The undulation of these flagella propels the dinoflagellate through the water like a spinning top. Indeed, the dinoflagellates' name is derived from the Greek *dinos*, meaning "whirling." Many marine dinoflagellates are bioluminescent.

Most dinoflagellates are photosynthetic and possess the photosynthetic pigments chlorophyll *a*, chlorophyll *c*, and carotenoids, including **fucoxanthin**, a special yellow-brown carotenoid. However, a number are colorless; some of these ingest other microorganisms for food. Dinoflagellates usually store energy reserves as oils or polysaccharides.

Many dinoflagellates are endosymbionts that reside in the bodies of marine invertebrates such as jellyfish, corals, and mollusks. These symbiotic dinoflagellates lack cellulose plates and flagella and are called **zooxanthellae**. Zooxanthellae photosynthesize and provide carbohydrates for their invertebrate partners. The contribution of zooxanthellae to the productiv-

ity of coral reefs is substantial. Other dinoflagellates that are endosymbionts lack pigments and do not photosynthesize; these heterotrophs are parasites that live off their hosts.

Reproduction in the dinoflagellates is primarily asexual, by longitudinal cell division, although a few species have been reported to reproduce sexually. The dinoflagellate nucleus is distinctive because the chromosomes are permanently condensed and always evident. Meiosis and mitosis are unusual because the nuclear envelope remains intact throughout cell division and the spindle is located *outside* the nucleus. (The chromosomes do not make direct contact with the spindle microtubules; instead, the chromosomes appear to be attached to the nuclear envelope, and the spindle separates the new nuclei from each other.)

Ecologically, dinoflagellates are one of the most important groups of producers in marine ecosystems. A few dinoflagellates are known to have occasional population explosions, or blooms. These blooms frequently color the water orange, red, or brown and are known as **red tides** (Fig. 24-9c). It is not known what environmental conditions initiate dinoflagellate blooms, but they are more common in the warm waters of late summer. Many experts think that human-produced coastal pollution triggers red tides, presumably by providing nutrients to the dinoflagellates. Some of the dinoflagellate species that form red tides produce a toxin that attacks the nervous systems of fishes, leading to massive fish kills. Birds such as cormorants suffer and sometimes die when exposed to the toxin from eating the dead fish. Scientists also determined that a red

tide of the dinoflagellate *Gymnodinium breve* was responsible for the deaths of 158 manatees on Florida's gulf coast in 1996.

In August 1997 more than 30,000 fish with open, bleeding sores died in several tributaries of the Chesapeake Bay. Water skiers, fishermen, and scientists that came into contact with the contaminated water developed breathing difficulty, skin rashes, and temporary memory loss. This event, which received national attention, was caused by a population explosion of toxic dinoflagellates that are relatively new to science. *Pfiesteria piscicida* was the first dinoflagellate of this type to be scientifically named and identified, in 1991, by Joann Burkholder at North Carolina State University. *Pfiesteria* and similar dinoflagellates have complex life cycles with about 24 stages, including dormant cysts, nontoxic amoeboid forms, and both nontoxic and toxic flagellated forms. The algal blooms have been circumstantially linked to nitrogen and phosphorus pollution in shallow estuaries near hog and chicken operations and municipal sewage treatment plants. When *Pfiesteria* and similar dinoflagellates change to toxic forms, they release a poison that eats into the fish's skin, causing open, bleeding sores. The dinoflagellates feed on the fish tissues and blood and then quickly convert to nontoxic forms.

Humans sometimes get paralytic shellfish poisoning by eating filter-feeding mollusks, such as oysters, mussels, or clams, that have fed on certain dinoflagellates. Paralytic shellfish poisoning causes respiratory problems in humans who eat the contaminated shellfish; death from respiratory failure occasionally occurs. The dinoflagellates do not appear to harm the shellfish.

Diatoms have shells composed of two parts

Most **diatoms** (phylum Bacillariophyta) are unicellular, although a few exist as colonies. The cell wall of each diatom consists of two shells that overlap where they fit together, much like a petri dish. Silica is deposited in the shell, and this glasslike material is laid down in intricate patterns (Fig. 24–10*a*). There are two basic groups of diatoms, those with radial symmetry (wheel-shaped) and those with bilateral symmetry (boat-shaped or needle-shaped). Although some diatoms are part of the floating plankton, others live on rocks and sediments, where they move by gliding. This gliding movement is facilitated by the secretion of a slimy material from a small groove along the shell.

(a)

100 μm

(b)

Figure 24–10 Diatoms. (a) LM of diatoms, unicellular algae with shells that contain silica. These algae have strikingly beautiful patterns on their symmetrical shells. (b) Asexual reproduction in diatoms. As cell division occurs, each new cell retains half of the original shell. The other half of the shell is synthesized, always to fit *inside* the original half. As a result, one of the new cells is smaller than the other. (a, The Stock Market/Phillip Harrington)

Figure 24–11 Golden algae. (a) LM of a colonial, freshwater golden alga (*Dinobryon* sp.). As flagella beat, water currents are produced that carry bacteria into the transparent casing surrounding each cell of the colony. These bacteria are ingested and supplement the food that *Dinobryon* produces by photosynthesis. (b) SEM of a coccolithophorid (*Emiliania huxleyi*), a golden alga that is an important component of nanoplankton. Coccolithophorids are covered by tiny, overlapping scales of calcium carbonate. (a, J.R. Waaland/Biological Photo Service; b, Dr. Elizabeth Venrick/Scripps Institution of Oceanography)

Diatoms contain the photosynthetic pigments chlorophyll *a*, chlorophyll *c*, and carotenoids, including fucoxanthin; their pigment composition gives them a yellow or brown color. Energy reserves are stored as oils or carbohydrates.

Diatoms most often reproduce asexually by cell division. When a diatom divides, the two halves of its shell separate, and each becomes the larger half of a new diatom shell (Fig. 24–10*b*). Because the glass shell cannot grow, some diatom cells get progressively smaller with each succeeding generation. When a diatom is a small fraction of its original size, sexual reproduction is triggered, with the production of shell-less gametes. Sexual reproduction restores the diatom to its original size because the resulting zygote grows substantially before producing a new shell.

Diatoms are common in fresh water, but they are especially abundant in relatively cool ocean water. They are major producers in aquatic ecosystems because of their extremely large numbers. When diatoms die, their shells trickle down to the ocean floor and accumulate in layers that eventually become sedimentary rock. After millions of years, some of these deposits have been exposed on land by geological upheaval. Called diatomaceous earth, these deposits are mined and used as filtering, insulating, and soundproofing material. As a filtering agent, diatomaceous earth is used to refine raw sugar and to process vegetable oils. Because of its abrasive properties, diatomaceous earth is a common ingredient in scouring powders and metal polishes; it is no longer added to most toothpastes because it is too abrasive for tooth enamel. The intricately detailed diatom shells are often used to test microscope resolution down to 1 μm .

Most golden algae are flagellated, unicellular organisms

Golden algae (phylum Chrysophyta) are a complex group found in both freshwater and marine environments. Most species are biflagellated, unicellular organisms, although some are colonial (Fig. 24–11*a*). A few lack flagella and are similar to amoebas in appearance except that they contain chloroplasts. Cells may be covered by tiny scales of either silica or calcium carbonate. Reproduction in golden algae is primarily asexual and involves the production of flagellated, motile spores called **zoospores**.

Most golden algae are photosynthetic and produce the same pigments as diatoms: chlorophyll *a*, chlorophyll *c*, and carotenoids, including fucoxanthin. The pigment composition of golden algae gives them a golden or golden brown color. As in diatoms, energy reserves are stored as oils or carbohydrates. A few species ingest bacteria and other particles of food. Ecologically, golden algae are an important group of producers in marine environments. They comprise a significant portion of the ocean's **nanoplankton**, extremely minute algae that are major producers because of their great abundance.

Classification of golden algae is controversial. Some biologists lump diatoms and golden algae in a single phylum, whereas others think they should be classified as brown algae (discussed shortly). At the other extreme, some biologists divide the golden algae into two phyla by placing many of the marine species, such as **coccolithophorids** (Fig. 24–11*b*), in a separate phylum.

(a)

Figure 24–12 Brown algae. (a) *Laminaria* sp. is a representative brown alga. Note its blade, stipe, and holdfast, all of which are visible in this photograph because this individual was removed from the water. Species of *Laminaria* are widely distributed on rocky coastlines of temperate and polar seas. (b) A kelp bed off the coast of California. These underwater forests are ecologically important, supporting large numbers of aquatic organisms. (a, J.R. Waaland/Biological Photo Service; b, Richard Herrmann)

(b)

Brown algae are multicellular seaweeds

Brown algae (phylum Phaeophyta) include the giants of the protist kingdom. All brown algae are multicellular and range in size from a few centimeters (an inch or so) to approximately 75 m (250 ft) in length. Their body forms may be branched filaments, tufts, “fleshy ropes,” or thick, flattened branches. The largest brown algae, called kelps, are tough and leathery in appearance; many kelps possess leaflike **blades**, stemlike **stipes**, and rootlike anchoring **holdfasts** (Fig. 24–12a). They often have gas-filled floats (*bladders*) that provide buoyancy. (The blades, stipes, and holdfasts of brown algae are not homologous to the leaves, stems, and roots of plants. Brown algae and plants arose from different unicellular ancestors.)

Brown algae are photosynthetic and possess chlorophyll *a*, chlorophyll *c*, and carotenoids, including fucoxanthin, in their chloroplasts. The main energy storage reserve in brown algae is a carbohydrate called *laminarin*.

Reproduction is varied and complex in the brown algae. Their reproductive cells, both asexual zoospores and sexual gametes, are usually flagellated. Most have life cycles with an **al-**

ternation of generations, in which they spend a portion of their life cycles as haploid organisms and a portion as diploid organisms (see Fig. 9–12c).

Brown algae are commercially important for several reasons. Their cell walls contain a polysaccharide called algin that possibly helps cement the cell walls of adjacent cells together. Algin is used as a thickening and stabilizing agent in ice creams, marshmallows, toothpastes, shaving creams, hair sprays, and hand lotions. Brown algae are an important human food, particularly in East Asian countries, and they are rich sources of certain vitamins and of minerals such as iodine. Brown algae are one source of the antiseptic tincture of iodine.

Brown algae are common in cooler marine waters, especially along rocky coastlines, where they can be found mainly in the intertidal zone or relatively shallow offshore waters. Kelps form extensive underwater “forests” called kelp beds (Fig. 24–12b). They are essential in that ecosystem for two reasons: they are the primary food producers and they provide habitats for many marine invertebrates, fish, and mammals. The diversity of life supported by kelp beds rivals that found in coral reefs. There is also an extensive population of floating brown

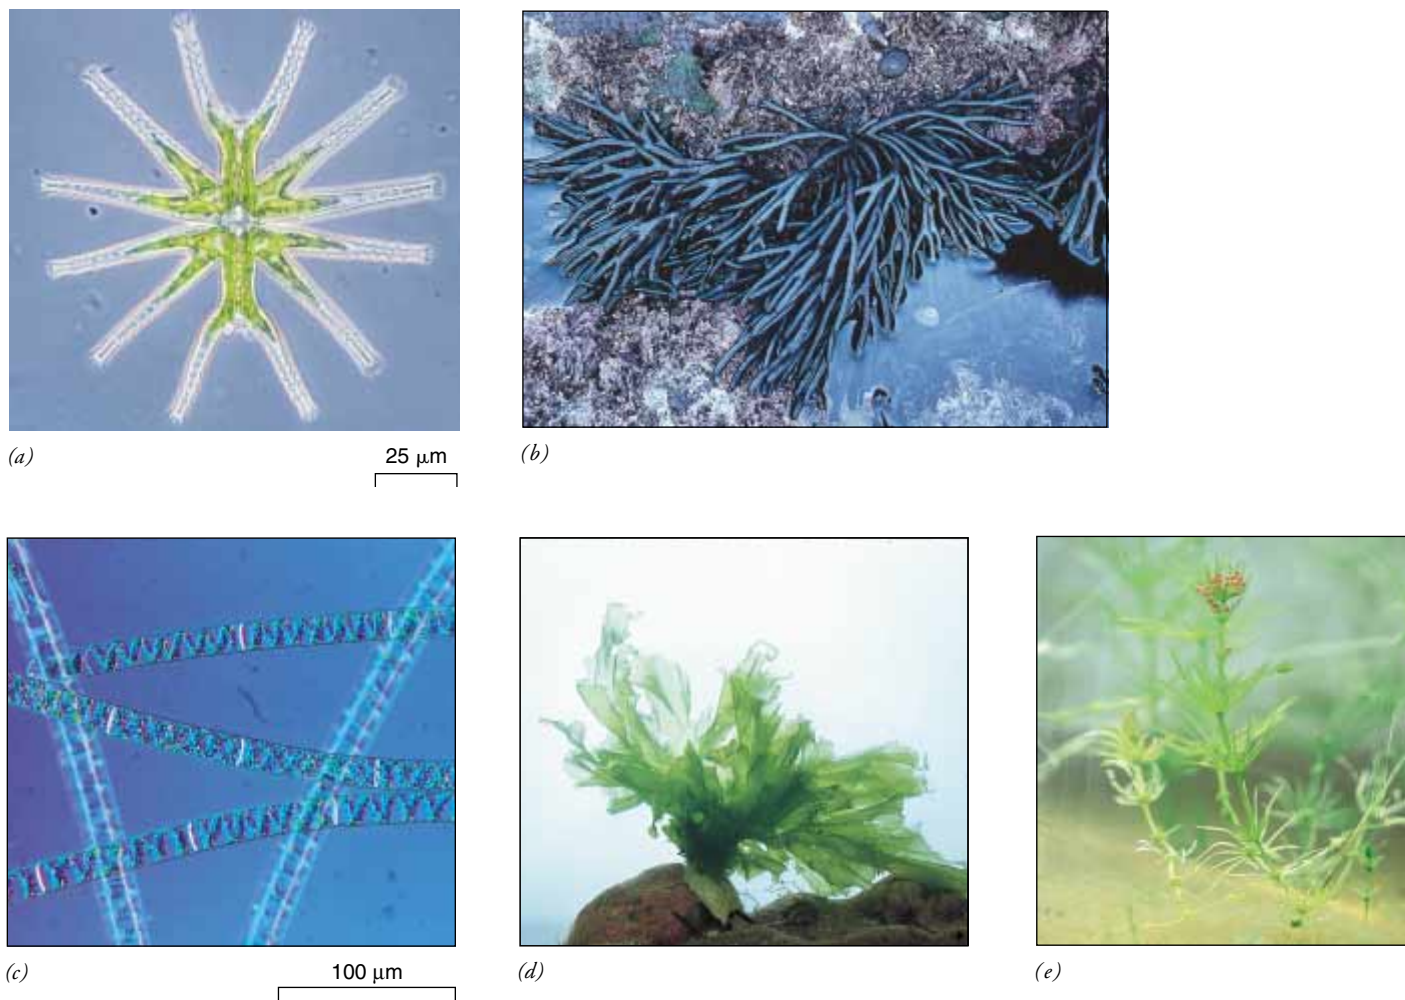

Figure 24 – 13 Green algae. (a) LM of a widely distributed desmid (*Micrasterias* sp.), a unicellular green alga with mirror-image halves. (b) Dead man's fingers (*Codium* sp.) exposed during low tide off Big Sur, California. A green alga like *Codium* is coenocytic. (c) Spiral-shaped chloroplasts visible in this LM are characteristic of *Spirogyra* sp., a widely distributed, multicellular green alga with a filamentous body form. (d) Some multicellular green algae are sheetlike. The thin, leaflike form has given *Ulva* sp. its common name, "sea lettuce." (e) *Chara* sp, a green alga commonly called a stonewort, is closely related to plants. *Chara* is widely distributed in fresh water, where it grows to 30 cm (1 ft) or more. (a, Biophoto Associates; b, David J. Wrobel/Biological Photo Service; c, Brian Parker/Tom Stack & Associates; d, J.M. Kingsbury; e, James W. Perry)

algae in a central area of the North Atlantic Ocean called the Sargasso Sea, named for the brown alga *Sargassum*. (The Sargasso Sea is not greatly affected by the surface ocean currents rotating around the margins of the North Atlantic, and so the floating *Sargassum* remains there.)

Green algae share many similarities with plants

Green algae (phylum Chlorophyta) have pigments, energy reserve products, and cell walls that are chemically identical to those of plants. Green algae are photosynthetic, with chlorophyll *a*, chlorophyll *b*, and carotenoids present in chloroplasts

of a wide variety of shapes. Their main energy reserves are stored as starch. Most green algae possess cell walls with cellulose, although some lack walls. Because of these and other similarities, it is generally accepted that plants arose from ancestral green algae. Taxonomy of the green algae is currently under study, and research in ultrastructure (cell structure studied with the aid of electron microscopy), molecular biology, and biochemistry is providing insights into this extremely diverse group.

Green algae exhibit a variety of body types, from single cells to colonial forms, to coenocytic algae, to multicellular filaments and sheets (Fig. 24–13). The multicellular forms do not have cells differentiated into tissues, a characteristic that

Figure 24–14 Life cycle of *Chlamydomonas* sp. *Chlamydomonas*, a haploid green alga with two mating types, (+) and (–), that are visually indistinguishable, is an example of isogamous sexual reproduction. Both mating types reproduce asexually by mitosis; only the (–) strain is shown. During sexual reproduction, a (+) gamete fuses with a (–) gamete, forming a diploid zygote. Meiosis occurs, and four haploid cells emerge, two (+) and two (–).

separates them from plants. Most green algae are flagellated or produce flagellated cells during their life history, although a few are totally nonmotile.

Reproduction in the green algae is as varied as their body forms. Both sexual and asexual reproduction occur, and many green algae have life cycles with an alternation of generations. Asexual reproduction may be by cell division in single cells or by fragmentation in multicellular forms. Many green algae produce spores asexually by mitosis; if these spores are flagellated and motile, they are called zoospores (Fig. 24–14). Sexual reproduction in the green algae involves the formation of gametes in unicellular gametangia. Three types of sexual reproduction—**isogamous**, **anisogamous**, and **oogamous**—are recognized in green algae. If the two flagellated gametes that fuse are identical in size and appearance, sexual reproduction is said to be **isogamous** (Fig. 24–14). **Anisogamous** sexual reproduction involves the fusion of two flagellated gametes of different sizes (Fig. 24–15). Some green algae are **oogamous** and produce a nonmotile egg and a flagellated male gamete. In addition to sexual reproduction by the fusion of gametes, some green algae exchange genetic information by a form of conjugation, in which the genetic material of one cell passes into a recipient cell (Fig. 24–16).

Green algae can be found in both aquatic and terrestrial environments. Aquatic green algae primarily inhabit fresh water, although there are a number of marine species. Terrestrial green algae are restricted to damp soil, cracks in tree bark, and other moist places. Many of the green algae are symbionts with other organisms; some live as endosymbionts in body cells of invertebrates, and a few grow together with fungi as “dual organisms” called lichens (see Chapter 25). Regardless of where they live, green algae are ecologically important as the base of the food web.

Red algae do not produce motile cells

The vast majority of **red algae** (phylum Rhodophyta) are multicellular organisms, although there are a few unicellular species. The multicellular body form of red algae is commonly composed of complex, interwoven filaments that are delicate and feathery (Fig. 24–17*a*); a few red algae are flattened sheets of cells (Fig. 24–17*b*). Most multicellular red algae attach to rocks or other substrates by a basal holdfast. Reproduction in the red algae is remarkably complex, with an alternation of sexual and asexual stages. Although sexual reproduction is com-

Figure 24–15 Life cycle of *Ulva* sp. The green alga *Ulva* alternates between haploid and diploid multicellular generations, which are identical in overall appearance. The male and female haploid algae produce anisogamous gametes that fuse and subsequently develop into the diploid alga. Special cells in the diploid generation undergo meiosis to form haploid zoospores that develop directly into haploid forms, and the cycle continues.

mon, at no stage in the life history of red algae do any flagellated cells develop.

The chloroplasts of red algae contain **phycoerythrin**, a red pigment, and **phycocyanin**, a blue pigment, in addition to chlorophyll *a* and carotenoids. Their energy reserves are stored as *floridean starch*, a polysaccharide similar to glycogen. The red algae have the same pigment composition as the cyanobacteria (a group of photosynthetic eubacteria; see Chapter 23).

The cell walls of red algae often contain thick, sticky polysaccharides that are of commercial value. For example, agar is a polysaccharide extracted from certain red algae and used as a food thickener and culture medium (a substance on which to grow microorganisms and propagate some plants, such as orchids). Another polysaccharide extracted from red algae, car-

rageenan, is a food additive used to stabilize chocolate milk and to provide a thick, creamy texture to ice creams and other soft, processed foods. (A stabilizer keeps the texture uniform by preventing different ingredients from settling out.) Carageenan is also used to stabilize paints and cosmetics. Red algae are a source of vitamins (particularly A and C) and minerals for humans, particularly in Japan and other East Asian countries where they are eaten fresh, dried, or roasted in such traditional foods as sushi and nori.

The red algae are primarily found in warm tropical ocean waters, although a few species occur in fresh water and in soil. Some red algae incorporate calcium carbonate in their cell walls from the ocean waters (Fig. 24–17*c*). These coralline red algae are extremely important in building “coral” reefs and are possibly more important than coral animals in this process.

◀ **Figure 24–16 Conjugation in *Spirogyra* sp.** (Top) Filaments of two different mating types of *Spirogyra*, a haploid green alga, line up, and conjugation tubes grow between cells of the two filaments. (LM on bottom) The contents of one cell passes into the other through the conjugation tube. The two protoplasts (cells without their walls) then fuse and form a diploid zygote. Following a period of dormancy, the zygote undergoes meiosis, restoring the haploid condition. (Biophoto Associates)

SLIME MOLDS AND WATER MOLDS ARE FUNGUS-LIKE PROTISTS

Some protists superficially resemble fungi in that they are not photosynthetic, and some have bodies formed of threadlike structures called *hyphae*. However, fungus-like protists are not fungi for several reasons. Many of these protists have centrioles and produce cellulose as a major component of their cell walls, whereas fungi lack centrioles and have cell walls of chitin. We consider three groups of fungus-like protists: plasmodial slime molds, cellular slime molds, and water molds (see Table 24–1).

Plasmodial slime molds feed as multinucleate plasmodia

The feeding stage of a **plasmodial slime mold** (phylum Myxomycota) is a **plasmodium**, a multinucleate mass of cytoplasm that can grow to 30 cm (1 ft) in diameter (Fig. 24–18a). The

(a)

(b)

(c)

Figure 24–17 Red algae. (a) *Polysiphonia* sp., which is widely distributed throughout the world, has a highly branched body of interwoven filaments. (b) *Rhodymenia* sp., which is common in the Northern Hemisphere, has a flattened, branching body. (c) *Bossiella* sp., which is found in the Pacific Ocean, is a coralline red alga with a hard, brittle body encrusted with calcium carbonate. (a, Philip Sze/Visuals Unlimited; b, Richard H. Gross; c, D. Gotshall/Visuals Unlimited)

(a)

(b)

Figure 24–18 The plasmodial slime mold *Physarum polycephalum*. (a) The plasmodium of *P. polycephalum* is brightly pigmented. This naked mass of cytoplasm is multinucleate and feeds on bacteria and other microorganisms. (b) The reproductive structures of *P. polycephalum* are stalked sporangia. (a, b, R. Calentine/CBR Images)

plasmodium, which is slimy in appearance, streams over damp, decaying logs and leaf litter, often forming a network of channels that covers a larger surface area. As it creeps along, it ingests bacteria, yeasts, spores, and decaying organic matter.

When the food supply dwindles or there is insufficient moisture, the plasmodium crawls to an exposed surface and initiates reproduction. Stalked structures of intricate complexity and beauty usually form from the drying plasmodium (Fig. 24–18b). Within these structures, called **sporangia**, meiosis produces haploid **spores** that are extremely resistant to adverse environmental conditions.

When conditions become favorable again, the spores germinate, and a haploid reproductive cell emerges from each. This haploid cell may be biflagellate (called a *swarm cell*) or amoeboid (called a *myxamoeba*), depending on how wet the environment is; flagellated cells form in wet conditions. Swarm cells and myxamoebas act as gametes. Eventually two gametes

fuse to form a zygote with a diploid nucleus. The resultant diploid nucleus divides many times by mitosis, but the cytoplasm does not divide, so the result is a multinucleate plasmodium.

The plasmodial slime mold *Physarum polycephalum* is a model organism that has been used to study many fundamental biological processes, such as growth and differentiation, cytoplasmic streaming, and the function of the cytoskeleton.

Cellular slime molds feed as single amoeboid cells

Although organisms in the phylum Acrasiomycota are called **cellular slime molds**, their resemblance to the plasmodial slime molds is superficial. Indeed, they have much closer affinities with amoebas, as shown in Figure 24–1. During its feeding stage, each cellular slime mold is an individual amoeboid cell that behaves as a separate, solitary organism. Each cell creeps over rotting logs and soil or swims in fresh water, ingesting bacteria and other particles of food as it goes. Each cell has a haploid nucleus.

When moisture or food becomes inadequate, certain cells send out a chemical signal, cyclic AMP (see Fig. 3–25), that causes them to aggregate by the hundreds or thousands (Fig. 24–19a). During this stage the cells creep about for short distances as a single multicellular unit, called a **pseudoplasmodium**, or “slug” (Fig. 24–19b). Each cell of the slug retains its plasma membrane and individual identity. Eventually the slug settles and constructs a stalked fruiting body, which is a structure that bears spores (Fig. 24–19c). After being released, each spore opens, a single haploid amoeboid cell emerges, and the cycle repeats. This reproductive cycle is asexual, although sexual reproduction has been observed occasionally. There are no flagellated stages for most cellular slime molds.

The cellular slime mold *Dictyostelium discoideum* is a model organism for the study of cell differentiation. Its biology has been studied intensively, particularly as it relates to signal molecules, such as cyclic AMP, which are found in many organisms in addition to the cellular slime molds.

Water molds produce flagellated reproductive cells

Water molds (phylum Oomycota) were once classified as fungi because of their superficial resemblance. Both water molds and fungi have a body, termed a **mycelium**, that grows over organic material, digesting it and then absorbing the predigested nutrients. The threadlike **hyphae** that make up the mycelium in water molds are coenocytic; there are no cross walls, and the body is like one giant multinucleate cell. The cell walls of water molds may be composed of cellulose (as in plants), chitin (as in fungi), or both. Most biologists classify the water molds as protists rather than as fungi.

When food is plentiful and environmental conditions are favorable, water molds reproduce asexually (Fig. 24–20). A hyphal tip swells and a cross wall is formed, separating the hyphal tip from the rest of the mycelium. Within this structure,

(a) 50 μm

(b) 50 μm

(c) 100 μm

Figure 24–19 The cellular slime mold *Dictyostelium discoideum*. (a) Aggregation of amoeboid cells. (b) The aggregation organizes into a migrating pseudoplasmodium, called a slug, that eventually forms a stalked fruiting body. (c) The mature fruiting body releases spores, each of which opens to liberate an amoeboid cell. (a, b, c, Cabisco/Visuals Unlimited)

Figure 24–20 Life cycle of *Saprolegnia* sp. *Saprolegnia*, a water mold, reproduces both sexually by antheridia and oogonia, and asexually by zoosporangia.

tiny biflagellate zoospores form, each of which can develop into a new mycelium. When environmental conditions worsen, water molds initiate sexual reproduction. After fusion of male and female nuclei, a thick-walled **oospore** develops from the zygote. Water molds often overwinter as oospores.

Some water molds have played infamous roles in human history. For example, the Irish potato famine of the 19th century was precipitated by the water mold *Phytophthora infestans*, which causes late blight of potatoes. Because of several rainy, cool summers in Ireland in the 1840s, the water mold multiplied unchecked, causing potato tubers to rot in the fields. Since potatoes were the staple of the Irish peasants' diet, many people starved to death. Estimates of the number of deaths that resulted from the outbreak of this plant disease range from 250,000 to more than 1 million. The famine prompted a mass migration out of Ireland to such countries as the United States.

Late blight is still a problem today. Beginning in the late 1980s and 1990s, new strains of the water mold that causes it were reported in many states in the United States. The new strains have also appeared in parts of Canada, northern Europe, South America, Japan, South Korea, the Middle East, and Africa. These water mold strains are resistant to metalaxyl, the fungicide usually used to control the disease. Because today most people eat a varied diet, late blight is not expected to cause a famine, but it costs potato growers millions of dollars in lost crops.

THE EARLIEST EUKARYOTES WERE PROTISTS

Protists are thought to have been the first eukaryotic cells to evolve from ancestral prokaryotes. They appeared in the fossil record 1.9 to 2.1 billion years ago. A few protists with hardened shells, for example, diatoms and foraminiferans, produced abundant fossils. However, most ancient protists did not leave extensive fossil records because their bodies were too soft to leave permanent traces. Therefore, evolutionary studies of protists are based primarily on comparisons of present-day organisms, which contain many clues about their evolutionary history. Some of the most useful data for evolutionary interpretations come from electron microscopy, biochemistry, and molecular biology (see section on molecular comparisons among organisms in Chapter 17).

From an evolutionary perspective, one of the most interesting groups of modern-day protists are the **diplomonads**, which are zooflagellates that may have one of the more ancient lineages of extant (living) protists. Comparative ribosomal RNA sequencing has revealed that diplomonads such as *Giardia* (discussed earlier in the chapter) are more closely related to prokaryotes than are any other protists (see Fig. 24–1). Interestingly, *Giardia*'s cell structure—it possesses two haploid nuclei—suggests a partial explanation of how diploid eukaryotes may have arisen from haploid prokaryotes (Fig. 24–21).

Figure 24–21 *Giardia intestinalis*. Colorized TEM of *Giardia* reveals two nuclei; this suggests that *Giardia*'s ancestors may have been an intermediate stage in the evolution of diploidy in eukaryotic life cycles. *Giardia intestinalis* is a parasite that can live in the small intestines of many vertebrates, including humans. (E. White/Visuals Unlimited)

Some biologists hypothesize that the first eukaryotes possessed a single haploid nucleus. Most eukaryotes today possess a single diploid nucleus that is formed at some stage in the life cycle when two haploid nuclei fuse. Perhaps the ancestors of *Giardia* represent an intermediate stage in eukaryotic evolution when cells each possessed two haploid nuclei but fusion had not yet occurred:

Haploid prokaryote → eukaryote with single haploid nucleus → eukaryote with two haploid nuclei → eukaryote with single diploid nucleus

Giardia also lacks mitochondria, which suggests that the nucleus may have evolved earlier than other membrane-bounded organelles such as mitochondria. Some molecular data dispute this idea, however. *Giardia* sp. contains a gene that codes for a protein thought to be associated with mitochondria in other organisms. This information suggests that an ancestor of *Giardia* may have possessed mitochondria, which were somehow lost at a later time during its evolutionary history.

How did mitochondria and other membrane-bounded organelles arise? The **endosymbiont theory**, popularized since the 1960s by Lynn Margulis, suggests that certain eukaryotic organelles (mitochondria, chloroplasts, and perhaps even cilia and flagella) arose from symbiotic relationships between larger prokaryotes and smaller prokaryotes that lived within them (see Fig. 20–6). Chloroplasts are thought to have originated from photosynthetic prokaryotes, and mitochondria from aerobic bacteria.

Figure 24-22 Evolution of multicellularity. Multicellularity may have evolved in this sequence: unicellular → colonial → multicellular organisms. (a) SEM of *Chlamydomonas*, a biflagellated unicellular green alga. (b) LM of *Volvox*, a colonial green alga composed of up to 50,000 *Chlamydomonas*-like cells. New colonies can be observed inside the parental colony, which eventually breaks apart to release them. (a, Courtesy of T.K. Mauget/University of Maryland; b, James W. Richardson/CBR Images)

Multicellularity arose several times in the protist kingdom

Until recently, the timing of the origin of multicellularity during the Precambrian era has been uncertain, largely because of the scarcity of fossils. In the mid-1990s, however, hundreds of fossils of multicellular organisms were discovered in the Tuan-shan Formation in north China, which has been dated at 1.7 billion years old. The fossils, which range up to about 1 cm in length and resemble multicellular algae, with leaflike blades, stipes, and holdfasts, suggest that multicellularity arose at least 1.7 billion years ago.

Green algae, red algae, and brown algae are extant protist phyla with multicellular species. However, multicellular green algae have more in common with unicellular green algae than with other multicellular protists. Similarly, multicellular forms of both red and brown algae have little in common with each other or with the multicellular green algae. Because these groups are so different, it is likely that multicellularity arose several times within the kingdom Protista. That is, the multicellular green algae, red algae, and brown algae probably had different unicellular ancestors.

Studying the protists living today provides clues about how multicellularity may have arisen. Colonies, for example, may

have been transitional stages between unicellular organisms and multicellular organisms. *Chlamydomonas* is a unicellular green alga that uses two flagella for motility (Fig. 24-22a). The green algae also include a number of colonial species that consist of attached *Chlamydomonas*-like cells. For example, *Gonium* is a colonial green alga that consists of four *Chlamydomonas*-like cells, and *Pandorina* is a colonial organism composed of 16 to 32 *Chlamydomonas*-like cells. The largest colonies of *Chlamydomonas*-like cells—from 1000 to 50,000 cells—are in the genus *Volvox* (Fig. 24-22b). Specialization in cell structure and function occurs in the larger colonies. *Volvox* sp., which has some division of labor among the cells (for example, only some cells are capable of carrying out reproduction), approaches multicellularity in complexity.

The **volvocine line** (the series of *Chlamydomonas*-like organisms just discussed) is an evolutionary dead end; that is, it did not give rise to multicellular green algae. However, the trend in increasing colony size and cell differentiation within the volvocine line indicates one possible way that multicellularity may have originated:

Single cells → colonies → multicellular organisms

S U M M A R Y W I T H K E Y T E R M S

- I. Kingdom Protista is composed of “simple” eukaryotic organisms, most of which are unicellular and live in aquatic environments.
 - A. **Protists** range in size from microscopic single cells to multicellular organisms 75m long.
 - B. Protists obtain their nutrients autotrophically or heterotrophically.
 - C. Protists may be free-living or symbiotic, with symbiotic relationships ranging from mutualism to parasitism.
 - D. Many protists reproduce both sexually and asexually; others reproduce only asexually.
 - E. Protists have various means of locomotion, including pseudopodia, flagella, and cilia. A few are nonmotile.
- II. **Protozoa** are heterotrophic, animal-like protists.
 - A. **Amoebas** move and obtain food using cytoplasmic extensions called **pseudopodia**.
 - B. **Foraminiferans** secrete many-chambered **tests** (shells) with pores through which cytoplasmic projections extend to move and obtain food.
 - C. **Actinopods** obtain food by means of **axopods**, slender cytoplasmic projections that extend through pores in their skeletons.
 - D. **Zooflagellates** are heterotrophic protozoa that move by means of whiplike **flagella**.
 - E. **Ciliates** move by hairlike **cilia**, have **micronuclei** (for sexual reproduction) and **macronuclei** (for controlling cell metabolism and growth), and undergo complex reproduction.
 - F. **Apicomplexans** are parasites that produce **spores** and are nonmotile. An apicomplexan causes malaria.
- III. **Algae** are autotrophic, plantlike protists.
 - A. **Euglenoids** are unicellular, flagellated algae. Many are not photosynthetic.
 - B. **Dinoflagellates** are mostly unicellular, biflagellated, photosynthetic organisms of great ecological importance as major producers in marine ecosystems. Some dinoflagellates produce toxic blooms known as red tides.
 - C. **Diatoms**, which are major producers in aquatic ecosystems, are mostly unicellular, with shells containing silica.
 - D. **Golden algae** are mostly unicellular, biflagellated freshwater and marine algae that are of ecological importance as a major component of the ocean’s nanoplankton.
 - E. **Brown algae** are multicellular seaweeds that are ecologically important in cooler ocean waters. They produce flagellated cells during their complex reproductive cycles.
 - F. **Green algae** exhibit a wide diversity in size, structural complexity, and reproduction. They share many similarities with plants, and it is thought that ancestral green algae gave rise to plants.
 - G. **Red algae**, which are mostly multicellular seaweeds, are ecologically important in warm tropical ocean waters. They lack motile cells and have complex reproductive cycles.
- IV. Fungus-like protists were originally classified with the fungi but have several protist features.
 - A. The feeding stage of **plasmodial slime molds** is a multinucleate **plasmodium**. Reproduction is by spores.
 - B. **Cellular slime molds** feed as individual amoeboid cells. They reproduce by aggregating into a **pseudoplasmodium** (slug), then forming asexual spores.
 - C. **Water molds** have a **coenocytic mycelium**. They reproduce asexually by forming biflagellate **zoospores** and sexually by forming **oospores**.
- V. Protists originated about 2.1 billion years ago and were the first eukaryotes.
 - A. Based on RNA sequencing data and cell ultrastructure studies, it is thought that **diplomonads**, which are a group of zooflagellates, may have one of the more ancient lineages of extant protists.
 - B. Some of the earliest fossils of multicellular organisms, dated at 1.7 billion years, were discovered in the Tuanshanzi Formation in north China. The fossils resemble multicellular algae.
 - C. Multicellularity probably evolved several times within the kingdom Protista, possibly by following a trend in greater complexity from single cells to colonies to multicellular organisms, as represented by the **volvocine line**.

P O S T - T E S T

1. Amoebas move and obtain food by means of (a) pseudopodia (b) flagella (c) cilia (d) gametangia (e) trichocysts
2. Foraminiferans (a) are endosymbionts in many marine invertebrates (b) were responsible for the Irish potato famine in the 19th century (c) secrete many-chambered tests with pores through which cytoplasmic extensions project (d) possess numerous trichocysts that may aid in trapping and holding prey (e) contain phycocyanin and phycoerythrin, pigments found in no other protist group
3. Unicellular protozoa that are free-living or parasitic, move by means of flagella, and do not photosynthesize are called (a) euglenoids (b) dinoflagellates (c) myxamoebas (d) zooflagellates (e) apicomplexans
4. *Paramecium* and other ciliates often display a sexual phenomenon called (a) oogamy (b) conjugation (c) anisogamy (d) red tide (e) macronucleus
5. Parasitic protozoa that form spores at some stage in their life belong to which group? (a) actinopods (b) ciliates (c) coccolithophorids (d) apicomplexans (e) dinoflagellates
6. Algae characterized by two flagella, one wrapped around the center of the cell like a belt and the other projecting behind the cell, are known as (a) actinopods (b) ciliates (c) coccolithophorids (d) apicomplexans (e) dinoflagellates
7. Photosynthetic protists with shells composed of two halves that fit together like a petri dish are known as (a) golden algae (b) diatoms (c) euglenoids (d) brown algae (e) foraminiferans
8. Chlorophyll *a*, chlorophyll *b*, and carotenoids are found in (a) green algae, red algae, and plants (b) green algae, euglenoids, and plants (c) brown algae, green algae, and golden algae (d) brown algae, diatoms, and golden algae (e) green algae, euglenoids, and diatoms
9. Which protists have photosynthetic pigments similar to those of the cyanobacteria? (a) golden algae (b) diatoms (c) euglenoids (d) brown algae (e) red algae
10. The multicellular bodies of _____ are differentiated into blades, stipes, holdfasts, and gas-filled floats. (a) golden algae (b) diatoms (c) euglenoids (d) kelps (e) green algae

REVIEW QUESTIONS

1. What are the features of a typical protist? Why are protists so difficult to classify?
2. Why are protists important to humans? How are they important ecologically?
3. What are the three main informal groups of protists? Describe and give at least three examples from each group.
4. Distinguish among amoebas, foraminiferans, and actinopods, and among zooflagellates, ciliates, and apicomplexans.
5. Distinguish among dinoflagellates, diatoms, golden algae, and euglenoids, and among green algae, red algae, and brown algae.
6. Distinguish among plasmodial slime molds, cellular slime molds, and water molds. What features do they share?
7. How is the structure of each of the following types of protists related to its way of life? (a) zooflagellates (b) green algae (c) water molds
8. Use the volvocine line to explain how multicellularity may have arisen within the protists.
9. Discuss the uncertainties surrounding the evolutionary relationships between the protists and the other eukaryotic kingdoms.
10. Label the diagram. Use Fig. 24–6b to check your answers.

YOU MAKE THE CONNECTION

1. Some biologists still classify the protozoa as animals, the algae as plants, and the water molds as fungi. Explain their rationale. Why do most biologists classify these organisms as protists?
2. Molecular analyses of DNA sequences in plant chloroplasts and in free-living cyanobacteria are compellingly similar. How do these data support the endosymbiont theory?

CHAPTER 25

Kingdom Fungi

Mushrooms, morels, and truffles, delights of the gourmet, have much in common with the black mold that forms on stale bread and the mildew that collects on damp shower curtains. These life forms belong to the kingdom Fungi, a diverse group of more than 81,000 known species, most of which are terrestrial. Although they vary strikingly in size and shape, all **fungi** (sing. *fungus*) are eukaryotes; their cells contain membrane-bounded nuclei, mitochondria, and other organelles. Like the cells of bacteria, certain protists, and plants, fungal cells are enclosed by cell walls during at least some stage in their life cycle. Fungal cell walls, however, have a different chemical composition than cell walls of other organisms. In most fungi, the cell wall is composed of complex carbohydrates, including **chitin**, a polymer that consists of subunits of a nitrogen-containing sugar (see Fig. 3–10). Chitin, which is coincidentally a component of the external skeletons of insects and other arthropods, is far more resistant to breakdown by microorganisms than are cellulose and lignin, which make up plant cell walls.

Fungi lack chlorophyll and are nonphotosynthetic. As heterotrophs, they cannot produce their own organic materials from a simple carbon source (carbon dioxide) but instead obtain preformed carbon molecules produced by other organisms. Fungi, however, do not ingest food as animals do, but secrete digestive enzymes and then absorb the predigested food (as small organic molecules) through their cell walls and plasma membranes. They obtain their nutrients from dead organic matter (as decomposers) or from other living organisms (as parasites). As decomposers, fungi, along with the bacteria (see Chapter 23), play an important ecological role.

Fungi grow best in moist habitats, but they are found universally wherever organic material is available. They require moisture to grow, and they can obtain water from a humid atmosphere as well as from the medium on which they live. When the environment becomes extremely dry, fungi survive by going into a resting stage or by producing spores that are resistant to desiccation (drying out). The rounded earthstar (*Geastrum saccatum*) shown in the photograph, for example, releases a puff of microscopic spores after the sac wall is hit by a raindrop. This fungus is common in leaf litter under trees.

Although the optimum pH for most species is about 5.6, different fungi can tolerate and grow in environments where the pH ranges from 2 to 9. Many fungi are less sensitive to high osmotic pressures than are bacteria. As a result, they can grow in concentrated salt solutions, or in sugar solutions such

(Jeff Lepore/Photo Researchers, Inc.)

as jelly, that discourage or prevent bacterial growth. Fungi may also thrive over a wide temperature range. Even refrigerated food is not immune to fungal invasion.

Fungi were classified originally in the plant kingdom, but biologists today recognize that they are not plants, and recent studies suggest that fungi are related more closely to animals than to plants. Because fungi are distinct from plants, animals, and protists in many ways, they are assigned to a separate kingdom.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Describe the distinguishing characteristics of the kingdom Fungi.
2. Describe the body plan of most fungi.
3. Trace the fate of a fungal spore that lands in an appropriate location, such as an overripe peach, and describe conditions that permit fungal growth.
4. Explain why biologists think chytridiomycetes may have been the earliest fungal group to have evolved from the flagellated protist hypothesized as the common ancestor of fungi.
5. List distinguishing characteristics, describe a typical life cycle, and give examples of each of the following fungal groups: chytridiomycetes, zygomycetes, ascomycetes, basidiomycetes, and imperfect fungi.
6. Characterize the unique nature of a lichen.
7. Explain the ecological significance of fungi as decomposers.
8. Describe the special ecological role of mycorrhizae.
9. Summarize the various uses of fungi.
10. Identify at least three fungal diseases of plants and three of animals.

MOST FUNGI HAVE A FILAMENTOUS BODY PLAN

The vegetative (nonreproductive) body plan of most fungi consists of long, branched, threadlike filaments called **hyphae** (sing., *hypha*) (Fig. 25–1*a,b*). Hyphae form a tangled mass or tissue-like aggregation known as a **mycelium** (pl., *mycelia*). The cobweb-like mold sometimes seen on bread is the mycelium of a fungus. What is not seen is the extensive mycelium that grows down into the bread.

Some hyphae are **coenocytic**; that is, they are not divided into individual cells and are instead an elongated, multinucleated giant cell (Fig. 25–1*c*). Other hyphae are divided by cross walls called **septa** (sing., *septum*) into individual cells containing one or more nuclei (Fig. 25–1*d,e*). The septa of many sep-

tate fungi are perforated by a pore that may be large enough to permit organelles to flow from cell to cell. Cytoplasm flows within the hypha, providing a system of internal transport.

MOST FUNGI REPRODUCE BY SPORES

Most fungi reproduce by means of microscopic **spores**, which are nonmotile reproductive cells dispersed by wind, water, or animals. Spores are usually produced on specialized aerial hyphae or in fruiting structures. This arrangement permits the spores to be more easily dispersed. The aerial hyphae of some fungi form large, complex reproductive structures, called **fruiting bodies**, in which spores are produced. The familiar part of a mushroom or toadstool is a large fruiting body. We do

Figure 25–1 The fungus body plan. (a) A fungal mycelium growing on agar in a culture dish. In nature, fungal mycelia are rarely so symmetrical. (b) SEM of a mycelium, which consists of a mass of threadlike hyphae. (c) A coenocytic hypha. (d) A hypha divided into cells by septa; each cell is monokaryotic (has one nucleus). In some taxa the septa are perforated (as shown), permitting cytoplasm to stream from one cell to another. (e) A septate hypha in which each cell is dikaryotic (has two genetically distinct nuclei). (a, Dennis Drenner; b, G.T. Cole, University of Texas/BPS)

Figure 25–2 Germination of a spore to form a mycelium.

not normally see the bulk of the fungus, a nearly invisible mycelium buried out of sight in the rotting material or soil on which it grows.

Fungi may produce spores either sexually or asexually. Unlike most animal and plant cells, fungal cells usually contain haploid nuclei. In sexual reproduction, the hyphae of two genetically compatible mating types come together, and their cytoplasm and nuclei fuse, forming a diploid cell known as a **zygote**.¹ In two fungal groups, the ascomycetes and basidiomycetes, the hyphae fuse, but the two different nuclei do not fuse immediately; rather, they remain separate within the fungal cytoplasm. Hyphae that contain two genetically distinct, sexually compatible nuclei within each cell are **dikaryotic**, a condition that is described as $n + n$ rather than $2n$ because there are two separate haploid nuclei. Hyphae that contain only one nucleus per cell are said to be **monokaryotic**.

¹In certain fungi (*Allomyces*, for example), zygotes are typically formed by the union of two haploid gametes rather than two haploid nuclei in compatible hyphae.

When a fungal spore comes into contact with an appropriate food source, perhaps an overripe peach that has fallen to the ground, it germinates and begins to grow (Fig. 25–2). A threadlike hypha emerges from the tiny spore and grows, branching frequently. Soon a mycelium infiltrates the peach, degrading its organic compounds to small molecules that the fungus can absorb. Fungi are extremely efficient at converting nutrients into new cell material. If excessive amounts of nutrients are available, fungi are able to store them, usually as lipid droplets or glycogen, in the mycelium.

FUNGI HAVE EVOLVED A VARIETY OF SPORES AND FRUITING BODIES

Classification of fungi traditionally was based mainly on the characteristics of their sexual spores and fruiting bodies, but molecular data, such as comparative DNA and RNA sequences, are playing an increasingly important role in determining relationships among fungi. Most biologists assign these diverse organisms to five phyla: Chytridiomycota, Zygomycota, Ascomycota, Basidiomycota, and Deuteromycota. Table 25–1 summarizes fungal classification. Slime molds and water molds were originally classified as fungi, but are now generally considered protists (see Chapter 24).

Chytridiomycetes are the most primitive fungi

Until recently, **chytridiomycetes** (phylum Chytridiomycota), also called *chytrids*, were considered by most biologists to be fungus-like protists similar in many respects to the water molds (see Chapter 24). However, molecular comparisons, particularly of DNA and RNA sequences, have provided compelling evidence that the approximately 750 species of chytridiomycetes are closely allied to fungi and not closely related to

TABLE 25–1 Phyla of Kingdom Fungi

Phylum	Common Types	Asexual Reproduction	Sexual Reproduction
Chytridiomycota (chytridiomycetes)	<i>Allomyces</i>	Zoospores	Flagellated gametes in some chytrids
Zygomycota (zygomycetes)	Black bread mold	Nonmotile spores form in a sporangium	Zygospores
Ascomycota (ascomycetes or sac fungi)	Yeasts, powdery mildews, molds, morels, truffles	Conidia pinch off from conidiophores	Ascospores
Basidiomycota (basidiomycetes or club fungi)	Mushrooms, bracket fungi, puffballs, rusts, smuts	Uncommon	Basidiospores
Deuteromycota (deuteromycetes or imperfect fungi)	Molds	Conidia	Sexual stage not observed

Figure 25–3 Fungal evolution. This diagram shows phylogenetic relationships among living fungi, based on current scientific evidence.

water molds or other fungus-like protists. The molecular evidence also indicates that chytridiomycetes, which are small, relatively simple aquatic fungi, are the most primitive group of fungi living today; *primitive* in this context implies that chytridiomycetes were probably the earliest fungal group to evolve from the ancient flagellated protist that has been hypothesized as the common ancestor of all fungi. Chytridiomycetes, which produce flagellated cells at some stage in their life history, have presumably retained this feature of their protist ancestor. All other fungal phyla are nonflagellated and apparently lost the ability to produce motile cells at some point in their evolutionary past, perhaps during the transition from aquatic to terrestrial habitats (Fig. 25–3).

Chytridiomycetes are parasites or decomposers that are found principally in fresh water, although a few species occur on land (in moist environments) and in marine water. Like other fungi, chytridiomycetes have cell walls containing chitin and store their food reserves as glycogen. Their motile cells possess a single, posterior flagellum. They reproduce both sexually and asexually.

One common chytridiomycete is *Allomyces*, which has an unusual life cycle compared to most fungi because it has an **alternation of generations**, spending part of its life as a haploid (n) **thallus** and part as a diploid ($2n$) thallus (Fig. 25–4). (The term *thallus* is used to describe the simple body plan of certain algae, fungi, or plants.) The haploid and diploid thalli are similar in appearance and consist of a stout trunklike part with slender branches. The haploid thallus bears male and female **gametangia**, which are structures in which gametes are formed, at the tips of the branches. When a flagellated male gamete fuses with a slightly larger, flagellated female gamete, the resulting zygote develops into a diploid thallus. The diploid thallus bears two kinds of spore cases, zoosporangia and resting sporangia. Zoosporangia produce flagellated diploid **zoospores** that may settle down and develop into new diploid

thalli. Meiosis occurs within resting sporangia to form haploid zoospores, each of which has the potential to settle down and develop into a haploid thallus.

Zygomycetes reproduce sexually by forming zygospores

About 800 species of **zygomycetes** (phylum Zygomycota) produce sexual spores, called **zygospores**. Their hyphae are coenocytic; that is, they lack regularly spaced septa. Septa do form, however, to separate the hyphae from reproductive structures. Most zygomycetes are decomposers that live in the soil on decaying plant or animal matter, although some are parasites of plants and animals and others are mycorrhizal fungi (discussed shortly).

One common zygomycete is the black bread mold, *Rhizopus stolonifer*, a decomposer that breaks down bread and other foods (Fig. 25–5). If preservatives are not added, bread left at room temperature often becomes covered with a black, fuzzy growth in a few days. Bread becomes moldy when a spore falls on it and then germinates and grows into a mycelium. Hyphae penetrate the bread and absorb nutrients. Eventually, certain hyphae grow upward and develop spore sacs called **sporangia** (sing., *sporangium*) at their tips. Clusters of black asexual spores develop within each sporangium and are released when the delicate sporangium ruptures. The spores give the black bread mold its characteristic color.

Sexual reproduction in the black bread mold occurs when the hyphae of two different mating types, designated as plus (+) and minus (–), grow into contact with one another. The bread mold is **heterothallic**, meaning that an individual fungal hypha is self-sterile and mates only with a hypha of a different mating type. That is, sexual reproduction occurs only between a member of a (+) strain and one of a (–) strain, not between members of two (+) strains or members of two (–)

Figure 25-4 The life cycle of *Allomyces arbuscula*. (Top) *Allomyces* alternates between haploid and diploid stages, which are similar in appearance. The haploid thallus gives rise to male and female gametes that fuse and subsequently develop into the diploid thallus. Meiosis occurs in the diploid resting sporangia to form haploid zoospores that develop into haploid thalli, and the cycle continues. (Bottom) *Allomyces* also reproduces asexually by forming diploid zoospores.

strains. Because there are no physical differences between the two mating types, it is not appropriate to refer to them as “male” and “female.”

When hyphae of opposite mating types grow in close proximity, hormones are produced that cause the tips of the hyphae to come together and form specialized sexual structures known as gametangia. These structures then unite, and the (+) and (−) nuclei fuse to form a diploid nucleus, the zygote. A zygospore develops, consisting of a thick protective covering around the zygote. The zygospore may lie dormant for several months and can survive desiccation and extreme temperatures. Meiosis probably occurs at or just before germination of the zygospore. When the zygospore germinates, an aerial

hypha develops with a haploid sporangium at the tip. Mitosis within the sporangium produces haploid spores that are released and that may germinate to form new hyphae. Only the zygote of a black bread mold is diploid; all of the hyphae and the asexual spores are haploid.

Ascomycetes reproduce sexually by forming ascospores

Ascomycetes (phylum Ascomycota) comprise a large group of fungi consisting of about 30,000 described species. Ascomycetes are sometimes referred to as *sac fungi* because their sexual spores are produced in microscopic sacs called **asci**

Figure 25-5 The life cycle of the black bread mold (*Rhizopus stolonifer*). (Top) Asexual reproduction involves the formation of haploid spores. (Bottom) Sexual reproduction takes place only between different mating types, designated (+) and (-). After their hyphae meet and the nuclei fuse, a zygospore develops (inset, stained LM). (Inset, Ed Reschke)

FOCUS ON

FIGHTING CHESTNUT BLIGHT

Prior to the twentieth century, the American chestnut (*Castanea dentata*) was a very important tree, both ecologically and economically, in eastern forests. Throughout its natural range, which extended from Maine to Georgia and west to Illinois, the chestnut tree provided food and shelter for forest animals, including squirrels, birds, and insects. The tree grew rapidly, forming a straight, tall trunk that provided valuable, decay-resistant wood for house foundations and interior trim, furniture, railroad ties, and fence posts. The wood was also an important source of tannin, which is a chemical used to convert animal hides into leather. The edible nuts of the American chestnut were harvested, roasted, and eaten directly or ground into flour.

Early in this century the chestnut blight fungus (*Cryphonectria parasitica*), an ascomycete, was accidentally imported on diseased oriental chestnuts and quickly attacked native chestnuts, which had no resistance to the fungus. First identified in New York in 1904, the blight had killed or dam-

aged several billion mature trees—almost every North American chestnut tree throughout its entire natural range—by the late 1940s (see figure).

A spore of the fungus enters a chestnut tree through a wound or crack in the bark, and the hyphae grow rapidly, attacking the inner bark. When the trunk is girdled (completely encircled) by the fungus, the portion of the plant above the injury dies. The fungus does not kill the roots, however, and they periodically produce new shoots, only to be killed back by the blight once again. The spores are carried by wind, water, and animals from tree to tree.

Although the American chestnut is on the brink of extinction, there are hopes for its eventual recovery. Some biologists have bred the American chestnut with the Chinese chestnut, a related species that is resistant to chestnut blight. With careful selective breeding over many years, it may be possible to develop a disease-resistant variety of American chestnut.

Some biologists are approaching the problem in a different way, by trying to isolate strains of the chestnut blight fungus that are less virulent (less deadly). A less virulent strain of the chestnut blight fungus was first identified in Europe in the 1950s; some of the trees there have been able to recover from the disease. More recently, a less virulent strain has appeared in the United States, and, even more encouraging, it appears that the less virulent strain is slowly spreading, replacing the more deadly strain. It is not known *why* the less virulent strain is replacing the more virulent one.

Biologists determined that the reduced virulence of the chestnut blight fungus is caused by the presence of a virus. They genetically engineered a synthetic form of the virus and introduced it into the virulent strain of the chestnut blight fungus, which subsequently lost its virulence. They plan to treat infected chestnut trees with the benign fungal strain, which they hope will spread rapidly and eventually replace the virulent strain.

American chestnuts. These massive trees, which were photographed in the late 1800s in the Great Smoky Mountains, and almost all other American chestnuts were killed by the chestnut blight fungus during the first part of the 20th century. (sing., *ascus*). Their hyphae usually have septa, but these cross walls have pores so that cytoplasm is continuous from one compartment to another.

The diverse ascomycetes include most yeasts; the powdery

mildews; most of the blue-green, pink, and brown molds that cause food to spoil; decomposer cup fungi; and the edible morels and truffles. Some ascomycetes cause serious plant diseases such as Dutch elm disease, ergot disease on rye, powdery

Figure 25–6 The life cycle of ascomycetes. (Top) Asexual reproduction involves the formation of haploid conidia. (Bottom) Sexual reproduction involves the fusion of two haploid hyphae of different mating types to form dikaryotic ($n + n$) hyphae from which asci develop. In each ascus the two nuclei fuse, followed by meiosis and mitosis to produce eight ascospores. The asci form the inner layer of a fruiting body called the ascocarp. Shown are ascocarps of the rainforest cup fungus (*Cookeina sulcipes*). (James L. Castner)

mildew on fruits and ornamental plants, and chestnut blight (see *Focus On: Fighting Chestnut Blight*).

In most ascomycetes, asexual reproduction involves production of spores called **conidia** (sing., *conidium*), which are formed at the tips of certain specialized hyphae known as **conidiophores** (from the Greek, meaning “dust-bearers”) (Fig. 25–6, top). Conidia are a means of rapidly propagating new

mycelia when environmental conditions are favorable. Conidia occur in various shapes, sizes, and colors in different species. The color of the conidia is responsible for the characteristic brown, blue-green, pink, or other tints of many of these molds.

Some species of ascomycetes are heterothallic and have different mating strains; others are **homothallic**, which means that they are self-fertile and have the ability to mate with them-

selves. In both heterothallic and homothallic ascomycetes, sexual reproduction takes place after two hyphae (or, in some species, gametangia) grow together and their cytoplasm mingles (Fig. 25–6, bottom). Within this fused structure, the two haploid nuclei, one from each parent hypha, pair but do not fuse. New hyphae, the cells of which are dikaryotic, develop from the fused structure and branch repeatedly until the hyphal tips reach the site where asci will be produced. As the many sac-shaped asci develop, each containing two dissimilar nuclei (one from each parent), they are surrounded by intertwining haploid (monokaryotic) hyphae that develop into a fruiting body known as an **ascocarp**.

Within a cell that develops into an ascus, the two nuclei fuse and form a diploid nucleus, the zygote that then undergoes meiosis to form four haploid nuclei. This process is usually followed by one mitotic division of each of the four nuclei, resulting in eight haploid nuclei. Each haploid nucleus becomes incorporated into a heavy-walled **ascospore**, so there are usually eight haploid ascospores within the ascus. The ascospores are released when the tip of the ascus breaks open. Individual ascospores are carried by air currents, often for long distances. If one lands in a suitable location, it germinates and forms a new mycelium.

Phylum Ascomycota includes more than 300 species of unicellular **yeasts** (Fig. 25–7). Asexual reproduction of yeasts is mainly by **budding**; in this process a small protuberance (bud) grows and eventually separates from the parent cell. Each bud can grow into a new yeast cell. Some yeasts also reproduce asexually by fission and sexually by forming ascospores. During sexual reproduction, two haploid yeasts fuse, forming a diploid zygote. The zygote undergoes meiosis, and the re-

Figure 25–7 LM of baker's yeast (*Saccharomyces* sp.). These unicellular ascomycetes possess mitochondria and carry out aerobic respiration when oxygen is present. In the absence of oxygen, yeasts carry out alcohol fermentation, which is used to produce alcohol and make bread rise. (Dwight R. Kuhn)

sulting haploid nuclei are incorporated into ascospores. These spores remain enclosed for a time within the original diploid cell wall, which corresponds to an ascus. Yeasts are essential in making bread and fermenting alcoholic beverages (discussed later in this chapter).

Basidiomycetes reproduce sexually by forming basidiospores

The 25,000 or more species of **basidiomycetes** (phylum Basidiomycota) include the most familiar of the fungi: the mushrooms, bracket fungi, and puffballs (Fig. 25–8). Some destructive plant parasites of important crops, such as wheat rust and corn smut, are also basidiomycetes. Basidiomycetes, sometimes called *club fungi*, derive their name from the fact that they develop microscopic club-shaped **basidia** (sing., *basidium*), structures comparable in function to the asci of ascomycetes. Each basidium is an enlarged hyphal cell, on the tip of which develop four **basidiospores**. Note that basidiospores develop on the *outside* of a basidium, whereas ascospores develop *within* an ascus.

Each individual fungus produces millions of basidiospores, and each basidiospore has the potential to give rise to a new **primary mycelium** (Fig. 25–9). Hyphae of a primary mycelium are composed of monokaryotic cells. The mycelium of a basidiomycete such as the cultivated mushroom, *Agaricus campestris*, consists of a mass of white, branching, threadlike hyphae that live mostly below ground. The hyphae are divided into cells by septa, but, as in ascomycetes, the septa are perforated and allow cytoplasmic streaming between cells.

When in the course of its growth a hypha of a primary mycelium encounters another monokaryotic hypha of a different mating type, the two hyphae fuse. As in the ascomycetes, the two haploid nuclei remain separate within each cell. In this way a dikaryotic **secondary mycelium** with dikaryotic hyphae is produced, in which each cell contains two haploid nuclei.

The $n + n$ hyphae of the secondary mycelium grow extensively and, when environmental conditions are favorable, form compact masses, called buttons, along the mycelium. Each button grows into a fruiting body that we call a mushroom. A mushroom, which consists of a stalk and a cap, is more formally referred to as a **basidiocarp**. Each basidiocarp consists of intertwined hyphae that are matted together. The lower surface of the cap usually consists of many thin perpendicular plates called **gills** that radiate from the stalk to the edge of the cap (Fig. 25–10a). On the gills of the mushroom, haploid nuclei of the dikaryotic cells within the young basidia fuse to form diploid zygotes. These are the only diploid cells that form during a basidiomycete's life history. Meiosis then takes place, forming four haploid nuclei that move to the outer edge of the basidium. Finger-like extensions of the basidium develop, into which the nuclei and some cytoplasm move; each of these extensions becomes a basidiospore. A septum forms that separates the basidiospore from the rest of the basidium by a delicate stalk that breaks when the basidiospore is forcibly discharged (Fig. 25–10b).

(b) A giant puffball (*Calvatia gigantea*) in White Plains, New York. At maturity, a dried-out puffball often has a pore through which the basidiospores are discharged as a puff of dust. (c) The stinkhorn (*Phallus ravenelii*) has a foul smell that attracts flies, which help disperse the slimy mass of basidiospores. (d) Bracket fungi (*Fomes* sp.) grow on both dead and living trees, producing shelflike fruiting bodies. Basidiospores are produced in pores located underneath each shelf. (a, Dennis Drenner; b, Ed Kanze/Dembinsky Photo Associates; c, Richard D. Poe/Visuals Unlimited; d, Richard H. Gross)

Imperfect fungi have no known sexual stage

About 25,000 species of fungi have been assigned to a *form phylum* referred to as the **deuteromycetes** (phylum Deuteromycota). Members of a form phylum are similar to one another in certain respects but probably do not share a common ancestry; that is, the group is polyphyletic (see Chapter 22). Deuteromycetes, also known as **imperfect fungi** because in

many of them no sexual stage has been observed at any point during their life cycle, are classified together simply as a matter of convenience. Should further study reveal a sexual stage, these species will be reassigned to a different phylum.

Increasingly, comparing DNA and/or RNA sequences among various species helps biologists determine relationships between imperfect fungi and their sexually reproducing relatives. Most imperfect fungi reproduce only by means of conidia and are closely related to the ascomycetes. A few appear to be more closely related to the basidiomycetes.

Figure 25–9 The life cycle of a typical basidiomycete. Sexual reproduction involves the fusion of two haploid hyphae of different mating types to form dikaryotic ($n + n$) hyphae from which basidia develop. In each basidium the two nuclei fuse, followed by meiosis to produce four basidiospores. In basidiomycetes in which the fruiting body is a mushroom, the basidia line the outer surfaces of the gills.

LICHENS ARE DUAL “ORGANISMS”

Although a **lichen** looks like a single organism, it is actually a symbiotic association between two organisms: a *phototroph* (a photosynthetic organism) and a fungus (Fig. 25–11*a*). (A symbiotic association is an intimate relationship between organisms of different species.) About 13,500 kinds of lichens have been described.

The phototrophic component of a lichen is either a green alga or a cyanobacterium. The fungus is most often an ascomycete, although in some tropical lichens the fungal partner is a basidiomycete. Most of the phototrophic organisms found in lichens also occur as free-living species in nature, but the fungal components are generally found only as a part of the lichen.

In the laboratory the fungal and phototrophic components can be isolated and grown separately in appropriate culture media. The phototroph grows more rapidly when separated, whereas the fungus grows more slowly and requires many complex carbohydrates. Neither organism resembles a lichen in appearance when grown separately. The phototroph and fungus can be reassembled as a lichen thallus, but only if they are

placed in a culture medium under conditions that cannot support either of them independently.

What is the nature of this partnership? The lichen was originally considered a definitive example of mutualism, a symbiotic relationship that is beneficial to both species. The phototroph carries on photosynthesis, producing food for both members of the lichen, but it is unclear how the phototroph benefits from the relationship. It has been suggested that the phototroph obtains water and minerals from the fungus as well as protection against desiccation. More recently some biologists have suggested that the lichen partnership is not really a case of mutualism but one of controlled parasitism of the phototroph by the fungus.

Lichens typically possess one of three different growth forms (Fig. 25–11*b*). *Crustose lichens* are flat and grow tightly against their substrate (the surface they are growing on); *foliose lichens* are also flat, but they have leaflike lobes and are not so tightly pressed to the substrate; *fruticose lichens* grow erect and have many branches.

Able to tolerate extremes of temperature and moisture, lichens grow in almost all terrestrial environments except polluted cities. They exist farther north than any plants of the arc-

Figure 25-10 Details of mushroom basidiocarps. (a) Interwoven hyphae from the vegetative mycelium form the basidiocarp commonly called a mushroom. Numerous basidia are borne along the gills. (b) SEM of a basidium. Each basidium produces four basidiospores. (Biophoto Associates)

tic region and are equally at home in the steaming equatorial rain forest. They grow on tree bark, leaves, and exposed rock surfaces, from solidified lava to tombstones. In fact, lichens are often the first organisms to inhabit rocky areas. Lichen growth in these areas plays an important role in the formation of soil from rock because they gradually etch tiny cracks in rock (see Chapter 52). This process sets the stage for further disintegration of the rock by wind and rain.

Reindeer mosses of the arctic region, which serve as the main source of food for migrating herds of caribou, are not mosses but lichens. Some lichens produce colored pigments. One of them, orchil, is used to dye woolens, and another, litmus, is widely used in chemistry laboratories as an acid-base (pH) indicator.

Lichens vary greatly in size. Some are almost invisible, whereas others, like the reindeer mosses, may cover kilometers of land with an ankle-deep growth. Growth proceeds slowly; the radius of a lichen may increase by less than one millimeter each year. Some mature lichens are thought to be thousands of years old.

Lichens absorb minerals mainly from the air, rainwater, and the surface on which they grow. They cannot excrete the elements they absorb, and perhaps for this reason they are extremely sensitive to toxic compounds. A reduction in lichen growth has been used as a sensitive indicator of air pollution,

particularly sulfur dioxide. In 1997, for example, Italian researchers were able to establish a relationship between lung cancer and air pollution by comparing the locations of low lichen biodiversity (and therefore of air pollution) with the locations of lung cancer deaths in young male residents. The return of lichens to an area indicates an improvement in air quality. (Recall from Chapter 1 that air pollution killed lichens on tree trunks in England, thereby affecting the evolution of peppered moths.)

Lichens reproduce mainly by asexual means, usually by fragmentation, a process in which special dispersal units of the lichen, called **soredia**, break off and, if they land on a suitable surface, establish themselves as new lichens. Soredia contain cells of both partners. In some lichens, the fungus produces ascospores, which may be dispersed by wind and find an appropriate algal partner only by chance.

FUNGI ARE ECOLOGICALLY IMPORTANT

Fungi make important contributions to the ecological balance of our world. Like bacteria, most fungi are **saprotrophs** (also called *saprobies*), decomposers that absorb nutrients from organic wastes and dead organisms. Unlike bacteria, many fun-

Figure 25–11 Lichens. (a) This cross section of a typical lichen shows distinct layers. The soredium (pl., *soredia*), an asexual reproductive structure, is composed of clusters of algal or cyanobacterial cells enclosed by fungal hyphae. (b) Lichens vary in color, shape, and overall appearance. Three growth forms—crustose, foliose, and fruticose—are shown. Crustose lichens grow tightly attached to tree trunks, rocks, and some other surfaces. Foliose lichens are leaflike in appearance, whereas fruticose lichens are branching and shrublike. (Fred M. Rhoades)

(b) These seedlings were grown under conditions identical to the control, except that their roots have formed mycorrhizal associations. (a, b, Courtesy of Randy Molina, U.S. Forest Service)

MAKING THE CONNECTION

FUNGI, FLOWERING PLANTS, AND MIMICRY

Do fungi ever resemble flowers? One of the most fascinating phenomena relating to living organisms is mimicry, in which, during the course of evolution, one organism comes to resemble another organism or an inanimate object (see Chapter 52). In 1993 the journal *Nature* reported an unusual example of mimicry that actually requires *two* different organisms, a fungus and a plant, to produce the deception.* The fungus (*Puccinia monoica*) is a plant parasite that causes a rust disease in rock cress (*Arabis holboellii*), a plant widely distributed across the northern part of North America.

When *Puccinia* infects rock cress, it doesn't kill the plant immediately, but it does change the plant's growth pattern. Infected plants grow much taller than normal and produce a cluster of leaves at the top of the plant. The fungal mycelium, which is bright yellow, grows over and covers these leaves, giving them the appearance of buttercup flowers (see figure). Even botany students have been fooled by the remarkable resemblance. The fungal mimicry is not only visual. The fungus also secretes a sugary solution and produces a strong scent, imitating the nectar and aroma of flowers (see Chapter 35).

What is the advantage of this elaborate mimicry? As you might guess, the answer involves the fungus' reproductive cycle. In the life cycles of flowers and *Puccinia monoica*, insects play the key role of increasing the chances of successful reproduction. The same characteristics that attract insects to real flowers also attract them to the fungal imitation.

In the case of flowers, the insects transfer pollen grains to the female part of another flower. In the case of *Puccinia*, a basidiomycete, sexual reproduction requires the union of nuclei from two different mating types. Insects, particularly flies, are attracted to the fungal "flowers," where they eat the sugary syrup. As the insects feed, pieces of the fungus cling to their bodies. Flying from one *Puccinia* "flower" to another, the insects distribute complementary mating types from fungus to fungus over a broad range. Thus, for the fungus, flower mimicry leads to better chances for its successful reproduction.

*Roy, B.A. "Floral Mimicry Induced by a Plant Pathogen." *Nature*, Vol. 362, 4 Mar. 1993.

A fungus (*Puccinia monoica*) that parasitizes rock cress (*Arabis holboellii*). As a result of this parasitic interaction, rock cress changes its growth habit and produces, with the fungus' help, fake flowers. The "flowers" are so realistic that they attract insect pollinators, which help the fungus (instead of the plant) reproduce. (Photograph by B.A. Roy, reprinted by permission from *Nature*, Vol. 362, cover and page 57)

gal saprotrophs are able to degrade cellulose and lignin, the main components of plant cell walls. When fungi degrade wastes and dead organisms, water, carbon (as CO₂), and mineral components of organic compounds are released, and these elements are recycled (see Chapter 53). Without this continuous decomposition, essential nutrients would soon become locked up in huge mounds of dead animals, feces, branches, logs, and leaves. The nutrients would be unavailable for use by new generations of organisms, and life would cease.

Although most fungi are saprotrophs, others form symbiotic relationships of various kinds. Some fungi are **parasites**, organisms that live in or on other organisms and are harmful to their hosts. Parasitic fungi absorb food from the living bod-

ies of their hosts. (See *Making the Connection: Fungi, Flowering Plants, and Mimicry* for an unusual example of a fungal parasite of a plant.)

Some types of fungi form mutualistic relationships with other organisms. **Mycorrhizae** (from Greek words meaning "fungus-roots") are mutualistic relationships between fungi and the roots of plants (Fig. 25–12; also see Fig. 34–11). Such relationships occur in more than 90% of all plant families. The mycorrhizal fungus benefits the plant by decomposing organic material in the soil and providing water and minerals such as phosphorus to the plant. At the same time, the roots supply sugars, amino acids, and other organic substances to the fungus.

*Source: Wilson, G.W.T., and D.C. Hartnett. "Effects of Mycorrhizae on Plant Growth and Dynamics in Experimental Tallgrass Prairie Microcosms." *American Journal of Botany*, Vol. 84, No. 4, 1997.

**Soil was treated with a fungicide to suppress mycorrhizal fungi.

The importance of mycorrhizae first became evident when horticulturalists observed that orchids do not grow unless an appropriate fungus lives with them. Similarly, it has been shown that many forest trees such as pines decline and eventually die from mineral deficiencies when transplanted to mineral-rich grassland soils that lack the appropriate mycorrhizal fungi. When forest soil containing the appropriate fungi or their spores is added to the soil around these trees, they quickly resume normal growth. Similar results were reported in 1997 for tallgrass prairie plant species with and without mycorrhizal fungi (Table 25–2).

FUNGI ARE ECONOMICALLY IMPORTANT

The same powerful digestive enzymes that enable fungi to decompose wastes and dead organisms also permit them to reduce wood, fiber, and food to their basic components with great efficiency. Thus, various fungi cause incalculable damage to stored goods and building materials each year. Bracket fungi, for example, cause enormous losses by decaying wood, both in living trees and in stored lumber.

Fungi cause economic gains as well as losses. People eat them and grow them to make various chemicals. At the other extreme, some fungi are harmful from a human perspective because they cause diseases in humans and other animals and are the most destructive disease-causing organisms of plants. Their activities cost billions of dollars in agricultural damage yearly.

Fungi provide beverages and food

The capability of yeasts to produce ethyl alcohol and carbon dioxide from sugars such as glucose by fermentation is exploited to make wine, beer, and other fermented beverages, and also to make bread. Wine is produced when yeasts ferment fruit sugars, and beer results when yeasts ferment sugars derived from starch in grains (usually barley). During the process of making bread, carbon dioxide produced by yeast becomes trapped in dough as bubbles, causing the dough to rise;

this is what gives leavened bread its light texture. Both the carbon dioxide and the alcohol produced by the yeast escape during baking (Fig. 25–13).

The unique flavor of cheeses such as Roquefort, Brie, Gorgonzola, and Camembert is produced by the action of species

Figure 25–13 Foods and beverages produced in part by fungi. Yeasts ferment sugars from fruits to make wine or from grains to make beer, producing ethyl alcohol. That same process produces the carbon dioxide bubbles responsible for making bread rise. The bluish areas in the cheese are patches of mycelium. (Raymond Tschoepe)

(a)

(b)

Figure 25–14 Edible ascomycetes. (a) The common morel (*Morchella esculenta*) and (b) the truffle (*Tuber* sp.) are expensive gourmet treats. Both are ascocarps that produce ascospores. Truffles are subterranean ascocarps that people find with the help of trained dogs or pigs. Here truffles are shown whole and sectioned. (a, Richard Shiell/Dembinsky Photo Associates; b, John D. Cunningham/Visuals Unlimited)

of *Penicillium* (Fig. 25–13). *Penicillium roquefortii*, for example, is found in caves near the French village of Roquefort; only cheeses produced in this area can be called Roquefort cheese. In Roquefort and certain other cheeses, the blue mycelium of the fungus is visible in the cheese.

Aspergillus tamarii and other imperfect fungi are used in the Orient to produce soy sauce by fermenting soybeans with the fungi for three or more months.² Soy sauce enriches other foods with more than just its special flavor. It also adds vital amino acids from both the soybeans and the fungi themselves to supplement the low-protein rice diet.

Among the basidiomycetes, there are some 200 kinds of edible mushrooms and about 70 species of poisonous ones, sometimes called toadstools. Some edible mushrooms are cultivated commercially. In fact, more than 350,000 metric tons (about 780 million pounds) are produced each year in the United States alone. The common mushroom (*Agaricus bisporus*) is the only fungal species grown extensively for food, although several exotic mushrooms, such as oyster, shiitake, portobello, and straw mushrooms, are becoming increasingly popular. Morels, which superficially resemble mushrooms, and truffles, which produce underground fruiting bodies, are ascomycetes (Fig. 25–14). These gourmet delights are now being cultivated as mycorrhizal fungi on the roots of tree seedlings.

Edible and poisonous mushrooms can look very much alike and may even belong to the same genus. There is no simple way to tell them apart; they must be identified by an expert. Some of the most poisonous mushrooms belong to the genus *Amanita* (Fig. 25–15). Toxic species of this genus have been appropriately called such names as “destroying angel”

(*Amanita virosa*) and “death cap” (*Amanita phalloides*). Eating a single mushroom of either species can be fatal.

Ingestion of certain species of mushrooms causes intoxi-

Figure 25–15 The destroying angel (*Amanita virosa*). This extremely poisonous mushroom is distinguished, as are other amanitas, by the ring of tissue around its stalk and the underground cup from which the stalk protrudes. About 50 grams (2 ounces) of this mushroom could kill an adult man. Initial symptoms include vomiting, diarrhea, and cramps. If the poisoning goes untreated, liver and kidney failure occur, resulting in death in five to ten days. (James W. Richardson/CBR Images)

²In the United States soy sauce is often made by adding flavoring to salt water rather than soaking fermented soybeans.

cation and hallucinations. The sacred mushrooms of the Aztecs, *Conocybe* and *Psilocybe*, are still used in religious ceremonies by Native Americans of Central America for their hallucinogenic properties. The chemical ingredient psilocybin, related to lysergic acid diethylamide (LSD), is responsible for the trances and visions experienced by those who eat these mushrooms. Ingestion of psychoactive mushrooms is not recommended, because negative reactions vary considerably, from mild indigestion, sweating, and heart palpitations, to death. In addition, the possession and use of such mushrooms are illegal in the United States.

Fungi produce useful drugs and chemicals

In 1928 Alexander Fleming noticed that one of his petri dishes containing a bacterial culture was contaminated by mold. The bacteria were not growing in the vicinity of the mold, leading Fleming to the conclusion that the mold was releasing some substance harmful to them. Within a decade or so of Fleming's discovery, penicillin produced by *Penicillium notatum* was purified and used in treating bacterial infections. Penicillin is still among the most widely used and effective antibiotics. Other drugs derived from fungi include the antibiotic griseofulvin (used clinically to inhibit the growth of fungi), lovastatin (used to lower blood cholesterol levels), and cyclosporine (used to suppress immune responses in patients receiving organ transplants).

The ascomycete *Claviceps purpurea* infects the flowers of rye plants and other cereals. It produces a structure called an *ergot* where a seed would normally form in the grain head. When livestock eat this grain or when humans eat bread made from ergot-contaminated rye flour, they may be poisoned by the extremely toxic substances in the ergot. These substances may cause nervous spasms, convulsions, psychotic delusions, and even gangrene. This condition, called ergotism, was known as St. Anthony's fire during the Middle Ages, when it occurred often. In the year 994, for example, an epidemic of St. Anthony's fire caused more than 40,000 deaths. In 1722, the cavalry of Czar Peter the Great was felled by ergotism on the eve of the battle for the conquest of Turkey. This was one of several recorded times that a fungus changed the course of human history. Lysergic acid, one of the constituents of ergot, is an intermediate in the synthesis of LSD. Some of the compounds produced by ergot are now used clinically in small quantities as drugs to induce labor, to stop uterine bleeding, to treat high blood pressure, and to relieve one type of migraine headache.

Some fungi are grown commercially to produce citric acid and other industrial chemicals. Also, biologists are using recombinant DNA techniques to manipulate yeasts and certain filamentous fungi in order to produce important biological molecules such as hormones.

Fungi cause many important plant diseases

Fungi are responsible for many serious plant diseases, including epidemic diseases that spread rapidly and often result in

Figure 25–16 How a fungus parasitizes a plant. In this example, the hypha enters the leaf through a stoma and then grows, branching extensively through the internal air spaces and penetrating plant cells with specialized hyphal extensions called haustoria.

complete crop failure. All plants are apparently susceptible to some fungal infection. Damage may be localized in certain tissues or structures of the plant, or the disease may be systemic and spread throughout the entire plant. Fungal infections may cause stunting of plant parts or of the entire plant, they may cause growths like warts, or they may kill the plant.

A plant often becomes infected after hyphae enter through stomata (pores) in the leaf (Fig. 25–16) or stem or through wounds in the plant body. Alternatively, the fungus may produce an enzyme called cutinase that dissolves the waxy cuticle that covers the surface of leaves and stems. After dissolving the cuticle, the fungus easily invades the plant tissues. As the mycelium grows, it may remain mainly between the plant cells or it may penetrate the cells. Parasitic fungi often produce special hyphal branches called **haustoria** (sing., *haustorium*) that penetrate the host cells and obtain nourishment from the cytoplasm.

Some important plant diseases caused by ascomycetes are powdery mildew; chestnut blight; Dutch elm disease; apple scab; and brown rot, which attacks cherries, peaches, plums, and apricots (Fig. 25–17*a*). Diseases caused by basidiomycetes include smuts and rusts that attack various plants, for example, corn, wheat, oats, and other grains (Fig. 25–17*b*). Some of these parasites, such as the stem rust of wheat, have complex life cycles that involve two or more different host plants and the production of several kinds of spores. For example, wheat rust must infect a barberry plant at one stage in its life cycle. Since this fact was discovered, the eradication of barberry plants in wheat-growing regions has reduced infection with wheat rust. Wheat rust has not been eliminated by eradication of the barberry, however, because the fungus overwinters on wheat at the southern end of the Grain Belt and forms asexual spores. During the spring, wind blows these spores for hundreds of miles, reinfecting northern areas of the United States and Canada.

(a)

(b)

Figure 25-17 Fungi that cause plant diseases. (a) Brown rot of peaches is caused by *Monilinia fruticola*, an ascomycete. (b) Corn smut on an ear of sweet corn is caused by *Ustilago maydis*, a basidiomycete. (a, Kathy Merrifield/ Photo Researchers, Inc.; b, Runk/Schoenberger, from Grant Heilman)

Certain imperfect fungi also cause plant diseases. Examples include verticillium wilt on potatoes, which is caused by the deuteromycete *Verticillium* sp., and bean anthracnose, which is caused by the deuteromycete *Colletotrichum lindemuthianum*.

Fungi cause certain animal diseases

Some fungi cause superficial infections in which only the skin, hair, or nails are infected. Ringworm and athlete's foot are examples of superficial fungal infections; both are caused by imperfect fungi. Candidiasis, a yeast infection of mucous membranes of the mouth, throat, or vagina, is among the most common fungal infections; it is also caused by an imperfect fungus.

Other fungi cause systemic infections that infect internal tissues and organs and may spread through many regions of the body. Histoplasmosis, for example, is a serious infection of the lungs caused by inhaling spores of a fungus common in soil contaminated with bird feces. Most people in the eastern and midwestern parts of the United States have been exposed to this fungus at some time, and an estimated 40 million American have had mild infections by this pathogen (disease-causing organism). Fortunately, the infection usually stays in the lungs and is of short duration, but if the infection spreads into

the bloodstream and from there into the heart, brain, eyes, kidneys, or other parts of the body, it can be serious and sometimes fatal.

Most pathogenic fungi are opportunists that cause infections only when the body's immunity is lowered. For example, the deuteromycete *Aspergillus fumigatus* does not usually cause disease in humans but does cause aspergillosis in people with defective immune systems, such as AIDS patients. During the course of this disease, the fungus can invade the lungs, heart, brain, kidneys, and other vital organs and can cause death. Other patients at high risk of acquiring life-threatening fungal infections include those with cancer and those with organ transplants.

Some fungi produce poisonous compounds collectively called **mycotoxins**. A few species of *Aspergillus*, for example, produce potent mycotoxins called *aflatoxins* that harm the liver and are known carcinogens. Foods on which aflatoxin-producing fungi commonly grow include peanuts, pecans, corn, and other grains. Other foods that may contain traces of aflatoxins include animal products such as milk, eggs, and meat (from animals that consumed feed contaminated by aflatoxin). It is impossible to avoid aflatoxin in the diet, but exposure should be minimized as much as possible. Any human food or animal forage product that has become moldy should be suspected of aflatoxin contamination and discarded.

S U M M A R Y W I T H K E Y T E R M S

- I. **Fungi** are eukaryotes with cell walls composed of **chitin**.
 - A. Fungi lack chlorophyll and are heterotrophic; they absorb predigested food molecules.
 - B. A fungus may be unicellular (**yeast**), coenocytic (mold), or multicellular (mold).
 1. The structure of a multicellular fungus consists of long, branched **hyphae** that form a **mycelium**.
 2. In the **zygomycetes**, the hyphae are **coenocytic** (undivided by septa).
 3. In other fungi, perforated **septa** are present that divide the hyphae into individual cells.
 - C. Most fungi reproduce both sexually and asexually by means of **spores**. When a fungal spore lands in a suitable spot, it germinates and begins to grow.
 1. Some hyphae infiltrate the substrate and digest its organic compounds.
 2. Spores are produced on aerial hyphae.
- II. Fungi are classified into phyla based largely on their modes of sexual reproduction.
 - A. **Chytridiomycetes** are simple aquatic fungi that produce motile cells with single, posterior flagella for both sexual (gametes) and asexual reproduction (**zoospores**).
 1. *Allomyces* is a representative of this group.
 2. Chytridiomycetes may have been the earliest fungal group to evolve from the ancient flagellated protist hypothesized as the common ancestor of all fungi.
 - B. **Zygomycetes** produce both asexual spores and sexual spores (**zygospores**). The black bread mold is a representative of this group.
 - C. **Ascomycetes** produce asexual spores called **conidia**; sexual spores called **ascospores** are produced in **asci**. Ascomycetes include yeasts, cup fungi, morels, truffles, and pink, brown, and blue-green molds.
 - D. **Basidiomycetes** produce sexual spores called **basidiospores** on the outside of a **basidium**; basidia develop on the surface of **gills** in mushrooms, a type of **basidiocarp**. Basidiomycetes include mushrooms, puffballs, bracket fungi, rusts, and smuts.
 - E. A sexual stage has not been observed in **imperfect fungi (deuteromycetes)**. Most reproduce asexually by forming conidia. Members of this group include *Aspergillus tamarii* (used to produce soy sauce), species of *Penicillium*, and fungi that cause certain human fungal infections.
 - F. A **lichen** is a symbiotic combination of a fungus and a phototroph (an alga or cyanobacterium); the association is one of controlled parasitism. Lichens have three main growth forms: crustose, foliose, and fruticose.
- III. Fungi are ecologically significant.
 - A. Many fungi are **saprotrophs** that break down organic compounds.
 - B. **Mycorrhizae** are mutualistic relationships between fungi and the roots of plants. The fungus supplies minerals to the plant, and the plant secretes organic compounds needed by the fungus.
 - C. Lichens play an important role in soil formation.
- IV. Fungi have both positive and negative economic importance.
 - A. Mushrooms, morels, and truffles are used as food; yeasts are vital in the production of beer, wine, and bread; certain fungi are used to produce cheeses and soy sauce.
 - B. Fungi are used to make penicillin and other antibiotics; ergot is used to produce certain drugs; other fungi make citric acid and many other industrial chemicals.
 - C. Fungi cause many plant diseases, including wheat rust, Dutch elm disease, and chestnut blight; they cause human diseases such as ringworm, athlete's foot, candidiasis, and histoplasmosis.

P O S T - T E S T

1. Which of the following fungi does NOT have a mycelium? (a) black bread mold (b) yeast (c) rainforest cup fungus (d) cultivated mushroom (e) *Penicillium*
2. With the exception of chytridiomycetes, fungi are generally disseminated by (a) water currents (b) fragmentation of hyphae (c) soredia (d) airborne spores (e) flagellated zoospores
3. Which statement is NOT true of the chytridiomycetes? (a) they are simple aquatic fungi (b) they produce motile cells with single, posterior flagella (c) they have both sexual and asexual reproduction (d) the black bread mold is a representative of this group (e) they are the most primitive group of fungi
4. Which statement is NOT true of the zygomycetes? (a) they are simple, aquatic fungi (b) their sexual spores are called zygospores (c) they have both sexual and asexual reproduction (d) the black bread mold is a representative of this group (e) they have coenocytic hyphae
5. Which statement is NOT true of the ascomycetes? (a) their sexual spores are produced in asci (b) they produce motile cells with single, posterior flagella (c) they have both sexual and asexual reproduction (d) their asexual spores are called conidia (e) some species cause serious plant diseases
6. Which statement is NOT true of the basidiomycetes? (a) they have a diploid thallus that produces zoospores (b) their sexual spores are called basidiospores (c) they produce a secondary mycelium with $n + n$ hyphae (d) mushrooms, bracket fungi, and puffballs are examples of this group (e) basidiomycetes include both edible and poisonous species
7. Which statement is NOT true of deuteromycetes? (a) they have a diploid thallus that produces zoospores (b) they are also known as imperfect fungi (c) they have both sexual and asexual reproduction (d) their asexual spores are called conidia (e) both a and c are not true
8. The familiar portion of a mushroom is actually a large fruiting body called a(an) _____. (a) ascocarp (b) basidium (c) basidiocarp (d) gametangium (e) ascus
9. A(an) _____ is a symbiotic association between a phototroph and a fungus. (a) soredium (b) basidiomycete (c) lichen (d) haustorium (e) saprotroph
10. Which characteristic is true of *all* fungi? (a) saprotrophic (b) parasitic (c) nonflagellated (d) pathogenic (e) heterotrophic
11. Mutualistic relationships between fungi and the roots of plants are called (a) lichens (b) mycorrhizae (c) deuteromycetes (d) haustoria (e) conidiophores

REVIEW QUESTIONS

1. What characteristics distinguish fungi from other organisms?
2. How does the body of a typical yeast differ from that of a mold?
3. What is the ecological importance of saprotrophic fungi? Of lichens? Of mycorrhizae?
4. Which fungal phylum is thought to be the most primitive? What evidence supports your answer?
5. Diagram the life cycle of the black bread mold.
6. Distinguish among each of the following: (a) ascocarp, ascus, and ascospore (b) basidiocarp, basidium, and basidiospore (c) conidium and ascospore (d) ascus and basidium (e) sporangium and conidium.
7. Some dictionaries erroneously define a morel as a type of mushroom. Why isn't a morel a mushroom?
8. Briefly describe three important fungal diseases of plants and three fungal diseases of humans.
9. Label the following diagram. Use Figure 25–10 to check your answers.

YOU MAKE THE CONNECTION

1. How are the life cycles of the marine alga *Ulva* (see Chapter 24) and *Albugines* similar?
2. What measures can you suggest to prevent bread from becoming moldy?
3. If you do not see any mushrooms in your lawn, can you conclude that no fungi live there? Why or why not?
4. Biologists have discovered that many mycorrhizal fungi are sensitive to a low pH. What human-caused environmental problem might prove catastrophic for these fungi? How might this problem affect their plant partners?

CHAPTER 26

The Plant Kingdom: Seedless Plants

About 440 million years ago planet Earth would have seemed a most inhospitable place because, although life abounded in the oceans, it did not yet exist in abundance on land. The oceans were filled with vast numbers of fish, mollusks, and crustaceans as well as countless microscopic algae, and the water along rocky coastlines was home to large seaweeds. Occasionally, perhaps, an animal would crawl out of the water onto land, but it never stayed there permanently because there was little to eat on land, not a single blade of grass, no fruit, and no seeds.

During the next 30 million years, a time corresponding roughly to the Silurian period of the Paleozoic era in geological time, plants appeared in abundance and colonized the land. Where did they come from? Although plants living today exhibit great diversity in size, form, and habitat, they are all thought to have evolved from a common ancestor, an ancient green alga. Biologists infer this relationship because modern green algae share a number of biochemical and metabolic traits with modern plants. Both green algae and plants contain the same photosynthetic pigments: chlorophylls *a* and *b* and accessory pigments, the yellow and orange carotenoids, including xanthophylls (yellow pigments) and carotenes (orange pigments). Also, both store their excess carbohydrates as starch and possess cellulose as a major component of their cell walls. In addition, certain details of cell division, including the formation of a cell plate during cytokinesis (see Chapter 9), are shared by plants and some green algae.

Recent ultrastructural and molecular data indicate that plants probably descended from a group of green algae called **charophytes** (see Fig. 24–13*e*). Molecular comparisons, particularly of DNA and RNA sequences, have provided compelling evidence that charophytes are closely allied to plants. These data include comparisons among plants and various green algae, including charophytes, of chloroplast DNA sequences, of certain nuclear DNA sequences, and of ribosomal RNA sequences. In each case, the closest match occurs between

(Sydney Karp/Photo/Nats, Inc.)

charophytes and plants, indicating that modern charophytes and plants probably shared a common charophyte ancestor.

Today the plant kingdom comprises hundreds of thousands of species that live in varied habitats, from frozen Arctic tundra to lush tropical rain forests to harsh deserts to moist stream banks, as shown by the mosses on rocks in Marron Creek, which is found in Snowmass Wilderness, Colorado. Plants are complex multicellular organisms that range in size from minute, almost microscopic duckweeds to massive giant sequoias, some of the largest organisms that have ever lived.

LEARNING OBJECTIVES

AFTER YOU HAVE STUDIED THIS CHAPTER YOU SHOULD BE ABLE TO

1. Discuss some of the environmental challenges of living on land and describe several adaptations that plants possess to meet these challenges.
2. Name the protist group from which plants are thought to have descended and describe supporting evidence.
3. Summarize the features that distinguish bryophytes from green algae and from other plants.
4. Name and briefly describe the three phyla of bryophytes.
5. Diagram the life cycle of mosses and compare their gametophyte and sporophyte generations.
6. Discuss the features that distinguish ferns and fern allies from algae and from other plants.
7. Name and briefly describe the four phyla of seedless vascular plants.
8. Diagram the life cycle of ferns and compare their sporophyte and gametophyte generations.
9. Compare the generalized life cycles of homosporous and heterosporous plants.

PLANTS HAVE ADAPTED TO LIFE ON LAND

What are some of the features of plants that have permitted them to colonize so many different environments? One important difference between plants and algae is that the aerial portion of a plant is covered by a waxy **cuticle**. A cuticle is essential for existence on land because it helps prevent the desiccation, or drying out, of plant tissues by evaporation. Plants are rooted in the ground and, unlike animals, cannot move to wetter areas during dry spells; therefore, a cuticle is critical to a land plant's survival.

Plants obtain the carbon they need for photosynthesis from the atmosphere as carbon dioxide (CO_2). In order for CO_2 to be fixed into organic molecules such as sugar, it must first diffuse into the chloroplasts that are inside green plant cells. Because the external surfaces of leaves and stems are covered by a waxy cuticle, however, gas exchange through the cuticle between the atmosphere and the insides of cells is negligible. To facilitate gas exchange, tiny pores called **stomata** (sing., *stoma*) dot the surfaces of leaves and stems; algae lack stomata.

Most plants possess multicellular sex organs called **gametangia** (sing., *gametangium*), while the gametangia of algae are single-celled (Fig. 26–1). Each plant gametangium has a layer of sterile (nonreproductive) cells that surrounds and protects the delicate gametes (eggs and sperm cells) it produces.

In plants, after fertilization occurs, the fertilized egg develops into a multicellular **embryo** within the female gametangium. Thus, the embryo is protected during its development. In algae, the fertilized egg develops away from its gametangium; in some algae, the gametes are released before fertilization, whereas in others the fertilized egg is released.

THERE ARE FOUR MAJOR GROUPS OF PLANTS

The plant kingdom consists of four major groups of plants: bryophytes, seedless vascular plants, gymnosperms, and flowering plants (Table 26–1 and Fig. 26–2). The mosses and other bryophytes are small nonvascular plants that lack a specialized vascular, or conducting, system to transport dissolved nutrients, water, and essential minerals throughout the plant body. In the absence of such a system, bryophytes rely on diffusion and osmosis to obtain needed materials. This reliance means that bryophytes are restricted in size; if they were much larger, some of their cells could not obtain the necessary materials in sufficient quantities. Bryophytes are seedless plants that reproduce and disperse primarily via haploid spores. Recent fossil evidence indicates that bryophytes may have been some of the earliest plants to colonize land (discussed later in the chapter).

Figure 26–1 Generalized reproductive structures of algae and plants. (a,b) In algae, gametangia are generally single-celled. When the gametes are released, the only thing remaining is the wall of the original cell. (c,d) In plants, the gametangia are multicellular, but only the inner cells become gametes. The gametangium is surrounded by a protective layer of sterile cells.

The other three groups of plants—ferns, gymnosperms, and flowering plants—possess vascular tissues: **xylem** for water and mineral conduction, and **phloem** for conduction of dissolved organic molecules such as sugar. A key step in the evolution of vascular plants was the ability to produce **lignin**, a strengthening polymer found in the walls of cells that function for support and conduction. The stiffening property of lignin enabled plants to grow tall and dominate the landscape. The successful occupation of the land by plants in turn made the evolution of terrestrial animals possible by providing them with both habitat and food (see *Making the Connection: Meeting the Environmental Challenges of Living on Land*).

Ferns and their allies (whisk ferns, horsetails, and club mosses) are seedless vascular plants that, like the bryophytes, reproduce and disperse primarily via spores. Seedless vascular plants arose and diversified during the Silurian and Devonian periods of the Paleozoic era, between 420 and 360 million years ago (discussed later in the chapter). Ferns and fern allies extend back more than 420 million years and were of consid-

TABLE 26-1 The Plant Kingdom

Nonvascular plants with a dominant gametophyte generation (bryophytes)

- Phylum Bryophyta (mosses)
- Phylum Hepaticophyta (liverworts)
- Phylum Anthocerotophyta (hornworts)

Vascular plants with a dominant sporophyte generation

Seedless plants

- Phylum Pterophyta (ferns)
- Phylum Psilotophyta (whisk ferns)
- Phylum Sphenophyta (horsetails)
- Phylum Lycophta (club mosses)

Seed plants

- Plants with naked seeds (gymnosperms)
 - Phylum Coniferophyta (conifers)
 - Phylum Cycadophyta (cycads)
 - Phylum Ginkgophyta (ginkgoes)
 - Phylum Gnetaophyta (gnetophytes)
- Seeds enclosed within a fruit
 - Phylum Anthophyta (angiosperms or flowering plants)
 - Class Dicotyledones (dicots)
 - Class Monocotyledones (monocots)

Figure 26-2 Plant evolution. This diagram shows possible phylogenetic relationships among living plants, based on current scientific evidence, along with several highlights in plant evolution. There are many questions, however, that remain to be resolved. We do not know whether the nonvascular plants descended directly from green algae, as depicted, or from early vascular plants. The exact relationship of the whisk ferns to other seedless vascular plants is also not clear.

MAKING THE CONNECTION

MEETING THE ENVIRONMENTAL CHALLENGES OF LIVING ON LAND

How have terrestrial organisms met the environmental challenges of living on land? Life began in the oceans, but many life forms have since adapted to terrestrial life in a sea of air. Every single organism living on land has to meet the same environmental challenges: obtaining enough water; preventing excessive water loss; obtaining sufficient energy; and, in temperate and polar regions, tolerating widely varying temperature extremes. How those challenges are met varies from one organism to another and in large part explains the diversity of life encountered on land today. Let us compare how vertebrates (animals with backbones) and plants meet several terrestrial challenges.

1. **Obtaining enough water.** Animals are motile; they walk, slither, fly, run, or crawl to water sources. This requires not only the ability to move (skeletal and muscular systems) but also the ability to sense the presence of water (a nervous system). Plants have adapted in a much different way to this challenge. They have roots that not only anchor the plant in the soil but also absorb water and essential dissolved minerals.
2. **Preventing excessive water loss.** The outer layers of terrestrial vertebrates and plants protect the moist inner tissues from drying out. Vertebrates that are adapted to living on land have an accumulation of a water-insoluble protein called keratin in their epithelial cells. Keratin is particularly thick in reptiles, where it forms scales that greatly reduce water loss by evaporation. Plants possess a water-insoluble, waxy coating called a cuticle over their epidermal cells. Most plants that are adapted to moister habitats may have a very thin layer of wax, whereas those adapted to drier environments often possess a thick, crusty cuticle. Many desert plants also possess a reduced surface area, particularly of leaves, that minimizes water loss.
3. **Obtaining sufficient energy.** Animals are heterotrophs that eat plants or other animals that eat plants. Almost all plants are autotrophs and must absorb enough sunlight for effective photosynthesis. Some plants obtain adequate sunlight by growing tall

(to maximize light interception); this adaptive approach required the evolution of strong supporting cells such as fibers, which contain the strengthening polymer lignin, because plants lack skeletal systems for support. Other plants have adapted to lower light intensities and so are able to grow in the shade of larger plants, albeit more slowly.

4. **Tolerating widely varying temperature extremes.** Air temperature varies greatly, particularly in temperate and polar regions. Many animals avoid hot temperatures by resting in the shade or by burrowing in the ground during the day when the temperatures are high; these animals become active at night when it is cooler. Sweat glands in mammalian skin produce sweat that cools the body by evaporation. Plants also rely on evaporative cooling; although they don't produce sweat, plants lose large quantities of water through tiny surface pores called stomata. As the water evaporates, enough heat leaves the plants to make them as much as 10°C cooler. To prevent overheating, desert plants reflect light from silvery colored leaves or stems, or shade themselves with pleated stems.

Vertebrates deal with the cold temperatures of winter in several ways. Mammalian hair and bird feathers trap air next to the skin's surface, thereby providing insulation and allowing the body to conserve heat. Some animals avoid colder temperatures by migrating to warmer climates for the winter; whereas others avoid the cold by passing the winter in a dormant state called hibernation. Many plants also spend winter in a dormant state. The aerial parts of some plants die during the winter, but the underground parts remain alive; the following spring, they resume metabolic activity and develop new aerial shoots. Many trees are deciduous, that is, they shed their leaves for the duration of their dormancy. Shedding leaves is actually an adaptation to the "dryness" of winter. Roots cannot absorb water from ground that is cold or frozen. By shedding its leaves, the plant reduces water loss during the cold winter months when obtaining water from the soil is impossible.

erable importance as Earth's dominant plants in past ages. Fossil evidence indicates that many species of these plants were the size of immense trees. Many ferns and most fern allies are extinct today; a few small representatives of the ancient groups survive.

The gymnosperms are vascular plants that reproduce by forming seeds (see Chapter 27). Gymnosperms produce seeds borne exposed (unprotected) on a stem or in a cone. Plants with seeds as their primary means of reproduction and dis-

persal first appeared about 360 million years ago, at the end of the Devonian period. These early seed plants diversified into many varied species of gymnosperms.

The most recent plant group to appear is the flowering plants, or angiosperms, which arose during the early Cretaceous period of the Mesozoic era about 130 million years ago. Like gymnosperms, flowering plants reproduce by forming seeds. Flowering plants, however, produce seeds enclosed within a fruit.

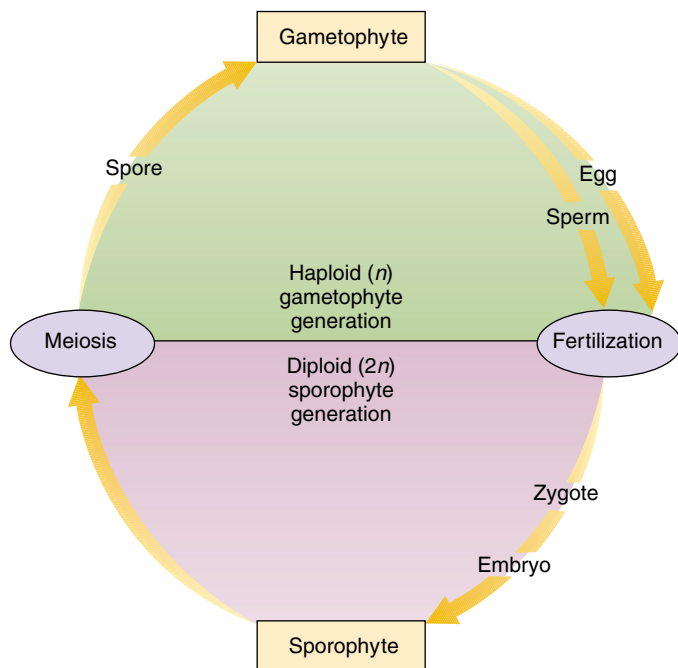

Figure 26-3 The basic plant life cycle. Plants alternate generations, spending part of the cycle in a haploid gametophyte stage and part in a diploid sporophyte stage. All plants have modifications of this cycle.

THE PLANT LIFE CYCLE ALTERNATES HAPLOID AND DIPLOID GENERATIONS

Plants have a clearly defined **alternation of generations** in which they spend part of their lives in a multicellular haploid stage and part in a multicellular diploid stage¹ (Fig. 26-3). The haploid portion of the life cycle is called the **gametophyte generation** because it gives rise to haploid gametes by mitosis. When two gametes fuse, the diploid portion of the life cycle, called the **sporophyte generation**, begins. The sporophyte generation produces haploid spores by the process of meiosis; these spores represent the first stage in the gametophyte generation.

Let us examine alternation of generations more closely. The haploid gametophytes produce antheridia (male gametangia), in which sperm cells form, and/or archegonia (female gametangia), each bearing a single egg (Fig. 26-4). Sperm cells reach the female gametangium in a variety of ways, and one sperm cell fertilizes the egg to form a zygote, or fertilized egg.

The diploid zygote is the first stage in the sporophyte generation. The zygote divides by mitosis and develops into a multicellular embryo. Embryo development takes place within the

Figure 26-4 Plant gametangia. (a) Each antheridium, the male gametangium, produces numerous sperm cells. (b) Each archegonium, the female gametangium, produces a single egg. Shown are generalized moss gametangia.

archegonium; thus, during its development, the embryo is protected. Eventually the embryo matures into a sporophyte. The sporophyte has special cells called *sporogenous cells* (spore-producing cells, also called *spore mother cells*) that divide by meiosis to form haploid spores. All plant spores are produced by meiosis, in contrast to algae and fungi, which may produce spores by meiosis or mitosis.

The spores represent the first stage in the gametophyte generation. Each spore divides by mitosis to produce a multicellular gametophyte, and the cycle continues. Plants therefore have an alternation of generations, alternating between a haploid gametophyte generation and a diploid sporophyte generation.

¹For convenience we limit our discussion to plants that are not polyploid, although polyploidy is very common in the plant kingdom. We therefore use the terms diploid and $2n$ (and haploid and n) interchangeably, although these terms are not actually synonymous.

TABLE 26–2 A Comparison of Major Groups of Seedless Plants

Plant Group	Dominant Stage of Life Cycle	Representative Genera
Nonvascular; reproduce by spores		
Mosses	Gametophyte: leafy plant	<i>Polytrichum</i> , <i>Sphagnum</i>
Liverworts	Gametophyte: thalloid or leafy plant	<i>Marchantia</i> , <i>Porella</i>
Hornworts	Gametophyte: thalloid plant	<i>Anthoceros</i>
Vascular; reproduce by spores		
Ferns	Sporophyte: roots, rhizomes, and leaves (megaphylls)	<i>Pteridium</i> , <i>Polypodium</i>
Whisk ferns	Sporophyte: rhizomes and erect stems; no true roots or leaves	<i>Psilotum</i> , <i>Tmesipteris</i>
Horsetails	Sporophyte: roots, rhizomes, erect stems, and leaves (reduced megaphylls)	<i>Equisetum</i>
Club mosses	Sporophyte: roots, rhizomes, erect stems, and leaves (microphylls)	<i>Lycopodium</i> , <i>Selaginella</i>

MOSSES AND OTHER BRYOPHYTES ARE NONVASCULAR PLANTS
